HARRISON'S®

PRINCIPLES OF INTERNAL MEDICINE

Editors

Joseph Loscalzo, MD, PhD
Hersey Professor of the Theory and Practice of Medicine, Harvard Medical School; Chairman, Department of Medicine; Soma Weiss MD Distinguished Chair in Medicine; Physician-in-Chief, Brigham and Women's Hospital, Boston, Massachusetts

Dennis L. Kasper, MD
William Ellery Channing Professor of Medicine and Professor of Immunology, Department of Immunology, Harvard Medical School; Division of Infectious Diseases, Brigham and Women's Hospital, Boston, Massachusetts

Dan L. Longo, MD
Professor of Medicine, Harvard Medical School; Senior Physician, Brigham and Women's Hospital; Deputy Editor, *New England Journal of Medicine,* Boston, Massachusetts

Anthony S. Fauci, MD
Chief, Laboratory of Immunoregulation; Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Stephen L. Hauser, MD
Robert A. Fishman Distinguished Professor, Department of Neurology; Director, UCSF Weill Institute for Neurosciences, University of California, San Francisco, San Francisco, California

J. Larry Jameson, MD, PhD
Robert G. Dunlop Professor of Medicine; Dean, Raymond and Ruth Perelman School of Medicine; Executive Vice President, University of Pennsylvania for the Health System, Philadelphia, Pennsylvania

TERMS OF USE

This is a copyrighted work and McGraw-Hill Education and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill Education's prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED "AS IS." McGRAW-HILL EDUCATION AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill Education and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Cover Illustration

Beginning with the 6th edition, the cover of *Harrison's* has included an image of a bright light—a patient's perception of being examined with an ophthalmoscope. This allegorical symbol of *Harrison's* is a reminder of how the light of knowledge empowers physicians to better diagnose and treat diseases that ultimately afflict all of humankind.

Author Disclosure Policy: McGraw Hill and the *Harrison's* Editorial Board require all contributors to disclose to the Editors and the Publisher any potential financial or professional conflicts that would raise the possibility of distorting the preparation of a *Harrison's* chapter.

Contents

Contributors xviii
Preface xxxix
Harrison's Related Resources xl

PART 1 The Profession of Medicine

1 The Practice of Medicine 1
The Editors
2 Promoting Good Health 8
Donald M. Lloyd-Jones, Kathleen M. McKibbin
3 Vaccine Opposition and Hesitancy 13
Julie A. Bettinger, Hana Mitchell
4 Decision-Making in Clinical Medicine 21
Daniel B. Mark, John B. Wong
5 Precision Medicine and Clinical Care 30
The Editors
6 Screening and Prevention of Disease 37
Katrina A. Armstrong, Gary J. Martin
7 Global Diversity of Health System Financing and Delivery 42
Richard B. Saltman
8 The Safety and Quality of Health Care 50
David W. Bates
9 Diagnosis: Reducing Errors and Improving Quality 54
Gordon Schiff
10 Racial and Ethnic Disparities in Health Care 59
Lenny López, Joseph R. Betancourt
11 Ethical Issues in Clinical Medicine 67
Christine Grady, Bernard Lo
12 Palliative and End-of-Life Care 72
Ezekiel J. Emanuel

PART 2 Cardinal Manifestations and Presentation of Diseases

SECTION 1 Pain

13 Pain: Pathophysiology and Management 91
James P. Rathmell, Howard L. Fields
14 Chest Discomfort 100
David A. Morrow
15 Abdominal Pain 108
Danny O. Jacobs
16 Headache 112
Peter J. Goadsby
17 Back and Neck Pain 117
John W. Engstrom

SECTION 2 Alterations in Body Temperature

18 Fever 130
Neeraj K. Surana, Charles A. Dinarello, Reuven Porat
19 Fever and Rash 133
Elaine T. Kaye, Kenneth M. Kaye
20 Fever of Unknown Origin 145
Chantal P. Bleeker-Rovers, Catharina M. Mulders-Manders, Jos W. M. van der Meer

SECTION 3 Nervous System Dysfunction

21 Syncope 152
Roy Freeman
22 Dizziness and Vertigo 159
Mark F. Walker, Robert B. Daroff
23 Fatigue 162
Jeffrey M. Gelfand, Vanja C. Douglas
24 Neurologic Causes of Weakness and Paralysis 165
Stephen L. Hauser
25 Numbness, Tingling, and Sensory Loss 168
Stephen L. Hauser
26 Gait Disorders, Imbalance, and Falls 173
Jessica M. Baker
27 Confusion and Delirium 178
S. Andrew Josephson, Bruce L. Miller
28 Coma 183
S. Andrew Josephson, Allan H. Ropper, Stephen L. Hauser
29 Dementia 189
William W. Seeley, Gil D. Rabinovici, Bruce L. Miller
30 Aphasia, Memory Loss, and Other Cognitive Disorders 195
M.-Marsel Mesulam
31 Sleep Disorders 204
Thomas E. Scammell, Clifford B. Saper, Charles A. Czeisler

SECTION 4 Disorders of Eyes, Ears, Nose, and Throat

32 Disorders of the Eye 215
Jonathan C. Horton
33 Disorders of Smell and Taste 232
Richard L. Doty, Steven M. Bromley
34 Disorders of Hearing 238
Anil K. Lalwani
35 Upper Respiratory Symptoms, Including Earache, Sinus Symptoms, and Sore Throat 247
Rachel L. Amdur, Jeffrey A. Linder
36 Oral Manifestations of Disease 256
Samuel C. Durso

SECTION 5 Alterations in Circulatory and Respiratory Functions

37 Dyspnea 263
Rebecca M. Baron
38 Cough 267
Christopher H. Fanta
39 Hemoptysis 270
Carolyn M. D'Ambrosio
40 Hypoxia and Cyanosis 272
Joseph Loscalzo
41 Edema 275
Joseph Loscalzo
42 Approach to the Patient with a Heart Murmur 278
Patrick T. O'Gara, Joseph Loscalzo
43 Palpitations 286
Joseph Loscalzo

SECTION 6 Alterations in Gastrointestinal Function

44 Dysphagia 287
Ikuo Hirano, Peter J. Kahrilas

45 Nausea, Vomiting, and Indigestion 291
William L. Hasler

46 Diarrhea and Constipation 297
Michael Camilleri, Joseph A. Murray

47 Unintentional Weight Loss 309
J. Larry Jameson

48 Gastrointestinal Bleeding 311
Loren Laine

49 Jaundice 315
Savio John, Daniel S. Pratt

50 Abdominal Swelling and Ascites 321
Lawrence S. Friedman

SECTION 7 Alterations in Renal and Urinary Tract Function

51 Interstitial Cystitis/Bladder Pain Syndrome 325
R. Christopher Doiron, J. Curtis Nickel

52 Azotemia and Urinary Abnormalities 331
David B. Mount

53 Fluid and Electrolyte Disturbances 338
David B. Mount

54 Hypercalcemia and Hypocalcemia 356
Sundeep Khosla

55 Acidosis and Alkalosis 359
Thomas D. DuBose, Jr.

SECTION 8 Alterations in the Skin

56 Approach to the Patient with a Skin Disorder 369
Kim B. Yancey, Thomas J. Lawley

57 Eczema, Psoriasis, Cutaneous Infections, Acne, and Other Common Skin Disorders 374
Leslie P. Lawley, Justin T. Cheeley, Robert A. Swerlick

58 Skin Manifestations of Internal Disease 383
Jean L. Bolognia, Jonathan S. Leventhal, Irwin M. Braverman

59 Immunologically Mediated Skin Diseases 400
Kim B. Yancey, Benjamin F. Chong, Thomas J. Lawley

60 Cutaneous Drug Reactions 407
Robert G. Micheletti, Misha Rosenbach, Bruce U. Wintroub, Kanade Shinkai

61 Photosensitivity and Other Reactions to Sunlight 417
Alexander G. Marneros, David R. Bickers

SECTION 9 Hematologic Alterations

62 Interpreting Peripheral Blood Smears 424
Dan L. Longo

63 Anemia and Polycythemia 431
John W. Adamson, Dan L. Longo

64 Disorders of Granulocytes and Monocytes 439
Steven M. Holland, John I. Gallin

65 Bleeding and Thrombosis 450
Barbara A. Konkle

66 Enlargement of Lymph Nodes and Spleen 457
Dan L. Longo

PART 3 Pharmacology

67 Principles of Clinical Pharmacology 465
Dan M. Roden

68 Pharmacogenomics 474
Dan M. Roden

PART 4 Oncology and Hematology

SECTION 1 Neoplastic Disorders

69 Approach to the Patient with Cancer 481
Dan L. Longo

70 Prevention and Early Detection of Cancer 490
Jennifer M. Croswell, Otis W. Brawley, Barnett S. Kramer

71 Cancer Genetics 498
Fred Bunz, Bert Vogelstein

72 Cancer Cell Biology 508
Jeffrey W. Clark, Dan L. Longo

73 Principles of Cancer Treatment 529
Edward A. Sausville, Dan L. Longo

74 Infections in Patients with Cancer 556
Robert W. Finberg

75 Oncologic Emergencies 565
Rasim Gucalp, Janice P. Dutcher

76 Cancer of the Skin 578
Brendan D. Curti, John T. Vetto, Sancy A. Leachman

77 Head and Neck Cancer 590
Everett E. Vokes

78 Neoplasms of the Lung 594
Leora Horn, Wade T. Iams

79 Breast Cancer 611
Daniel F. Hayes, Marc E. Lippman

80 Upper Gastrointestinal Tract Cancers 626
David Kelsen

81 Lower Gastrointestinal Cancers 636
Robert J. Mayer

82 Tumors of the Liver and Biliary Tree 643
Josep M. Llovet

83 Pancreatic Cancer 657
Daniel D. Von Hoff

84 Gastrointestinal Neuroendocrine Tumors 663
Matthew H. Kulke

85 Renal Cell Carcinoma 673
Robert J. Motzer, Martin H. Voss

86 Cancer of the Bladder and Urinary Tract 676
Noah M. Hahn

87 Benign and Malignant Diseases of the Prostate 681
Howard I. Scher, James A. Eastham

88 Testicular Cancer 689
David J. Vaughn

89 Gynecologic Malignancies 695
David Spriggs

90 Primary and Metastatic Tumors of the Nervous System 701
Lisa M. DeAngelis, Patrick Y. Wen

91 Soft Tissue and Bone Sarcomas and Bone Metastases 712
Shreyaskumar R. Patel

92 Carcinoma of Unknown Primary 716
Kanwal Raghav, James L. Abbruzzese, Gauri R. Varadhachary

93 Paraneoplastic Syndromes: Endocrinologic/Hematologic 721
J. Larry Jameson, Dan L. Longo

94 Paraneoplastic Neurologic Syndromes and Autoimmune Encephalitis 728
Josep Dalmau, Myrna R. Rosenfeld, Francesc Graus

95 Cancer Survivorship and the Long-Term Impact of Cancer and Its Treatment 736
Mark Roschewski, Dan L. Longo

SECTION 2 Hematopoietic Disorders

96 Hematopoietic Stem Cells 743
David T. Scadden, Dan L. Longo

97 Iron Deficiency and Other Hypoproliferative Anemias 747
John W. Adamson

98 Disorders of Hemoglobin 754
Martin H. Steinberg

99 Megaloblastic Anemias 766
A. Victor Hoffbrand

100 Hemolytic Anemias 776
Lucio Luzzatto, Lucia De Franceschi

101 Anemia Due to Acute Blood Loss 791
Dan L. Longo

102 Bone Marrow Failure Syndromes Including Aplastic Anemia and Myelodysplasia 792
Neal S. Young

103 Polycythemia Vera and Other Myeloproliferative Neoplasms 802
Jerry L. Spivak

104 Acute Myeloid Leukemia 809
William Blum

105 Chronic Myeloid Leukemia 818
Hagop Kantarjian, Elias Jabbour, Jorge Cortes

106 Acute Lymphoid Leukemia 828
Dieter Hoelzer

107 Chronic Lymphocytic Leukemia 834
Jennifer A. Woyach, John C. Byrd

108 Non-Hodgkin's Lymphoma 841
Caron A. Jacobson, Dan L. Longo

109 Hodgkin's Lymphoma 852
Caron A. Jacobson, Dan L. Longo

110 Less Common Lymphoid and Myeloid Malignancies 855
Ayalew Tefferi, Dan L. Longo

111 Plasma Cell Disorders 866
Nikhil C. Munshi, Dan L. Longo, Kenneth C. Anderson

112 Amyloidosis 878
John L. Berk, Vaishali Sanchorawala

113 Transfusion Therapy and Biology 884
Pierre Tiberghien, Olivier Garraud, Jacques Chiaroni

114 Hematopoietic Cell Transplantation 897
Frederick R. Appelbaum

SECTION 3 Disorders of Hemostasis

115 Disorders of Platelets and Vessel Wall 903
Barbara A. Konkle

116 Coagulation Disorders 910
Jean M. Connors

117 Arterial and Venous Thrombosis 919
Jane E. Freedman, Joseph Loscalzo

118 Antiplatelet, Anticoagulant, and Fibrinolytic Drugs 924
Jeffrey I. Weitz

PART 5 Infectious Diseases

SECTION 1 Basic Considerations in Infectious Diseases

119 Approach to the Patient with an Infectious Disease 941
Neeraj K. Surana, Dennis L. Kasper

120 Molecular Mechanisms of Microbial Pathogenesis 948
Thomas E. Wood, Marcia B. Goldberg

121 Microbial Genomics and Infectious Disease 960
Roby P. Bhattacharyya, Yonatan H. Grad, Deborah T. Hung

122 Approach to the Acutely Ill Infected Febrile Patient 973
Tamar F. Barlam

123 Immunization Principles and Vaccine Use 981
Sarah Mbaeyi, Amanda Cohn, Nancy Messonnier

124 Health Recommendations for International Travel 989
Jesse Waggoner, Henry M. Wu

125 Climate Change and Infectious Disease 1001
Aaron S. Bernstein

SECTION 2 Clinical Syndromes: Community-Acquired Infections

126 Pneumonia 1009
Lionel A. Mandell, Michael S. Niederman

127 Lung Abscess 1020
Rebecca M. Baron, Beverly W. Baron, Miriam Baron Barshak

128 Infective Endocarditis 1022
Sara E. Cosgrove, Adolf W. Karchmer

129 Infections of the Skin, Muscles, and Soft Tissues 1034
Dennis L. Stevens, Amy E. Bryant

130 Infectious Arthritis 1040
Lawrence C. Madoff, Nongnooch Poowanawittayakom

131 Osteomyelitis 1046
Werner Zimmerli

132 Intraabdominal Infections and Abscesses 1054
Miriam Baron Barshak, Dennis L. Kasper

133 Acute Infectious Diarrheal Diseases and Bacterial Food Poisoning 1061
Richelle C. Charles, Regina C. LaRocque

134 *Clostridioides difficile* Infection, Including Pseudomembranous Colitis 1066
Dale N. Gerding, Stuart Johnson

135 Urinary Tract Infections, Pyelonephritis, and Prostatitis 1070
Kalpana Gupta, Barbara W. Trautner

136 Sexually Transmitted Infections: Overview and Clinical Approach 1078
Jeanne M. Marrazzo, King K. Holmes

137 Encephalitis 1094
Karen L. Roos, Michael R. Wilson, Kenneth L. Tyler

138 Acute Meningitis 1100
Karen L. Roos, Kenneth L. Tyler

139 Chronic and Recurrent Meningitis 1110
Avindra Nath, Walter J. Koroshetz, Michael R. Wilson

140 Brain Abscess and Empyema 1117
Karen L. Roos, Kenneth L. Tyler

141 Infectious Complications of Bites 1124
Sandeep S. Jubbal, Florencia Pereyra Segal, Lawrence C. Madoff

SECTION 3 Clinical Syndromes: Health Care–Associated Infections

142 Infections Acquired in Health Care Facilities 1128
Robert A. Weinstein

143 Infections in Transplant Recipients 1136
Robert W. Finberg

SECTION 4 Therapy for Bacterial Diseases

144 Treatment and Prophylaxis of Bacterial Infections 1148
David C. Hooper, Erica S. Shenoy, Ramy H. Elshaboury

145 Bacterial Resistance to Antimicrobial Agents 1163
David C. Hooper

SECTION 5 Diseases Caused by Gram-Positive Bacteria

146 Pneumococcal Infections 1169
David Goldblatt, Katherine L. O'Brien

147 Staphylococcal Infections 1178
Franklin D. Lowy

148 Streptococcal Infections 1188
Michael R. Wessels

149 Enterococcal Infections 1197
William R. Miller, Cesar A. Arias, Barbara E. Murray

150 Diphtheria and Other Corynebacterial Infections 1203
William R. Bishai, John R. Murphy

151 *Listeria monocytogenes* Infections 1208
Jennifer P. Collins, Patricia M. Griffin

152 Tetanus 1211
C. Louise Thwaites, Lam Minh Yen

153 Botulism 1214
Carolina Lúquez, Jeremy Sobel

154 Gas Gangrene and Other Clostridial Infections 1220
Amy E. Bryant, Dennis L. Stevens

SECTION 6 Diseases Caused by Gram-Negative Bacteria

155 Meningococcal Infections 1225
Manish Sadarangani, Andrew J. Pollard

156 Gonococcal Infections 1234
Sanjay Ram, Peter A. Rice

157 *Haemophilus* and *Moraxella* Infections 1241
Timothy F. Murphy

158 Infections Due to the HACEK Group and Miscellaneous Gram-Negative Bacteria 1246
Tamar F. Barlam

159 *Legionella* Infections 1249
Steven A. Pergam, Thomas R. Hawn

160 Pertussis and Other *Bordetella* Infections 1257
Karina A. Top, Scott A. Halperin

161 Diseases Caused by Gram-Negative Enteric Bacilli 1261
Thomas A. Russo, James R. Johnson

162 *Acinetobacter* Infections 1275
Rossana Rosa, L. Silvia Munoz-Price

163 *Helicobacter pylori* Infections 1279
John C. Atherton, Martin J. Blaser

164 Infections Due to *Pseudomonas*, *Burkholderia*, and *Stenotrophomonas* Species 1284
Reuben Ramphal

165 Salmonellosis 1291
David A. Pegues, Samuel I. Miller

166 Shigellosis 1298
Philippe J. Sansonetti, Jean Bergounioux

167 Infections Due to *Campylobacter* and Related Organisms 1302
Martin J. Blaser

168 Cholera and Other Vibrioses 1305
Matthew K. Waldor, Edward T. Ryan

169 Brucellosis 1310
Nicholas J. Beeching

170 Tularemia 1314
Max Maurin, Didier Raoult

171 Plague and Other *Yersinia* Infections 1320
Michael B. Prentice

172 *Bartonella* Infections, Including Cat-Scratch Disease 1328
Michael Giladi, Moshe Ephros

173 Donovanosis 1334
Nigel O'Farrell

SECTION 7 Miscellaneous Bacterial Infections

174 Nocardiosis 1335
Gregory A. Filice

175 Actinomycosis 1340
Thomas A. Russo

176 Whipple's Disease 1344
Thomas A. Russo, Seth R. Glassman

177 Infections Due to Mixed Anaerobic Organisms 1347
Neeraj K. Surana, Dennis L. Kasper

SECTION 8 Mycobacterial Diseases

178 Tuberculosis 1357
Mario C. Raviglione, Andrea Gori

179 Leprosy 1382
Jan H. Richardus, Hemanta K. Kar, Zoica Bakirtzief, Wim H. van Brakel

180 Nontuberculous Mycobacterial Infections 1392
Steven M. Holland

181 Antimycobacterial Agents 1397
Divya Reddy, Sebastian G. Kurz, Max R. O'Donnell

SECTION 9 Spirochetal Diseases

182 Syphilis 1406
Sheila A. Lukehart

183 Endemic Treponematoses 1413
Sheila A. Lukehart, Lorenzo Giacani

184 Leptospirosis 1417
Jiři F. P. Wagenaar, Marga G.A. Goris

185 Relapsing Fever and *Borrelia miyamotoi* Disease 1421
Alan G. Barbour

186 Lyme Borreliosis 1425
Allen C. Steere

SECTION 10 Diseases Caused by Rickettsiae, Mycoplasmas, and Chlamydiae

187 Rickettsial Diseases 1431
David H. Walker, J. Stephen Dumler, Lucas S. Blanton, Chantal P. Bleeker-Rovers

188 Infections Due to Mycoplasmas 1441
R. Doug Hardy

189 Chlamydial Infections 1444
Charlotte A. Gaydos, Thomas C. Quinn

SECTION 11 Viral Diseases: General Considerations

190 Principles of Medical Virology 1453
David M. Knipe

191 Antiviral Chemotherapy, Excluding Antiretroviral Drugs 1460
Jeffrey I. Cohen, Eleanor Wilson

SECTION 12 Infections Due to DNA Viruses

192 Herpes Simplex Virus Infections 1470
Lawrence Corey

193 Varicella-Zoster Virus Infections 1479
Richard J. Whitley

194 Epstein-Barr Virus Infections, Including Infectious Mononucleosis 1483
Jeffrey I. Cohen

195 Cytomegalovirus and Human Herpesvirus Types 6, 7, and 8 1487
Camille Nelson Kotton, Martin S. Hirsch

196 Molluscum Contagiosum, Monkeypox, and Other Poxvirus Infections 1492
Inger K. Damon

197 Parvovirus Infections 1495
Kevin E. Brown

198 Human Papillomavirus Infections 1498
Darron R. Brown, Aaron C. Ermel

SECTION 13 Infections Due to DNA and RNA Respiratory Viruses

199 Common Viral Respiratory Infections, Including COVID-19 1504
James E. Crowe, Jr.

200 Influenza 1515
Kathleen M. Neuzil, Peter F. Wright

SECTION 14 Infections Due to Human Immunodeficiency Virus and Other Human Retroviruses

201 The Human Retroviruses 1521
Dan L. Longo, Anthony S. Fauci

202 Human Immunodeficiency Virus Disease: AIDS and Related Disorders 1527
Anthony S. Fauci, Gregory K. Folkers, H. Clifford Lane

SECTION 15 Infections Due to RNA Viruses

203 Viral Gastroenteritis 1597
Umesh D. Parashar, Roger I. Glass

204 Enterovirus, Parechovirus, and Reovirus Infections 1602
Jeffrey I. Cohen

205 Measles (Rubeola) 1608
Kaitlin Rainwater-Lovett, William J. Moss

206 Rubella (German Measles) 1612
Laura A. Zimmerman, Susan E. Reef

207 Mumps 1615
Jessica Leung, Mariel Marlow

208 Rabies and Other Rhabdovirus Infections 1618
Alan C. Jackson

209 Arthropod-Borne and Rodent-Borne Virus Infections 1624
Jens H. Kuhn, Ian Crozier

210 Ebolavirus and Marburgvirus Infections 1645
Jens H. Kuhn, Ian Crozier

SECTION 16 Fungal Infections

211 Pathogenesis, Diagnosis, and Treatment of Fungal Infections 1652
Michail S. Lionakis, John E. Edwards Jr.

212 Histoplasmosis 1658
Chadi A. Hage, L. Joseph Wheat

213 Coccidioidomycosis 1661
Neil M. Ampel

214 Blastomycosis 1664
Gregory M. Gauthier, Bruce S. Klein

215 Cryptococcosis 1668
Arturo Casadevall

216 Candidiasis 1671
Michail S. Lionakis, Shakti Singh, Ashraf S. Ibrahim, John E. Edwards, Jr.

217 Aspergillosis 1677
David W. Denning

218 Mucormycosis 1681
Brad Spellberg, Ashraf S. Ibrahim

219 Less Common Systemic Mycoses and Superficial Mycoses 1686
Carol A. Kauffman

220 *Pneumocystis* Infections 1691
Alison Morris, Henry Masur

SECTION 17 Protozoal and Helminthic Infections: General Considerations

221 Introduction to Parasitic Infections 1696
Sharon L. Reed

222 Agents Used to Treat Parasitic Infections 1701
Thomas A. Moore

SECTION 18 Protozoal Infections

223 Amebiasis and Infection with Free-Living Amebae 1714
Rosa M. Andrade, Sharon L. Reed

224 Malaria 1720
Nicholas J. White, Elizabeth A. Ashley

225 Babesiosis 1736
Edouard Vannier, Jeffrey A. Gelfand

226 Leishmaniasis 1741
Shyam Sundar

227 Chagas Disease and African Trypanosomiasis 1748
François Chappuis, Yves Jackson

228 *Toxoplasma* Infections 1757
Kami Kim

229 Protozoal Intestinal Infections and Trichomoniasis 1764
Peter F. Weller

SECTION 19 Helminthic Infections

230 Introduction to Helminthic Infections 1768
Peter F. Weller

231 Trichinellosis and Other Tissue Nematode Infections 1770
Peter F. Weller

232 Intestinal Nematode Infections 1773
Thomas B. Nutman, Peter F. Weller

233 Filarial and Related Infections 1778
Thomas B. Nutman, Peter F. Weller

234 Schistosomiasis and Other Trematode Infections 1784
Birgitte Jyding Vennervald

235 Cestode Infections 1790
A. Clinton White, Jr., Peter F. Weller

PART 6 Disorders of the Cardiovascular System

SECTION 1 Introduction to Cardiovascular Disorders

236 Approach to the Patient with Possible Cardiovascular Disease 1797
Joseph Loscalzo

237 Basic Biology of the Cardiovascular System 1799
Joseph Loscalzo, John F. Keaney, Jr., Calum A. MacRae

238 Epidemiology of Cardiovascular Disease 1810
Thomas A. Gaziano, J. Michael Gaziano

SECTION 2 Diagnosis of Cardiovascular Disorders

239 Physical Examination of the Cardiovascular System 1815
Patrick T. O'Gara, Joseph Loscalzo

240 Electrocardiography 1824
Ary L. Goldberger

241 Noninvasive Cardiac Imaging: Echocardiography, Nuclear Cardiology, and Magnetic Resonance/Computed Tomography Imaging 1832
Marcelo F. Di Carli, Raymond Y. Kwong, Scott D. Solomon

242 Diagnostic Cardiac Catheterization and Coronary Angiography 1859
Jane A. Leopold, David P. Faxon

SECTION 3 Disorders of Rhythm

243 Principles of Clinical Cardiac Electrophysiology 1866
William H. Sauer, Bruce A. Koplan, Paul C. Zei

244 The Bradyarrhythmias: Disorders of the Sinoatrial Node 1873
William H. Sauer, Bruce A. Koplan

245 The Bradyarrhythmias: Disorders of the Atrioventricular Node 1880
William H. Sauer, Bruce A. Koplan

246 Approach to Supraventricular Tachyarrhythmias 1888
William H. Sauer, Paul C. Zei

247 Physiologic and Nonphysiologic Sinus Tachycardia 1891
William H. Sauer, Paul C. Zei

248 Focal Atrial Tachycardia 1893
William H. Sauer, Paul C. Zei

249 Paroxysmal Supraventricular Tachycardias 1894
William H. Sauer, Paul C. Zei

250 Common Atrial Flutter and Macroreentrant and Multifocal Atrial Tachycardias 1899
William H. Sauer, Paul C. Zei

251 Atrial Fibrillation 1903
William H. Sauer, Paul C. Zei

252 Approach to Ventricular Arrhythmias 1910
William H. Sauer, Usha B. Tedrow

253 Premature Ventricular Contractions, Nonsustained Ventricular Tachycardia, and Accelerated Idioventricular Rhythm 1915
William H. Sauer, Usha B. Tedrow

254 Sustained Ventricular Tachycardia 1919
William H. Sauer, Usha B. Tedrow

255 Polymorphic Ventricular Tachycardia and Ventricular Fibrillation 1923
William H. Sauer, Usha B. Tedrow

256 Electrical Storm and Incessant Ventricular Tachycardia 1927
William H. Sauer, Usha B. Tedrow

SECTION 4 Disorders of the Heart, Muscles, Valves, and Pericardium

257 Heart Failure: Pathophysiology and Diagnosis 1930
Michael M. Givertz, Mandeep R. Mehra

258 Heart Failure: Management 1940
Akshay S. Desai, Mandeep R. Mehra

259 Cardiomyopathy and Myocarditis 1954
Neal K. Lakdawala, Lynne Warner Stevenson, Joseph Loscalzo

260 Cardiac Transplantation and Prolonged Assisted Circulation 1973
Mandeep R. Mehra

261 Aortic Stenosis 1978
Patrick T. O'Gara, Joseph Loscalzo

262 Aortic Regurgitation 1986
Patrick T. O'Gara, Joseph Loscalzo

263 Mitral Stenosis 1991
Patrick T. O'Gara, Joseph Loscalzo

264 Mitral Regurgitation 1995
Patrick T. O'Gara, Joseph Loscalzo

265 Mitral Valve Prolapse 1999
Patrick T. O'Gara, Joseph Loscalzo

266 Tricuspid Valve Disease 2001
Patrick T. O'Gara, Joseph Loscalzo

267 Pulmonic Valve Disease 2004
Patrick T. O'Gara, Joseph Loscalzo

268 Multiple and Mixed Valvular Heart Disease 2005
Patrick T. O'Gara, Joseph Loscalzo

269 Congenital Heart Disease in the Adult 2008
Anne Marie Valente, Michael J. Landzberg

270 Pericardial Disease 2019
Joseph Loscalzo

271 Atrial Myxoma and Other Cardiac Tumors 2025
Eric H. Awtry

272 Cardiac Trauma 2028
Eric H. Awtry

SECTION 5 Coronary and Peripheral Vascular Disease

273 Ischemic Heart Disease 2030
Elliott M. Antman, Joseph Loscalzo

274 Non-ST-Segment Elevation Acute Coronary Syndrome (Non-ST-Segment Elevation Myocardial Infarction and Unstable Angina) 2046
Robert P. Giugliano, Christopher P. Cannon, Eugene Braunwald

275 ST-Segment Elevation Myocardial Infarction 2053
Elliott M. Antman, Joseph Loscalzo

276 Percutaneous Coronary Interventions and Other Interventional Procedures 2066
David P. Faxon, Deepak L. Bhatt

277 Hypertension 2072
Theodore A. Kotchen

278 Renovascular Disease 2088
Stephen C. Textor

279 Deep-Venous Thrombosis and Pulmonary Thromboembolism 2091
Samuel Z. Goldhaber

280 Diseases of the Aorta 2101
Mark A. Creager, Joseph Loscalzo

281 Arterial Diseases of the Extremities 2107
Mark A. Creager, Joseph Loscalzo

282 Chronic Venous Disease and Lymphedema 2115
Mark A. Creager, Joseph Loscalzo

283 Pulmonary Hypertension 2121
Bradley A. Maron, Joseph Loscalzo

PART 7 Disorders of the Respiratory System

SECTION 1 Diagnosis of Respiratory Disorders

284 Approach to the Patient with Disease of the Respiratory System 2131
Bruce D. Levy

285 Disturbances of Respiratory Function 2133
Edward T. Naureckas, Julian Solway

286 Diagnostic Procedures in Respiratory Disease 2140
George R. Washko, Hilary J. Goldberg, Majid Shafiq

SECTION 2 Diseases of the Respiratory System

287 Asthma 2147
Elliot Israel

288 Hypersensitivity Pneumonitis and Pulmonary Infiltrates with Eosinophilia 2160
Praveen Akuthota, Michael E. Wechsler

289 Occupational and Environmental Lung Disease 2166
John R. Balmes

290 Bronchiectasis 2173
Rebecca M. Baron, Beverly W. Baron, Miriam Baron Barshak

291 Cystic Fibrosis 2176
Eric J. Sorscher

292 Chronic Obstructive Pulmonary Disease 2180
Edwin K. Silverman, James D. Crapo, Barry J. Make

293 Interstitial Lung Disease 2190
Gary M. Hunninghake, Ivan O. Rosas

294 Disorders of the Pleura 2197
Richard W. Light

295 Disorders of the Mediastinum 2200
Richard W. Light

296 Disorders of Ventilation 2201
John F. McConville, Julian Solway, Babak Mokhlesi

297 Sleep Apnea 2204
Andrew Wellman, Daniel J. Gottlieb, Susan Redline

298 Lung Transplantation 2209
Hilary J. Goldberg, Hari R. Mallidi

299 Interventional Pulmonary Medicine 2214
Lonny Yarmus, David Feller-Kopman

PART 8 Critical Care Medicine

SECTION 1 Respiratory Critical Care

300 Approach to the Patient with Critical Illness 2217
Rebecca M. Baron, Anthony F. Massaro

301 Acute Respiratory Distress Syndrome 2225
Rebecca M. Baron, Bruce D. Levy

302 Mechanical Ventilatory Support 2230
Scott Schissel

SECTION 2 Shock and Cardiac Arrest

303 Approach to the Patient with Shock 2235
Anthony F. Massaro

304 Sepsis and Septic Shock 2241
Emily B. Brant, Christopher W. Seymour, Derek C. Angus

305 Cardiogenic Shock and Pulmonary Edema 2250
David H. Ingbar, Holger Thiele

306 Cardiovascular Collapse, Cardiac Arrest, and Sudden Cardiac Death 2257
Christine Albert, William H. Sauer

SECTION 3 Neurologic Critical Care

307 Nervous System Disorders in Critical Care 2267
J. Claude Hemphill, III, Wade S. Smith, S. Andrew Josephson, Daryl R. Gress

PART 9 Disorders of the Kidney and Urinary Tract

308 Approach to the Patient with Renal Disease or Urinary Tract Disease 2279
Julian L. Seifter

309 Cell Biology and Physiology of the Kidney 2287
Alfred L. George, Jr., Eric G. Neilson

310 Acute Kidney Injury 2296
Sushrut S. Waikar, Joseph V. Bonventre

311 Chronic Kidney Disease 2309
Joanne M. Bargman, Karl Skorecki

312 Dialysis in the Treatment of Kidney Failure 2320
Kathleen D. Liu, Glenn M. Chertow

313 Transplantation in the Treatment of Renal Failure 2325
Jamil Azzi, Naoka Murakami, Anil Chandraker

314 Glomerular Diseases 2331
Julia B. Lewis, Eric G. Neilson

315 Polycystic Kidney Disease and Other Inherited Disorders of Tubule Growth and Development 2350
Jing Zhou, Martin R. Pollak

316 Tubulointerstitial Diseases of the Kidney 2357
Laurence H. Beck Jr., David J. Salant

317 Vascular Injury to the Kidney 2364
Ronald S. Go, Nelson Leung

318 Nephrolithiasis 2368
Gary C. Curhan

319 Urinary Tract Obstruction 2373
Julian L. Seifter

320 Interventional Nephrology 2377
Dirk M. Hentschel

PART 10 Disorders of the Gastrointestinal System

SECTION 1 Disorders of the Alimentary Tract

321 Approach to the Patient with Gastrointestinal Disease 2381
William L. Hasler, Chung Owyang

322 Gastrointestinal Endoscopy 2387
Louis Michel Wong Kee Song, Mark Topazian

323 Diseases of the Esophagus 2423
Peter J. Kahrilas, Ikuo Hirano

324 Peptic Ulcer Disease and Related Disorders 2434
John Del Valle

325 Disorders of Absorption 2458
Deborah C. Rubin

326 Inflammatory Bowel Disease 2469
Sonia Friedman, Richard S. Blumberg

327 Irritable Bowel Syndrome 2490
Chung Owyang

328 Diverticular Disease and Common Anorectal Disorders 2497
Susan L. Gearhart

329 Mesenteric Vascular Insufficiency 2506
Maryam Ali Khan, Jaideep Das Gupta, Mahmoud Malas

330 Acute Intestinal Obstruction 2508
Danny O. Jacobs

331 Acute Appendicitis and Peritonitis 2513
Danny O. Jacobs

SECTION 2 Nutrition

332 Nutrient Requirements and Dietary Assessment 2517
Johanna T. Dwyer

333 Vitamin and Trace Mineral Deficiency and Excess 2523
Paolo M. Suter

334 Malnutrition and Nutritional Assessment 2534
Gordon L. Jensen

335 Enteral and Parenteral Nutrition 2539
L. John Hoffer, Bruce R. Bistrian, David F. Driscoll

SECTION 3 Liver and Biliary Tract Disease

336 Approach to the Patient with Liver Disease 2546
Marc G. Ghany, Jay H. Hoofnagle

337 Evaluation of Liver Function 2553
Emily D. Bethea, Daniel S. Pratt

338 The Hyperbilirubinemias 2557
Allan W. Wolkoff

339 Acute Viral Hepatitis 2562
Jules L. Dienstag

340 Toxic and Drug-Induced Hepatitis 2584
William M. Lee, Jules L. Dienstag

341 Chronic Hepatitis 2591
Jules L. Dienstag

342 Alcohol-Associated Liver Disease 2617
Bernd Schnabl

343 Nonalcoholic Fatty Liver Diseases and Nonalcoholic Steatohepatitis 2619
Manal F. Abdelmalek, Anna Mae Diehl

344 Cirrhosis and Its Complications 2624
Alex S. Befeler, Bruce R. Bacon

345 Liver Transplantation 2633
Raymond T. Chung, Jules L. Dienstag

346 Diseases of the Gallbladder and Bile Ducts 2641
Norton J. Greenberger, Gustav Paumgartner, Daniel S. Pratt

SECTION 4 Disorders of the Pancreas

347 Approach to the Patient with Pancreatic Disease 2652
Somashekar G. Krishna, Darwin L. Conwell, Phil A. Hart

348 Acute and Chronic Pancreatitis 2657
Phil A. Hart, Darwin L. Conwell, Somashekar G. Krishna

PART 11 Immune-Mediated, Inflammatory, and Rheumatologic Disorders

SECTION 1 The Immune System in Health and Disease

349 Introduction to the Immune System 2671
Barton F. Haynes, Kelly A. Soderberg, Anthony S. Fauci

350 Mechanisms of Regulation and Dysregulation of the Immune System 2701
Barton F. Haynes, Kelly A. Soderberg, Anthony S. Fauci

351 Primary Immune Deficiency Diseases 2709
Alain Fischer

SECTION 2 Disorders of Immune-Mediated Injury

352 Urticaria, Angioedema, and Allergic Rhinitis 2719
Katherine L. Tuttle, Joshua A. Boyce

353 Anaphylaxis 2727
David Hong, Joshua A. Boyce

354 Mastocytosis 2729
Matthew P. Giannetti, Joshua A. Boyce

355 Autoimmunity and Autoimmune Diseases 2731
Betty Diamond, Peter E. Lipsky

356 Systemic Lupus Erythematosus 2736
Bevra Hannahs Hahn, Maureen McMahon

357 Antiphospholipid Syndrome 2749
Haralampos M. Moutsopoulos, Clio P. Mavragani

358 Rheumatoid Arthritis 2751
Ankoor Shah, E. William St. Clair

359 Acute Rheumatic Fever 2766
Joseph Kado, Jonathan Carapetis

360 Systemic Sclerosis (Scleroderma) and Related Disorders 2771
John Varga

361 Sjögren's Syndrome 2787
Haralampos M. Moutsopoulos, Clio P. Mavragani

362 Spondyloarthritis 2790
Joel D. Taurog, Lianne S. Gensler, Nigil Haroon

363 The Vasculitis Syndromes 2802
Carol A. Langford, Anthony S. Fauci

364 Behçet Syndrome 2817

Yusuf Yazici

365 Inflammatory Myopathies 2819
Steven A. Greenberg, Anthony A. Amato

366 Relapsing Polychondritis 2826
Carol A. Langford

367 Sarcoidosis 2829
Robert P. Baughman, Elyse E. Lower

368 IgG4-Related Disease 2837
John H. Stone

369 Familial Mediterranean Fever and Other Hereditary Autoinflammatory Diseases 2840
Daniel L. Kastner

SECTION 3 Disorders of the Joints and Adjacent Tissues

370 Approach to Articular and Musculoskeletal Disorders 2844
John J. Cush

371 Osteoarthritis 2854
David T. Felson, Tuhina Neogi

372 Gout and Other Crystal-Associated Arthropathies 2862
Hyon K. Choi

373 Fibromyalgia 2868
Leslie J. Crofford

374 Arthritis Associated with Systemic Disease, and Other Arthritides 2871
Carol A. Langford, Brian F. Mandell

375 Periarticular Disorders of the Extremities 2878
Carol A. Langford

PART 12 Endocrinology and Metabolism

SECTION 1 Endocrinology

376 Approach to the Patient with Endocrine Disorders 2881
J. Larry Jameson

377 Mechanisms of Hormone Action 2884
J. Larry Jameson

378 Physiology of Anterior Pituitary Hormones 2891
Shlomo Melmed, J. Larry Jameson

379 Hypopituitarism 2896
Shlomo Melmed, J. Larry Jameson

380 Pituitary Tumor Syndromes 2902
Shlomo Melmed, J. Larry Jameson

381 Disorders of the Neurohypophysis 2918
Gary L. Robertson, Daniel G. Bichet

382 Thyroid Gland Physiology and Testing 2926
J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

383 Hypothyroidism 2933
J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

384 Hyperthyroidism and Other Causes of Thyrotoxicosis 2938
J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

385 Thyroid Nodular Disease and Thyroid Cancer 2946
J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

386 Disorders of the Adrenal Cortex 2955
Wiebke Arlt

387 Pheochromocytoma 2976
Hartmut P. H. Neumann

388 Multiple Endocrine Neoplasia Syndromes 2983
R. V. Thakker

389 Autoimmune Polyendocrine Syndromes 2992
Peter A. Gottlieb, Aaron W. Michels

SECTION 2 Sex- and Gender-Based Medicine

390 Sex Development 2997
Courtney Finlayson, J. Larry Jameson, John C. Achermann

391 Disorders of the Testes and Male Reproductive System 3006
Shalender Bhasin, J. Larry Jameson

392 Disorders of the Female Reproductive System 3027
Janet E. Hall, Anuja Dokras

393 Menstrual Disorders and Pelvic Pain 3033
Janet E. Hall, Anuja Dokras

394 Hirsutism 3039
David A. Ehrmann

395 Menopause and Postmenopausal Hormone Therapy 3043
JoAnn E. Manson, Shari S. Bassuk

396 Infertility and Contraception 3050
Anuja Dokras, Janet E. Hall

397 Sexual Dysfunction 3055
Kevin T. McVary

398 Women's Health 3063
Emily Nosova, Andrea Dunaif

399 Men's Health 3069
Shalender Bhasin

400 Lesbian, Gay, Bisexual, and Transgender (LGBT) Health 3078
Baligh R. Yehia, Zachary B. R. McClain

SECTION 3 Obesity, Diabetes Mellitus, and Metabolic Syndrome

401 Pathobiology of Obesity 3080
Stephen O'Rahilly, I. Sadaf Farooqi

402 Evaluation and Management of Obesity 3087
Robert F. Kushner

403 Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology 3094
Alvin C. Powers, Kevin D. Niswender, Carmella Evans-Molina

404 Diabetes Mellitus: Management and Therapies 3104
Alvin C. Powers, Michael J. Fowler, Michael R. Rickels

405 Diabetes Mellitus: Complications 3120
Alvin C. Powers, John M. Stafford, Michael R. Rickels

406 Hypoglycemia 3129
Stephen N. Davis, Philip E. Cryer

407 Disorders of Lipoprotein Metabolism 3135
Daniel J. Rader

408 The Metabolic Syndrome 3150
Robert H. Eckel

SECTION 4 Disorders of Bone and Mineral Metabolism

409 Bone and Mineral Metabolism in Health and Disease 3157
F. Richard Bringhurst, Henry M. Kronenberg, Eva S. Liu

410 Disorders of the Parathyroid Gland and Calcium Homeostasis 3169
John T. Potts, Jr., Harald Jüppner

411 Osteoporosis 3191

Robert Lindsay, Blossom Samuels

412 Paget's Disease and Other Dysplasias of Bone 3209
Rajesh K. Jain, Tamara J. Vokes

SECTION 5 Disorders of Intermediary Metabolism

413 Heritable Disorders of Connective Tissue..... 3217
Joan C. Marini, Fransiska Malfait

414 Hemochromatosis..... 3230
Lawrie W. Powell, David M. Frazer

415 Wilson's Disease 3235
Stephen G. Kaler

416 The Porphyrias 3237
Robert J. Desnick, Manisha Balwani

417 Disorders of Purine and Pyrimidine Metabolism 3248
John N. Mecchella, Christopher M. Burns

418 Lysosomal Storage Diseases 3254
Robert J. Hopkin, Gregory A. Grabowski

419 Glycogen Storage Diseases and Other Inherited Disorders of Carbohydrate Metabolism..... 3261
Priya S. Kishnani

420 Inherited Disorders of Amino Acid Metabolism in Adults..... 3268
Nicola Longo

421 Inherited Defects of Membrane Transport 3274
Nicola Longo

PART 13 Neurologic Disorders

SECTION 1 Diagnosis of Neurologic Disorders

422 Approach to the Patient with Neurologic Disease 3277
Daniel H. Lowenstein, S. Andrew Josephson, Stephen L. Hauser

423 Neuroimaging in Neurologic Disorders 3282
William P. Dillon

424 Pathobiology of Neurologic Diseases..... 3293
Stephen L. Hauser, Arnold R. Kriegstein, Stanley B. Prusiner

SECTION 2 Diseases of the Central Nervous System

425 Seizures and Epilepsy..... 3305
Vikram R. Rao, Daniel H. Lowenstein

426 Introduction to Cerebrovascular Diseases..... 3324
Wade S. Smith, S. Claiborne Johnston, J. Claude Hemphill, III

427 Ischemic Stroke 3335
Wade S. Smith, S. Claiborne Johnston, J. Claude Hemphill, III

428 Intracranial Hemorrhage..... 3348
Wade S. Smith, J. Claude Hemphill, III, S. Claiborne Johnston

429 Subarachnoid Hemorrhage 3353
J. Claude Hemphill, III, Wade S. Smith, Daryl R. Gress

430 Migraine and Other Primary Headache Disorders..... 3357
Peter J. Goadsby

431 Alzheimer's Disease 3370
Gil D. Rabinovici, William W. Seeley, Bruce L. Miller

432 Frontotemporal Dementia 3378
William W. Seeley, Bruce L. Miller

433 Vascular Dementia..... 3381
Steven M. Greenberg, William W. Seeley

434 Dementia with Lewy Bodies..... 3385
Irene Litvan, William W. Seeley, Bruce L. Miller

435 Parkinson's Disease 3386
C. Warren Olanow, Anthony H.V. Schapira

436 Tremor, Chorea, and Other Movement Disorders 3400
C. Warren Olanow, Christine Klein

437 Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases 3410
Robert H. Brown, Jr.

438 Prion Diseases 3416
Stanley B. Prusiner, Michael Geschwind

439 Ataxic Disorders 3422
Roger N. Rosenberg

440 Disorders of the Autonomic Nervous System 3427
Richard J. Barohn, John W. Engstrom

441 Trigeminal Neuralgia, Bell's Palsy, and Other Cranial Nerve Disorders 3436
Vanja C. Douglas, Stephen L. Hauser

442 Diseases of the Spinal Cord..... 3445
Stephen L. Hauser

443 Concussion and Other Traumatic Brain Injuries..... 3456
Geoffrey T. Manley, Benjamin L. Brett, Michael McCrea

444 Multiple Sclerosis 3462
Bruce A. C. Cree, Stephen L. Hauser

445 Neuromyelitis Optica..... 3477
Bruce A. C. Cree, Stephen L. Hauser

SECTION 3 Nerve and Muscle Disorders

446 Peripheral Neuropathy 3480
Anthony A. Amato, Richard J. Barohn

447 Guillain-Barré Syndrome and Other Immune-Mediated Neuropathies..... 3501
Stephen L. Hauser, Anthony A. Amato

448 Myasthenia Gravis and Other Diseases of the Neuromuscular Junction 3509
Anthony A. Amato

449 Muscular Dystrophies and Other Muscle Diseases 3516
Anthony A. Amato, Robert H. Brown, Jr.

SECTION 4 Myalgic Encephalomyelitis/Chronic Fatigue Syndrome

450 Myalgic Encephalomyelitis/Chronic Fatigue Syndrome 3532
Elizabeth R. Unger, Jin-Mann S. Lin, Jeanne Bertolli

SECTION 5 Psychiatric and Addiction Disorders

451 Biology of Psychiatric Disorders..... 3534
Robert O. Messing, Eric J. Nestler, Matthew W. State

452 Psychiatric Disorders 3540
Victor I. Reus

453 Alcohol and Alcohol Use Disorders 3556
Marc A. Schuckit

454 Nicotine Addiction 3563
David M. Burns

455 Marijuana and Marijuana Use Disorders 3567
Nora D. Volkow, Aidan Hampson, Ruben Baler

456 Opioid-Related Disorders..... 3569
Thomas R. Kosten, Colin N. Haile

457 Cocaine, Other Psychostimulants, and Hallucinogens..... 3573
Karran A. Phillips, Wilson M. Compton

PART 14 Poisoning, Drug Overdose, and Envenomation

458 Heavy Metal Poisoning 3579
Howard Hu

459 Poisoning and Drug Overdose 3582
Mark B. Mycyk

460 Disorders Caused by Venomous Snakebites and Marine Animal Exposures 3596
Erik Fisher, Alex Chen, Charles Lei

461 Ectoparasite Infestations and Arthropod Injuries 3608
Richard J. Pollack, Scott A. Norton

PART 15 Disorders Associated with Environmental Exposures

462 Altitude Illness 3617
Buddha Basnyat, Geoffrey Tabin

463 Hyperbaric and Diving Medicine 3623
Michael H. Bennett, Simon J. Mitchell

464 Hypothermia and Peripheral Cold Injuries 3630
Daniel F. Danzl

465 Heat-Related Illnesses 3635
Daniel F. Danzl

PART 16 Genes, the Environment, and Disease

466 Principles of Human Genetics 3639
J. Larry Jameson, Peter Kopp

467 The Practice of Genetics in Clinical Medicine 3662
Susan M. Domchek, J. Larry Jameson, Susan Miesfeldt

468 Mitochondrial DNA and Heritable Traits and Diseases 3668
Karl L. Skorecki, Bruce H. Cohen

469 Telomere Disease 3680
Rodrigo T. Calado, Neal S. Young

470 Gene- and Cell-Based Therapy in Clinical Medicine 3685
Katherine A. High, Marcela V. Maus

471 The Human Microbiome 3690
Neeraj K. Surana, Dennis L. Kasper

PART 17 Global Medicine

472 Global Issues in Medicine 3703
Joseph J. Rhatigan, Paul Farmer

473 Emerging and Reemerging Infectious Diseases 3713
George W. Rutherford, Jaime Sepúlveda

474 Primary Care and Global Health 3718
Tim Evans, Kumanan Rasanathan

475 Health Effects of Climate Change 3726
Eugene T. Richardson, Maxine A. Burkett, Paul E. Farmer

PART 18 Aging

476 Biology of Aging 3733
Rafael de Cabo, David Le Couteur

477 Caring for the Geriatric Patient 3739
Joseph G. Ouslander, Bernardo Reyes

PART 19 Consultative Medicine

478 Approach to Medical Consultation 3761
Jeffrey Berns, Jack Ende

479 Medical Disorders During Pregnancy 3762
Sarah Rae Easter, Robert L. Barbieri

480 Medical Evaluation of the Surgical Patient 3769
Prashant Vaishnava, Kim A. Eagle

PART 20 Frontiers

481 Behavioral Economics and Health 3775
Kevin G. Volpp, George Loewenstein, David A. Asch

482 Complementary and Integrative Therapies and Practices 3784
Helene M. Langevin

483 The Role of Epigenetics in Disease and Treatment 3790
Brian C. Capell, Shelley L. Berger

484 Applications of Stem Cell Biology in Clinical Medicine 3796
John A. Kessler

485 The Role of Circadian Biology in Health and Disease 3800
Jonathan Cedernaes, Kathryn Moynihan Ramsey, Joseph Bass

486 Network Medicine: Systems Biology in Health and Disease 3812
Joseph Loscalzo

487 Emerging Neurotherapeutic Technologies 3819
Jyoti Mishra, Karunesh Ganguly

488 Machine Learning and Augmented Intelligence in Clinical Medicine 3826
Arjun K. Manrai, Isaac S. Kohane

489 Metabolomics 3831
Jared R. Mayers, Mathew G. Vander Heiden

490 Circulating Nucleic Acids as Liquid Biopsies and Noninvasive Disease Biomarkers 3836
Ash A. Alizadeh, Kiran K. Khush, Yair J. Blumenfeld

491 Protein Folding Disorders 3846
Richard I. Morimoto, G. Scott Budinger

492 Novel Approaches to Diseases of Unknown Etiology 3851
David Adams, Camilo Toro, Joseph Loscalzo

Index I-1

The following chapters are available online. They can be viewed by opening the table of contents of *Harrison's* 21st edition at *www.accessmedicine.com/harrisons.*

Video Collection

V1 Video Library of Gait Disorders
Gail Kang, Nicholas B. Galifianakis, Michael D. Geschwind

V2 Primary Progressive Aphasia, Memory Loss, and Other Focal Cerebral Disorders
Maria Luisa Gorno-Tempini, Jennifer Ogar, Joel Kramer, Bruce L. Miller, Gil D. Rabinovici, Maria Carmela Tartaglia

V3 Video Library of Neuro-Ophthalmology
Jonathan C. Horton

V4 Examination of the Comatose Patient
S. Andrew Josephson

V5 Video Atlas of Gastrointestinal Endoscopic Lesions
Louis Michel Wong Kee Song, Mark Topazian

V6 The Neurologic Screening Exam
Daniel H. Lowenstein

V7 Video Atlas of the Detailed Neurologic Examination
Martin A. Samuels

Supplementary Topics

S1 Fluid and Electrolyte Imbalances and Acid-Base Disturbances: Case Examples
David B. Mount, Thomas D. DuBose, Jr.

S2 Cerebrospinal Fluid Disturbances: Case Examples
Prashanth S. Ramachandran, Michael R. Wilson

S3 Microbial Bioterrorism
H. Clifford Lane, Anthony S. Fauci

S4 Chemical Terrorism
James A. Romano, Jr., Jonathan Newmark

S5 Radiation Terrorism
Christine E. Hill-Kayser, Eli Glatstein, Zelig A. Tochner

S6 Infections in War Veterans
Andrew W. Artenstein

S7 Health Care for Military Veterans
Stephen C. Hunt, Lucile Burgo-Black, Charles W. Hoge

S8 Primary Immunodeficiencies Associated with (or Secondary to) Other Diseases
Alain Fischer

S9 Technique of Lumbar Puncture
Elizabeth Robbins, Stephen L. Hauser

S10 The Clinical Laboratory in Modern Health Care
Anthony A. Killeen

S11 Laboratory Diagnosis of Infectious Diseases
Manfred Brigl, Alexander J. McAdam

S12 Laboratory Diagnosis of Parasitic Infections
Sharon L. Reed, Sanjay R. Mehta

Atlases

A1 Atlas of Rashes Associated with Fever
Kenneth M. Kaye, Elaine T. Kaye

A2 Atlas of Blood Smears of Malaria and Babesiosis
Nicholas J. White, Elizabeth A. Ashley

A3 Atlas of Oral Manifestations of Disease
Samuel C. Durso, Janet A. Yellowitz

A4 Atlas of Urinary Sediments and Renal Biopsies
Agnes B. Fogo, Eric G. Neilson

A5 Atlas of Skin Manifestations of Internal Disease
Thomas J. Lawley, Benjamin K. Stoff, Calvin O. McCall

A6 Atlas of Hematology
Dan L. Longo

A7 Atlas of Electrocardiography
Ary L. Goldberger

A8 Atlas of Cardiac Arrhythmias
Ary L. Goldberger

A9 Atlas of Noninvasive Imaging
Marcelo F. Di Carli, Raymond Y. Kwong, Scott D. Solomon

A10 Atlas of Atherosclerosis
Peter Libby

A11 Atlas of Percutaneous Revascularization and Adult Structural Heart Interventions
Jane A. Leopold, Deepak L. Bhatt, David P. Faxon

A12 Atlas of Chest Imaging
Samuel Y. Ash, George R. Washko

A13 Atlas of Liver Biopsies
Jules L. Dienstag, Atul K. Bhan

A14 Atlas of the Vasculitic Syndromes
Carol A. Langford, Anthony S. Fauci

A15 Atlas of Clinical Manifestations of Endocrine and Metabolic Diseases
J. Larry Jameson

A16 Atlas of Neuroimaging
Michael F. Regner, Andre D. Furtado, Luciano Villarinho, William P. Dillon

Contributors

James L. Abbruzzese, MD, FACP, FASCO, DSc (hon)
Professor, Division of Medical Oncology, Duke Cancer Institute, Durham, North Carolina [92]

Manal F. Abdelmalek, MD, MPH
Professor of Medicine, Division of Gastroenterology and Hepatology, Duke University, Durham, North Carolina [343]

John C. Achermann, MD, PhD
Wellcome Trust Senior Research Fellow in Clinical Science, Genetics & Genomic Medicine, UCL GOS Institute of Child Health, University College London, London, United Kingdom [390]

David Adams, MD, PhD
Deputy Director of Clinical Genomics, Office of the Clinical Director/ NHGRI and Undiagnosed Diseases Program, National Institutes of Health, Bethesda, Maryland [492]

John W. Adamson, MD
Clinical Professor, Division of Hematology/Oncology, Department of Medicine, University of California at San Diego, San Diego, California [63, 97]

Praveen Akuthota, MD
Associate Clinical Professor, Division of Pulmonary, Critical Care & Sleep Medicine, University of California, San Diego, San Diego, California [288]

Christine Albert, MD, MPH
Chair, Department of Cardiology; Lee and Harold Kapelovitz Endowed Chair in Research Cardiology, Smidt Heart Institute, Cedars-Sinai Medical Center, Los Angeles, California [306]

Ash A. Alizadeh, MD, PhD
Professor of Medicine (Oncology), Stanford University School of Medicine, Stanford, California [490]

Anthony A. Amato, MD
Professor of Neurology, Harvard Medical School; Distinguished Chair of Neurology and Chief, Neuromuscular Division, Brigham and Women's Hospital, Boston, Massachusetts [365, 446–449]

Rachel L. Amdur, MD
Assistant Professor of Medicine, Division of General Internal Medicine and Geriatrics, Northwestern University Feinberg School of Medicine, Chicago, Illinois [35]

Neil M. Ampel, MD
Professor Emeritus of Medicine and Immunobiology, University of Arizona, Tucson, Arizona [213]

Kenneth C. Anderson, MD
Kraft Family Professor of Medicine, Harvard Medical School; Chief, Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute, Boston, Massachusetts [111]

Rosa M. Andrade, MD
Assistant Professor of Medicine, University of California, Irvine School of Medicine, Irvine, California [223]

Derek C. Angus, MD, MPH
Distinguished Professor and Mitchell P. Fink Endowed Chair, Department of Critical Care Medicine; University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania [304]

Elliott M. Antman, MD
Professor of Medicine; Harvard Medical School; Senior Physician; Senior Investigator, TIMI Study Trial, Brigham and Women's Hospital, Boston, Massachusetts [273, 275]

Frederick R. Appelbaum, MD
Deputy Director, Fred Hutchinson Cancer Research Center, Seattle, Washington [114]

Cesar A. Arias, MD, PhD, MSc, FIDSA
Chief, Division of Infectious Diseases, Houston Methodist Hospital; Professor and John F. III and Ann H. Bookout Distinguished Chair; Co-Director Center for Infectious Diseases Research, Houston Methodist Research Institute and Weill Cornell Medical College, Houston, Texas [149]

Wiebke Arlt, MD, DSc, FRCP, FMedSci
William Withering Chair of Medicine, Institute of Metabolism and Systems Research, University of Birmingham; Consultant Endocrinologist, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom [386]

Katrina A. Armstrong, MD
Physician in Chief, Massachusetts General Hospital, Boston, Massachusetts [6]

Andrew W. Artenstein, MD
Chief Physician Executive and Chief Academic Officer, Baystate Health; Regional Executive Dean and Professor of Medicine, University of Massachusetts Chan Medical School-Baystate, Springfield, Massachusetts [S6]

David A. Asch, MD, MBA
Executive Director, Penn Medicine Center for Health Care Innovation; John Morgan Professor, Perelman School of Medicine and the Wharton School, University of Pennsylvania, Philadelphia, Pennsylvania [481]

Samuel Y. Ash, MD, MPH
Assistant Professor of Medicine, Harvard Medical School; Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [A12]

Elizabeth A. Ashley, MB, BS, MRCP, FRCPath
Professor of Tropical Medicine, Oxford University; Director, Lao-Oxford-Mahosot Hospital-Wellcome Trust Research Unit, Vientiane, Lao PDR [224, A2]

John C. Atherton, MD, FRCP
Professor of Gastroenterology and Dean of the Faculty of Medicine and Health Sciences, University of Nottingham, Nottingham, United Kingdom [163]

Eric H. Awtry, MD
Associate Professor of Medicine, Boston University School of Medicine; Associate Chair for Clinical Affairs, Section of Cardiology, Boston Medical Center, Boston, Massachusetts [271, 272]

Jamil Azzi, MD
Associate Physician, Renal Division, Brigham and Women's Hospital; Director, Renal Transplant Fellowship; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts [313]

Bruce R. Bacon, MD
Emeritus Professor of Internal Medicine, Saint Louis University School of Medicine, St. Louis, Missouri [344]

Jessica M. Baker, MD
Assistant Professor, Department of Neurology, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin [26]

Zoica Bakirtzief, PhD
Guest Professor of Psychology, Vocational Teacher Certification Program, Federal University of Santa Maria, Santa Maria, Rio Grande do Sul, Brazil [179]

Ruben Baler, PhD
Health Scientist, Office of Science Policy and Communications, National Institute on Drug Abuse, National Institutes of Health, Bethesda, Maryland [455]

John R. Balmes, MD
Professor of Medicine, University of California San Francisco School of Medicine, San Francisco, California [289]

Manisha Balwani, MD, MS
Professor, Department of Genetics and Genomic Sciences and Medicine, Icahn School of Medicine at Mount Sinai, New York, New York [416]

Robert L. Barbieri, MD
Kate Macy Ladd Distinguished Professor of Obstetrics, Gynecology and Reproductive Biology, Harvard Medical School; Chief of Obstetrics, Department of Obstetrics and Gynecology, Brigham and Women's Hospital, Boston, Massachusetts [479]

Alan G. Barbour, MD
Distinguished Professor of Medicine and Microbiology and Molecular Genetics, University of California, Irvine, Irvine, California [185]

Joanne M. Bargman, MD, FRCPC
Professor of Medicine, University of Toronto; Staff Nephrologist, University Health Network; Clinician Investigator, Toronto General Hospital Research Institute; Director, Peritoneal Dialysis Program, Co-Director, Renal-Rheumatology Lupus Clinic, University Health Network [311]

Tamar F. Barlam, MD, MSc
Professor of Medicine, Boston University School of Medicine; Chief, Section of Infectious Diseases, Boston Medical Center, Boston, Massachusetts [122, 158]

Richard J. Barohn, MD
Executive Vice Chancellor for Health Affairs; Executive Director, NextGen Precision Health, University of Missouri, Columbia, Missouri [440, 446]

Beverly W. Baron, MD
Professor of Pathology, Retired, University of Chicago, Chicago, Illinois [127, 290]

Rebecca M. Baron, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Pulmonary Division and Critical Care, Boston, Massachusetts [37, 127, 290, 300, 301]

Miriam Baron Barshak, MD
Assistant Professor of Medicine, Harvard Medical School; Physician, Massachusetts General Hospital, Boston, Massachusetts [127, 132, 290]

Buddha Basnyat, MSc, MD, FACP, FRCP(Edinburgh)
Director, Oxford University Clinical Research Unit—Nepal, Patan Hospital, Kathmandu, Nepal [462]

Joseph Bass, MD, PhD
Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Feinberg School of Medicine, Department of Neurobiology, Northwestern University, Chicago, Illinois [485]

Shari S. Bassuk, ScD
Epidemiologist, Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts [395]

David W. Bates, MD, MSc
Professor of Medicine, Harvard Medical School; Chief, Division of General Internal Medicine and Primary Care, Brigham and Women's Hospital, Phyllis Jen Center for Primary Care, Boston, Massachusetts [8]

Robert P. Baughman, MD
Department of Internal Medicine, University of Cincinnati Medical Center, Cincinnati, Ohio [367]

Laurence H. Beck, Jr., MD, PhD
Associate Professor of Medicine, Boston University School of Medicine, Boston, Massachusetts [316]

Nicholas J. Beeching, FRCP, FRACP, FFTM RCPS(Glasg), FESCMID, FISTM, DTM&H, DCH
Consultant in Tropical and Infectious Diseases, Tropical and Infectious Disease Unit, Royal Liverpool University Hospitals Foundation NHS Trust; Emeritus Professor of Tropical and Infectious Diseases, Clinical Sciences, Liverpool School of Tropical Medicine, Liverpool, United Kingdom [169]

Alex S. Befeler, MD
Medical Director Liver Transplant, Professor of Internal Medicine, Division of Gastroenterology and Hepatology, Saint Louis University, St. Louis, Missouri [344]

Michael H. Bennett, MD, MBBS, MM (Clin Epi)
Conjoint Professor in Anesthesia and Hyperbaric Medicine; Faculty of Medicine, University of New South Wales; Academic Head of Department, Wales Anaesthesia, Prince of Wales Hospital, Sydney, Australia [463]

Shelley L. Berger, PhD
Daniel S. Och University Professor, Departments of Cell and Developmental Biology; Biology; Genetics; Director, Penn Epigenetics Institute, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania [483]

Jean Bergounioux, MD, PhD
Professor of Medicine, Versailles Saint Quentin University - Paris Saclay, UFR Simone Veil - Motigney le Bretonneux, France; Director, Department of Pediatric Neurology and Intensive Care Medicine, Assistance Publique des Hôpitaux de Paris, Garches, France [166]

John L. Berk, MD
Professor of Medicine, Boston University School of Medicine, Assistant Director, Amyloidosis Center, Boston Medical Center, Boston, Massachusetts [112]

Jeffrey Berns, MD
Professor of Medicine and Pediatrics; Associate Chief, Renal Electrolyte and Hypertension Division; Vice-President and Associate Dean for Graduate Medical Education, Perelman School of Medicine of the University of Pennsylvania, Philadelphia, Pennsylvania [478]

Aaron S. Bernstein, MD, MPH
Assistant Professor of Pediatrics, Harvard Medical School; Hospitalist, Division of General Pediatrics, Boston Children's Hospital; Interim Director, Center for Climate, Health and the Global Environment, Harvard T.H. Chan School of Public Health, Boston, Massachusetts [125]

Jeanne Bertolli, PhD
Division of High-Consequence Pathogens and Pathology, National Center for Zoonotic and Emerging Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [450]

Joseph R. Betancourt, MD, MPH
Associate Professor of Medicine, Massachusetts General Hospital; Harvard Medical School, Boston, Massachusetts [10]

Emily D. Bethea, MD
Instructor in Medicine, Harvard Medical School; Associate Clinical Director of Liver Transplantation, Gastroenterology and Hepatology Division, Massachusetts General Hospital, Boston, Massachusetts [337]

Julie A. Bettinger, MPH, PhD
Professor, Department of Pediatrics, Vaccine Evaluation Center, BC Children's Hospital, University of British Columbia, Vancouver, British Columbia, Canada [3]

Atul K. Bhan, MBBS, MD
Professor of Pathology, Harvard Medical School, Associate Director, Center for the Study of Inflammatory Bowel Disease, Massachusetts General Hospital, Boston, Massachusetts [A13]

Shalender Bhasin, MB, BS
Professor of Medicine, Harvard Medical School; Director, Research Program in Men's Health: Aging and Metabolism; Director, Boston Claude D. Pepper Older Americans Independence Center; Brigham and Women's Hospital, Boston, Massachusetts [391, 399]

Deepak L. Bhatt, MD, MPH, FACC, FAHA, FSCAI, FESC
Professor of Medicine, Harvard Medical School; Executive Director of Interventional Cardiovascular Programs, Brigham and Women's Hospital Heart & Vascular Center, Boston, Massachusetts [276, A11]

Roby P. Bhattacharyya, MD, PhD
Assistant Professor of Medicine, Harvard Medical School and Massachusetts General Hospital; Associate Member, Broad Institute of MIT and Harvard, Boston, Massachusetts [121]

Daniel G. Bichet, MD
Professor of Medicine, Pharmacology and Physiology, University of Montreal; Staff Nephrologist, Hôpital du Sacré-Cœur de Montréal, Montréal, Quebec, Canada [381]

David R. Bickers, MD
Carl Truman Nelson Professor and Chair, Department of Dermatology, Columbia University Irving Medical Center, New York, New York [61]

William R. Bishai, MD, PhD
Professor of Medicine, Division of Infectious Diseases, Johns Hopkins School of Medicine, Baltimore, Maryland [150]

Bruce R. Bistrian, MD, PhD, MPH
Professor of Medicine, Harvard Medical School; Chief, Clinical Nutrition, Beth Israel Deaconess Medical Center, Boston, Massachusetts [335]

Lucas S. Blanton, MD
Assistant Professor, Division of Infectious Diseases, Department of Internal Medicine University of Texas Medical Branch, Galveston, Texas [187]

Martin J. Blaser, MD
Henry Rutgers Chair of the Human Microbiome; Director, Center for Advanced Biotechnology and Medicine, Rutgers University, Piscataway, New Jersey [163, 167]

Chantal P. Bleeker-Rovers, MD, PhD
Department of Internal Medicine, Radboud University Medical Center, Nijmegen, The Netherlands [20, 187]

William Blum, MD
Director, Acute Leukemia Program; Professor, Department of Hematology and Oncology, Winship Cancer Institute and Emory University, Atlanta, Georgia [104]

Richard S. Blumberg, MD
Vice-Chair for Research in Department of Medicine, Brigham and Women's Hospital, Professor of Medicine, Harvard Medical School, Boston, Massachusetts [326]

Yair J. Blumenfeld, MD
Associate Professor of Obstetrics and Gynecology (Maternal Fetal Medicine), Stanford University School of Medicine, Stanford, California [490]

Jean L. Bolognia, MD
Professor, Department of Dermatology, Yale University School of Medicine, New Haven, Connecticut [58]

Joseph V. Bonventre, MD, PhD
Chief, Renal Division and Engineering in Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [310]

Joshua A. Boyce, MD
Professor of Medicine and Pediatrics; Albert L. Sheffer Professor of Medicine, Harvard Medical School; Director, Inflammation and Allergic Disease Research Section, Brigham and Women's Hospital, Boston, Massachusetts [352–354]

Emily B. Brant, MD, MS
Assistant Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania [304]

Eugene Braunwald, MD
Distinguished Hersey Professor of the Theory and Practice of Medicine, Harvard Medical School; Brigham and Women's Hospital, BWH/Founding Chair, TIMI Group, Boston, Massachusetts [274]

Irwin M. Braverman, MD
Professor Emeritus; Senior Research Scientist, Department of Dermatology, Yale University School of Medicine, New Haven, Connecticut [58]

Otis W. Brawley, MD, MACP, FRCP(L), FASCO, FACE
Bloomberg Distinguished Professor, Johns Hopkins School of Medicine and Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland [70]

Benjamin L. Brett, PhD
Medical College of Wisconsin, Assistant Professor, Departments of Neurosurgery and Neurology (Division Neuropsychology), Milwaukee, Wisconsin [443]

Manfred Brigl, MD
Assistant Professor of Pathology, Harvard Medical School, Boston, Massachusetts [S11]

F. Richard Bringhurst, MD
Associate Professor of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts [409]

Steven M. Bromley, MD
Director, South Jersey MS Center, Bromley Neurology PC, Audubon, New Jersey [33]

Darron R. Brown, MD
Professor of Medicine, Microbiology, and Immunology, Division of Infectious Diseases, Indiana University School of Medicine, Indianapolis, Indiana [198]

Kevin E. Brown, MD, MRCP, FRCPath
Consultant Medical Virologist, Immunisation and Vaccine Preventable Diseases Division, UK Health Security Agency, London, United Kingdom [197]

Robert H. Brown, Jr., MD, PhD
Chairman, Department of Neurology, University of Massachusetts Medical School, Worcester, Massachusetts [437, 449]

Amy E. Bryant, PhD
Research Professor, Department of Biomedical and Pharmaceutical Sciences College of Pharmacy, Idaho State University, Meridian, Idaho [129, 154]

G. Scott Budinger, MD
Ernest S. Bazley Professor of Airway Diseases; Chief, Pulmonary and Critical Care Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois [491]

Fred Bunz, MD, PhD
Associate Professor, Johns Hopkins University School of Medicine, Baltimore, Maryland [71]

Lucile Burgo-Black, MD, FACP
National Co-Director, VA Post-Deployment Integrated Care Initiative, Assistant Clinical Professor of Medicine, Department of General Internal Medicine, Yale University School of Medicine, New Haven, Connecticut [S7]

Maxine A. Burkett, JD
Professor of Law, William S. Richardson School of Law, University of Hawaii at Mānoa, Honolulu, Hawaii [475]

Christopher M. Burns, MD
Associate Professor of Medicine, Geisel School of Medicine at Dartmouth, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire [417]

David M. Burns, MD
Professor Emeritus, University of California, San Diego School of Medicine Del Mar, California [454]

John C. Byrd, MD
D. Warren Brown Chair of Leukemia Research; Distinguished University Professor of Medicine, Medicinal Chemistry, and Veterinary Biosciences; Director, Division of Hematology, Department of Medicine, The Ohio State University, Columbus, Ohio [107]

Rodrigo T. Calado, MD, PhD
Associate Professor of Medicine, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, Brazil [469]

Michael Camilleri, MD
Atherton and Winifred W. Bean Professor; Professor of Medicine, Pharmacology, and Physiology, Mayo Clinic School of Medicine, Rochester, Minnesota [46]

Christopher P. Cannon, MD
Professor of Medicine, Harvard Medical School; Education Director, Cardiovascular Innovation, Preventive Cardiology Section, Brigham and Women's Hospital, Boston, Massachusetts [274]

Brian C. Capell, MD, PhD
Assistant Professor of Dermatology and Genetics, Departments of Dermatology and Genetics, Penn Epigenetics Institute, Abramson Cancer Center, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania [483]

Jonathan Carapetis, MBBS, FRACP, FAFPHM, PhD
Executive Director, Telethon Kids Institute, Perth Children's Hospital, Nedlands, Western Australia [359]

Arturo Casadevall, MD, PhD
Professor and Chair, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, Maryland [215]

Jonathan Cedernaes, MD, PhD
Visiting Postdoctoral Fellow, Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [485]

Anil K. Chandraker, MB, ChB
Associate Professor of Medicine, Harvard Medical School; Medical Director, Kidney and Pancreas Transplantation, Brigham and Women's Hospital; Boston, Massachusetts [313]

François Chappuis, MD, MCTM, PhD
Head of Division, Division of Tropical and Humanitarian Medicine, Geneva University Hospitals, Geneva, Switzerland [227]

Richelle C. Charles, MD, FIDSA
Associate Professor of Medicine, Harvard Medical School, Massachusetts General Hospital; Associate Professor of Immunology and Infectious Diseases, Harvard T.H. Chan School of Public Health, Boston, Massachusetts [133]

Justin T. Cheeley, MD, FAAD
Assistant Professor, Divisions of Dermatology and Internal Medicine and Geriatrics, Emory University School of Medicine, Atlanta, Georgia [57]

Alex Chen, MD
Associate Physician, Department of Emergency Medicine, Kaiser Permanente, South Sacramento Campus, Sacramento, California [460]

Glenn M. Chertow, MD, MPH
Professor of Medicine, Division of Nephrology, Stanford University School of Medicine, Palo Alto, California [312]

Jacques Chiaroni, MD, PhD
Professor, Aix Marseille Univ, CNRS, EFS, ADES, UMR 7268; Etablissement Francais du Sang Provence Alpes Côté d'Azur et Corse, Marseille, France [113]

Hyon K. Choi, MD, DrPH
Professor of Medicine, Harvard Medical School; Director, Gout and Crystal Arthropathy Center; Director, Clinical Epidemiology and Health Outcomes, Division of Rheumatology, Allergy, and Immunology, Department of Medicine, Massachusetts General Hospital, Boston, Massachusetts [372]

Benjamin F. Chong, MD, MSCS
Associate Professor, Department of Dermatology, University of Texas Southwestern Medical Center, Dallas, Texas [59]

Raymond T. Chung, MD
Professor of Medicine, Harvard Medical School; Director of Hepatology and Liver Center; Vice Chief, Gastroenterology Division; Kevin and Polly Maroni MGH Research Scholar, Massachusetts General Hospital, Boston, Massachusetts [345]

Jeffrey W. Clark, MD
Associate Professor of Medicine, Harvard Medical School; Medical Director, Clinical Trials Core, Dana-Farber Harvard Cancer Center; Massachusetts General Hospital, Boston, Massachusetts [72]

Bruce H. Cohen, MD, FAAN
Professor of Pediatrics, Northeast Ohio Medical University; Professor of Integrative Medical Sciences, Northeast Ohio Medical University; Considine Family Endowed Chair in Research – Akron Children's Hospital; Director; NeuroDevelopmental Science Center, Akron Children's Hospital; Divisions of Neurology, Neurosurgery, NeuroBehavioral Health, Physiatry and Developmental Pediatrics; Interim Vice President and Medical Director, Rebecca D. Considine Research Institute, Akron Children's Hospital, Akron, Ohio [468]

Jeffrey I. Cohen, MD
Chief, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [191, 194, 204]

Amanda Cohn, MD
Chief Medical Officer, National Center for Immunization and Respiratory Diseases (NCIRD), Atlanta, Georgia [123]

Jennifer P. Collins, MD, MSc
Enteric Diseases Epidemiology Branch, Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [151]

Wilson M. Compton, MD, MPE
Deputy Director, National Institute on Drug Abuse, National Institutes of Health, U.S. Department of Health and Human Services, Bethesda, Maryland [457]

Jean M. Connors, MD
Hematology Division, Brigham and Women's Hospital; Harvard Medical School, Boston, Massachusetts [116]

Darwin L. Conwell, MD, MS
Professor of Medicine, The Ohio State University College of Medicine; Director, Division of Gastroenterology, Hepatology and Nutrition; The Ohio State University Wexner Medical Center, Columbus, Ohio [347, 348]

Lawrence Corey, MD
Professor of Medicine and Laboratory Medicine and Pathology, University of Washington; Past President & Director, Fred Hutchinson Cancer Research Center; Professor, Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Research Center, Seattle, Washington [192]

Jorge Cortes, MD
Jane and John Justin Distinguished Chair in Leukemia Research; Deputy Chairman; Section Chief of AML and CML, The University of Texas MD Anderson Cancer Center, Houston, Texas [105]

Sara E. Cosgrove, MD, MS
Professor of Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, Maryland [128]

James D. Crapo, MD
Professor of Medicine, Department of Medicine; Division of Pulmonary and Critical Care & Sleep Medicine, National Jewish Health, Denver, Colorado [292]

Mark A. Creager, MD
Professor of Medicine, Professor of Surgery, Geisel School of Medicine at Dartmouth; Director, Heart and Vascular Center, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire [280–282]

Bruce A. C. Cree, MD, PhD, MAS
George A. Zimmermann Endowed Professor in Multiple Sclerosis; Professor of Clinical Neurology; Clinical Research Director, UCSF Weill Institute for Neurosciences, Department of Neurology, University of California San Francisco, San Francisco, California [444, 445]

Leslie J. Crofford, MD
Professor, Departments of Medicine and Pathology, Microbiology and Immunology, Vanderbilt University; Chief, Division of Rheumatology and Immunology, Vanderbilt University Medical Center, Nashville, Tennessee [373]

Jennifer M. Croswell, MD, MPH
Senior Program Officer, Office of the Chief Science Officer, Patient-Centered Outcomes Research Institute (PCORI), Washington, DC [70]

James E. Crowe, Jr., MD
Director, Vanderbilt Vaccine Center; Ann Scott Carell Chair and Professor, Departments of Pediatrics, Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, Tennessee [199]

Ian Crozier, MD
NIH/NIAID/DCR Integrated Research Facility at Fort Detrick, Clinical Monitoring Research Program Directorate, Frederick National Laboratory for Cancer Research, Frederick, Maryland [209, 210]

Philip E. Cryer, MD
Professor Emeritus of Medicine, Division of Endocrinology, Metabolism & Lipid Research, Washington University School of Medicine in St. Louis, St. Louis, Missouri [406]

Gary C. Curhan, MD
Professor of Medicine, Harvard Medical School; Professor of Epidemiology, Harvard School of Public Health; Channing Division of Network Medicine/ Renal Division, Brigham and Women's Hospital, Boston, Massachusetts [318]

Brendan D. Curti, MD
Director, Cytokine and Adoptive Immunotherapy; Director, Genitourinary Oncology Research and Director, Melanoma Program; Robert W. Franz Endowed Chair for Clinical Research, Earle A. Chiles Research Institute, a Division of the Providence Cancer Institute, Portland, Oregon [76]

John J. Cush, MD
Executive Editor, RheumNow.com; Professor of Internal Medicine, University of Texas Southwestern Medical School, Dallas, Texas [370]

Charles A. Czeisler, MD, PhD
Frank Baldino, Jr., PhD Professor of Sleep Medicine, Professor of Medicine and Director, Division of Sleep Medicine, Harvard Medical School; Chief, Division of Sleep and Circadian Disorders, Departments of Medicine and Neurology, Brigham and Women's Hospital, Boston, Massachusetts [31]

Carolyn M. D'Ambrosio, MS, MD
Associate Professor of Medicine, Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts [39]

Josep Dalmau, MD, PhD
ICREA Professor, Institut d'Investigacions Biomèdiques August Pi i Sunyer, Hospital Clínic, University of Barcelona, Barcelona, Spain; Adjunct Professor, University of Pennsylvania, Philadelphia, Pennsylvania [94]

Inger K. Damon, MD, PhD
Director, Division of High-Consequence Pathogens and Pathology (DHCPP), Centers for Disease Control and Prevention, Atlanta, Georgia [196]

Daniel F. Danzl, MD
Professor and Emeritus Chair, Department of Emergency Medicine, University of Louisville, Louisville, Kentucky [464, 465]

Robert B. Daroff, MD
Professor and Chair Emeritus, Department of Neurology, Case Western Reserve University School of Medicine; University Hospitals–Cleveland Medical Center, Cleveland, Ohio [22]

Jaideep Das Gupta, MD
Vascular Surgery Fellow, Vascular Surgery Division, University of California, San Diego, La Jolla, California [329]

Stephen N. Davis, MBBS, FRCP, FACE, MACP
Theodore E. Woodward Professor of Medicine; Professor of Physiology; Chairman, Department of Medicine, University of Maryland School of Medicine; Director, Institute for Clinical and Translational Research; Vice President of Clinical Translational Science
University of Maryland, Baltimore; Physician-in-Chief, University of Maryland Medical Center, Baltimore, Maryland [406]

Lisa M. DeAngelis, MD
Professor of Neurology, Weill Cornell Medical College; Physician-in-Chief and Chief Medical Officer, Memorial Sloan Kettering Cancer Center, New York, New York [90]

Rafael de Cabo, PhD
Chief, Translational Gerontology Branch, National Institute on Aging, National Institutes of Health, Baltimore, Maryland [476]

Lucia De Franceschi, MD
Department of Medicine, University of Verona and AOUI Verona, Verona, Italy [100]

John Del Valle, MD
Professor and Vice Chair of Medicine, Department of Internal Medicine, University of Michigan School of Medicine, Ann Arbor, Michigan [324]

David W. Denning, MBBS, FRCP, FRCPath, FMedSci
Professor of Infectious Diseases in Global Health, The University of Manchester, Manchester, United Kingdom [217]

Akshay S. Desai, MD, MPH
Associated Professor of Medicine, Harvard Medical School; Director, Cardiomyopathy and Heart Failure, Advanced Heart Disease Section, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts [258]

Robert J. Desnick, PhD, MD
Dean for Genetic and Genomic Medicine Emeritus; Professor and Chairman Emeritus, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, Mount Sinai Health System, New York, New York [416]

Betty Diamond, MD
The Feinstein Institutes for Medical Research, Northwell Health System; Center for Autoimmunity and Musculoskeletal Diseases, Manhasset, New York [355]

Marcelo F. Di Carli, MD
Professor, Department of Radiology and Medicine, Harvard Medical School; Chief, Division of Nuclear Medicine and Molecular Imaging; Executive Director, Noninvasive Cardiovascular Imaging Program, Brigham and Women's Hospital, Boston, Massachusetts [241, A9]

Anna Mae Diehl, MD
Florence McAlister Professor of Medicine; Director, Duke Liver Center, Duke University, Durham, North Carolina [343]

Jules L. Dienstag, MD
Carl W. Walter Professor of Medicine, Harvard Medical School; Physician, Gastrointestinal Unit, Department of Medicine, Massachusetts General Hospital, Boston, Massachusetts [339–341, 345, A13]

William P. Dillon, MD
Professor and Executive Vice-Chair, Department of Radiology and Biomedical Imaging, University of California, San Francisco, San Francisco, California [423, A16]

Charles A. Dinarello, MD
Distinguished Professor of Medicine, University of Colorado School of Medicine, Aurora, Colorado [18]

R. Christopher Doiron, MD, FRCS(C)
Assistant Professor, Queens University at Kingston Canada; Staff Urologist, Department of Urology, Kingston Health Sciences Centre, Kingston, Ontario, Canada [51]

Anuja Dokras, MD, PhD
Professor of Obstetrics and Gynecology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [392, 393, 396]

Susan M. Domchek, MD
Basser Professor of Oncology, Abramson Cancer Center, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [467]

Richard L. Doty, PhD
Professor, Department of Otorhinolaryngology: Head and Neck Surgery; Director, Smell and Taste Center, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [33]

Vanja C. Douglas, MD
Professor of Neurology and Sara and Evan Williams Foundation Endowed Neurohospitalist Chair, University of California, San Francisco, San Francisco, California [23, 441]

David F. Driscoll, PhD
Associate Professor of Medicine, University of Massachusetts Medical School, Worcester, Massachusetts [335]

Thomas D. DuBose, Jr., MD, MACP
Emeritus Professor of Medicine, Wake Forest School of Medicine, Winston Salem, North Carolina [55, S1]

J. Stephen Dumler, MD
Professor and Chairman, Department of Pathology, Uniformed Services University of the Health Sciences, Walter Reed National Military Medical Center, Joint Pathology Center, Bethesda, Maryland [187]

Andrea Dunaif, MD
Lillian and Henry M. Stratton Professor of Molecular Medicine, System Chief, Hilda and J. Lester Gabrilove Division of Endocrinology, Diabetes and Bone Disease, Icahn School of Medicine and Mount Sinai Health System, New York, New York [398]

Samuel C. Durso, MD, MBA
Mason F. Lord Professor of Medicine; Executive Vice Chair, Johns Hopkins University Department of Medicine; Director, Department of Medicine, Johns Hopkins Bayview Medical Center, Baltimore, Maryland [36, A3]

Janice P. Dutcher, MD
Associate Director, Cancer Research Foundation of New York, Chappaqua, New York; Former Professor of Medicine, New York Medical College, Valhalla, New York [75]

Johanna T. Dwyer, DSc, RD
Professor of Medicine and Community Health, Tufts Medical School; Senior Nutrition Scientist (Contractor), Office of Dietary Supplements, National Institutes of Health, Boston, Massachusetts [332]

Kim A. Eagle, MD
Albion Walter Hewett Professor of Internal Medicine; Professor of Health Management Policy, School of Public Health; Director, Samuel and Jean Frankel Cardiovascular Center, University of Michigan, Ann Arbor, Michigan [480]

Sarah Rae Easter, MD
Assistant Professor of Obstetrics, Gynecology and Reproductive Biology, Harvard Medical School; Director of Obstetric Critical Care, Brigham and Women's Hospital, Boston, Massachusetts [479]

James A. Eastham, MD
Chief, Urology Service; Peter T. Scardino Chair in Oncology, Department of Surgery, Sidney Kimmel Center for Prostate and Urologic Cancers, Memorial Sloan Kettering Cancer Center, New York, New York [87]

Robert H. Eckel, MD
Professor of Medicine, Emeritus; University of Colorado School of Medicine, Aurora, Colorado [408]

John E. Edwards, Jr., MD
Distinguished Professor of Medicine Emeritus, David Geffen School of Medicine, University of California, Los Angeles; Senior Investigator, The Lundquist Institute and Emeritus Chief, Division of Infectious Disease at Harbor-UCLA Medical Center, Torrance, California [211, 216]

David A. Ehrmann, MD
Professor of Medicine, Section of Endocrinology; Director, University of Chicago Center for PCOS, University of Chicago, Chicago, Illinois [394]

Ramy H. Elshaboury, PharmD
Clinical Pharmacy Manager; Director, PGY2 Infectious Diseases Pharmacy Residency, Massachusetts General Hospital, Boston, Massachusetts [144]

Ezekiel J. Emanuel, MD, PhD
Chair, Department of Medical Ethics and Health Policy, Levy University Professor, Perelman School of Medicine and Wharton School, University of Pennsylvania, Philadelphia, Pennsylvania [12]

Jack Ende, MD
The Schaeffer Professor of Medicine; Assistant Vice President, University of Pennsylvania Health System; Assistant Dean for Advanced Medical Practice, Perelman School of Medicine of the University of Pennsylvania, Philadelphia, Pennsylvania [478]

John W. Engstrom, MD
Betty Anker Fife Distinguished Professor and Vice-Chairman; Neurology Residency Program Director, University of California, San Francisco, San Francisco, California [17, 440]

Moshe Ephros, MD
Clinical Associate Professor of Pediatrics, Faculty of Medicine, Technion–Israel Institute of Technology, Haifa, Israel [172]

Aaron C. Ermel, MD
Assistant Professor of Clinical Medicine, Department of Internal Medicine, Division of Infectious Diseases, Indiana University School of Medicine, Indianapolis, Indiana [198]

Tim Evans, DPhil, MD
Associate Dean and Director, School of Population and Global Health, McGill University, Montreal, Quebec, Canada [474]

Carmella Evans-Molina, MD, PhD
Eli Lilly Professor of Pediatric Diabetes; Professor, Departments of Pediatrics and Medicine; Director of the Center for Diabetes and Metabolic Diseases; Director of Diabetes Research, Herman B. Wells Center for Pediatric Research; Indiana University School of Medicine; Staff Physician, Richard L. Roudebush VA Medical Center, Indianapolis, Indiana [403]

Christopher H. Fanta, MD
Professor of Medicine, Harvard Medical School; Member, Pulmonary and Critical Care Medicine Division, Brigham and Women's Hospital; Director, Partners Asthma Center, Boston, Massachusetts [38]

Paul E. Farmer, MD, PhD
Kolokotrones University Professor, Harvard University; Chair, Department of Global Health and Social Medicine, Harvard Medical School; Chief, Division of Global Health Equity, Brigham and Women's Hospital; Chief Strategist, Co-Founder, Partners In Health, Boston, Massachusetts [472, 475]

I. Sadaf Farooqi, PhD, FRCP, FMedSci, FRS
Professor of Metabolism and Medicine, Wellcome-MRC Institute of Metabolic Science, University of Cambridge, Cambridge, United Kingdom [401]

Anthony S. Fauci, MD
Chief, Laboratory of Immunoregulation; Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [1, 5, 201, 202, 349, 350, 363, A14, S3]

David P. Faxon, MD
Senior Lecturer, Harvard Medical School; Associate Chief, Cardiovascular Medicine, Department of Medicine; Brigham and Women's Hospital, Boston, Massachusetts [242, 276, A11]

David Feller-Kopman, MD
Professor of Medicine, Dartmouth Geisel School of Medicine; Section Chief, Pulmonary and Critical Care Medicine, Dartmouth Hitchcock Medical Center, Lebanon, New Hampshire [299]

David T. Felson, MD, MPH
Professor of Medicine and Epidemiology, Boston University School of Medicine, Boston, Massachusetts [371]

Howard L. Fields, MD, PhD
Professor, Department of Neurology, University of California, San Francisco, San Francisco, California [13]

Gregory A. Filice, MD
Staff Physician, Veterans Affairs Medical Center, Professor of Medicine and Adjunct Professor of Public Health, University of Minnesota, Minneapolis, Minnesota [174]

Robert W. Finberg, MD‡
Richard M. Haidack Distinguished Professor of Medicine; Professor, Microbiology and Physiological Systems; Chair, Department of Medicine, University of Massachusetts Chan Medical School, Worcester, Massachusetts [74, 143]

Courtney Finlayson, MD
Associate Professor, Division of Endocrinology, Department of Pediatrics, Ann & Robert H. Lurie Children's Hospital of Chicago, Northwestern University Feinberg School of Medicine, Chicago, Illinois [390]

Alain Fischer, MD, PhD
Imagine Institute; Professor at College de France, Paris, France [351, S8]

Erik Fisher, MD
Clinical Assistant Professor of Emergency Medicine, University of South Carolina School of Medicine Greenville; Director, Medical Toxicology, Department of Emergency Medicine, Prisma Health-Update, Greenville, South Carolina [460]

Agnes B. Fogo, MD
John L. Shapiro Endowed Chair in Pathology; Professor of Pathology, Medicine and Pediatrics; Director, Renal Pathology/Electron Microscopy Laboratory, Vanderbilt University Medical Center, Nashville, Tennessee [A4]

‡Deceased

Gregory K. Folkers, MS, MPH
Chief of Staff, Office of the Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [202]

Michael J. Fowler, MD
Associate Professor of Medicine, Division of Diabetes, Endocrinology and Metabolism, Department of Medicine; Course Director, Physical Diagnosis; Medical Director, Glucose Management Service; Director of Clinical Skills Development in Undergraduate Medical Education, Vanderbilt University School of Medicine, Nashville, Tennessee [404]

David M. Frazer, PhD
Associate Professor, Molecular Nutrition Laboratory, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia [414]

Jane E. Freedman, MD
Director, Division of Cardiology, Physician-in-Chief, Vanderbilt Medical Center, Nashville, Tennessee [117]

Roy Freeman, MD
Professor of Neurology, Harvard Medical School; Director, Center for Autonomic and Peripheral Nerve Disorders, Beth Israel Deaconess Medical Center, Boston, Massachusetts [21]

Lawrence S. Friedman, MD
Professor of Medicine, Harvard Medical School; Professor of Medicine, Tufts University School of Medicine; The Anton R. Fried, MD Chair, Department of Medicine, Newton-Wellesley Hospital, Newton, Massachusetts; Assistant Chief of Medicine, Massachusetts General Hospital, Boston, Massachusetts [50]

Sonia Friedman, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts [326]

Andre D. Furtado, MD
Assistant Professor, Department of Radiology, School of Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania [A16]

Nicholas B. Galifianakis, MD, MPH
Associate Professor of Neurology, Movement Disorder and Neuromodulation Center Weill Institute for Neurosciences, Department of Neurology, University of California, San Francisco, San Francisco, California [V1]

John I. Gallin, MD
Associate Director for Clinical Research; Chief Scientific Officer, Clinical Center, National Institutes of Health, Bethesda, Maryland [64]

Karunesh Ganguly, MD, PhD
Department of Neurology, University of California, San Francisco; Neurology & Rehabilitation Service, San Francisco VA Medical Center, San Francisco, California [487]

Olivier Garraud, MD, PhD
Professor, INSERM 1059, University of Lyon, Faculty of Medicine of Saint-Etienne, Saint-Etienne, France [113]

Gregory M. Gauthier, MD
Associate Professor, Department of Medicine, Division of Infectious Disease, School of Medicine and Public Health, University of Wisconsin, Madison, Madison, Wisconsin [214]

Charlotte A. Gaydos, MS, MPH, DrPH
Professor of Medicine, Division of Infectious Diseases, Johns Hopkins University, Baltimore, Maryland [189]

J. Michael Gaziano, MD, MPH
Professor of Medicine, Harvard Medical School; Physician, Brigham and Women's Hospital and the VA Boston Healthcare System, Boston, Massachusetts [238]

Thomas A. Gaziano, MD, MSc
Associate Professor of Medicine, Harvard Medical School; Associate Professor, Health Policy and Management, Center for Health Decision Sciences, Harvard School of Public Health; Director, Global Cardiovascular Health Policy and Prevention Unit, Cardiovascular Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [238]

Susan L. Gearhart, MD
Associate Professor, Surgery, Johns Hopkins Medical Institutions, Baltimore, Maryland [328]

Jeffrey A. Gelfand, MD
Professor of Medicine (Part-Time), Harvard Medical School; Attending Physician, Infectious Diseases Division, Massachusetts General Hospital, Boston, Massachusetts [225]

Jeffrey M. Gelfand, MD, MAS, FAAN
Associate Professor of Neurology, Department of Neurology, University of California, San Francisco, San Francisco, California [23]

Lianne S. Gensler, MD
Professor of Medicine; Rheumatology Fellowship Program Director; Director, Spondyloarthritis Research Program and Clinic, University of California, San Francisco, San Francisco, California [362]

Alfred L. George, Jr., MD
Magerstadt Professor and Chair, Department of Pharmacology, Northwestern University Feinberg School of Medicine, Chicago, Illinois [309]

Dale N. Gerding, MD
Research Physician, Edward Hines Jr. VA Hospital, Hines, Illinois; Professor of Medicine (Retired), Loyola University Chicago Stritch School of Medicine, Maywood, Illinois [134]

Michael D. Geschwind, MD, PhD
Professor of Neurology; Michael J. Homer Chair in Neurology, Memory and Aging Center, University of California, San Francisco, San Francisco, California [438, V1]

Marc G. Ghany, MD, MHSc
Tenure-Track Investigator, Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland [336]

Lorenzo Giacani, PhD
Associate Professor of Medicine, Department of Medicine, Division of Allergy & Infectious Diseases, University of Washington, Seattle, Washington [183]

Matthew P. Giannetti, MD
Division of Allergy and Clinical Immunology, Brigham and Women's Hospital; Harvard Medical School, Boston, Massachusetts [354]

Michael Giladi, MD, MSc
Associate Professor of Medicine, Sackler Faculty of Medicine, Tel Aviv University; Senior Physician, The Infectious Disease Unit; Director, The Bernard Pridan Laboratory for Molecular Biology of Infectious Diseases, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel [172]

Robert P. Giugliano, MD, SM, FACC, FAHA
Professor of Medicine, Harvard Medical School; Senior Investigator, TIMI Study Group, Cardiovascular Medicine, Brigham and Women's Hospital, Boston, Massachusetts [274]

Michael M. Givertz, MD
Professor of Medicine, Harvard Medical School; Medical Director, Heart Transplant and Mechanical Circulatory Support, Brigham and Women's Hospital, Boston, Massachusetts [257]

Roger I. Glass, MD, PhD
Director, Fogarty International Center; Associate Director for International Research National Institutes of Health, Bethesda, Maryland [203]

Seth R. Glassman, MD
Assistant Clinical Professor of Medicine, Division of Infectious Diseases, University at Buffalo Jacobs School of Medicine and the Biomedical Sciences, Buffalo, New York [176]

Eli Glatstein, MD‡
Professor Emeritus, Department of Radiation Oncology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania [S5]

Ronald S. Go, MD
Chair, Core/Consultative Hematology, Division of Hematology, Mayo Clinic Rochester, Rochester, Minnesota [317]

‡Deceased

Peter J. Goadsby, MD, PhD, DSc, FRACP, FRCP, FMedSci
Professor, NIHR-Wellcome Trust King's Clinical Research Facility, King's College London, United Kingdom; Professor, Department of Neurology, University of California, Los Angeles, Los Angeles, California [16, 430]

Hilary J. Goldberg, MD, MPH
Assistant Professor of Medicine, Harvard Medical School; Medical Director, Lung Transplant Program; Clinical Director, Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts [286, 298]

Marcia B. Goldberg, MD
Professor of Medicine and Microbiology, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts [120]

Ary L. Goldberger, MD
Professor of Medicine, Harvard Medical School & Wyss Institute for Biotechnology Inspired Engineering at Harvard University; Director, Margret and H.A. Rey Institute for Nonlinear Dynamics in Medicine; Associate Chief, Division of Interdisciplinary Medicine and Biotechnology, Beth Israel Deaconess Medical Center, Boston, Massachusetts [240, A7, A8]

David Goldblatt, MB, ChB, PhD
Professor of Vaccinology and Immunology, University College London Institute of Child Health, London, United Kingdom [146]

Samuel Z. Goldhaber, MD
Professor of Medicine, Harvard Medical School; Associate Chief and Clinical Director, Division of Cardiovascular Medicine; Director, Thrombosis Research Group, Brigham and Women's Hospital, Boston, Massachusetts [279]

Andrea Gori, MD
Full Professor of Infectious Diseases, School of Medicine and Surgery, Department of Pathophysiology and Transplantation; Co-Director, Centre for Multidisciplinary Research in Health Science (MACH), University of Milan; Director, Infectious Diseases Unit, Department of Internal Medicine, Fondazione IRCCS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy [178]

Marga G.A. Goris, PhD, MSC
Head OIE and National Collaborating Centre for Reference and Research on Leptospirosis, Department of Medical Microbiology, Amsterdam University Medical Centers, Amsterdam, The Netherlands [184]

Maria Luisa Gorno-Tempini, MD, PhD
Professor, Department of Neurology; Language Neurobiology Lab, Memory and Aging Center; Dyslexia Center, University of California, San Francisco, San Francisco, California [V2]

Daniel J. Gottlieb, MD, MPH
Associate Professor of Medicine, Harvard Medical School; Director, Sleep Disorders Center, VA Boston Healthcare System, Sleep Medicine Division, Brigham and Women's Hospital, Boston, Massachusetts [297]

Peter A. Gottlieb, MD
Professor of Pediatrics and Medicine, Barbara Davis Center for Childhood Diabetes, University of Colorado School of Medicine, Aurora, Colorado [389]

Gregory A. Grabowski, MD
Professor Emeritus, University of Cincinnati College of Medicine; Departments of Pediatrics, and Molecular Genetics, Biochemistry and Microbiology, Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio [418]

Yonatan H. Grad, MD, PhD
Associate Professor of Immunology and Infectious Diseases, Harvard T.H. Chan School of Public Health, Boston, Massachusetts [121]

Christine Grady, RN, PhD
Chief, Department of Bioethics, National Institutes of Health Clinical Center, Bethesda, Maryland [11]

Francesc Graus, MD, PhD
Neuroimmunology Program, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Hospital Clínic, Barcelona, Spain [94]

Steven A. Greenberg, MD
Professor of Neurology, Harvard Medical School; Associate Neurologist, Brigham and Women's Hospital, Boston, Massachusetts [365]

Steven M. Greenberg, MD, PhD
Professor of Neurology, Harvard Medical School; Vice Chair of Neurology, Massachusetts General Hospital, MGH Stroke Research Center, Boston, Massachusetts [433]

Norton J. Greenberger, MD‡
Clinical Professor of Medicine, Harvard Medical School; Senior Physician, Division of Gastroenterology, Brigham and Women's Hospital, Boston, Massachusetts [346]

Daryl R. Gress, MD
Professor of Neurological Sciences; Director of Neurocritical Care, University of Nebraska Medical Center, Omaha, Nebraska [307, 429]

Patricia M. Griffin, MD
Chief, Enteric Diseases Epidemiology Branch, Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [151]

Rasim Gucalp, MD, FACP
Professor of Medicine, Albert Einstein College of Medicine; Associate Chairman for Educational Programs, Department of Oncology; Director, Hematology/Oncology Fellowship, Montefiore Medical Center, Bronx, New York [75]

Kalpana Gupta, MD, MPH
Associate Chief of Staff and Chief, Infectious Diseases, Veterans Affairs Boston Healthcare System, West Roxbury, Massachusetts; Professor of Medicine, Boston University School of Medicine, Boston, Massachusetts [135]

Chadi A. Hage, MD
Associate Professor of Clinical Medicine, Indiana University School of Medicine, Pulmonary Critical Care Medicine, Indianapolis, Indiana [212]

Bevra Hannahs Hahn, MD
Distinguished Professor of Medicine (Emeritus), University of California, Los Angeles, Los Angeles, California [356]

Noah M. Hahn, MD
Associate Professor of Oncology and Urology, Johns Hopkins University School of Medicine; Johns Hopkins University Greenberg Bladder Cancer Institute, Baltimore, Maryland [86]

Colin N. Haile, MD, PhD
Assistant Professor, Menninger Department of Psychiatry and Behavioral Sciences, Baylor College of Medicine; Michael E. DeBakey VA Medical Center, Houston, Texas [456]

Janet E. Hall, MD
Clinical Director and Senior Investigator, Division of Intramural Research, NIH/NIEHS, Research Triangle Park, North Carolina [392, 393, 396]

Scott A. Halperin, MD
Professor of Pediatrics and Microbiology & Immunology, Dalhousie University, Halifax, Nova Scotia, Canada [160]

Aidan Hampson, PhD
Program and Scientific Officer, Special Content Expert on Cannabis, Clinical Research Grants Branch, Division of Therapeutics & Medical Consequences, National Institute on Drug Abuse, National Institutes of Health, Rockville, Maryland [455]

R. Doug Hardy, MD
ID Specialists, Dallas, Texas [188]

Nigil Haroon, MD, PhD, DM, FRCPC
Associate Professor of Medicine and Rheumatology, University of Toronto; Clinician Scientist and Attending Physician, University Health Network and Mount Sinai Hospital; Scientist, Krembil Research Institute, Toronto, Ontario, Canada [362]

‡Deceased

Phil A. Hart, MD
Associate Professor of Medicine; Director, Section of Pancreatic Disorders, Division of Gastroenterology, Hepatology, and Nutrition, The Ohio State University Wexner Medical Center, Columbus, Ohio [347, 348]

William L. Hasler, MD
Professor, Division of Gastroenterology and Hepatology, University of Michigan Health System, Ann Arbor, Michigan [45, 321]

Stephen L. Hauser, MD
Robert A. Fishman Distinguished Professor, Department of Neurology, University of California, San Francisco; Director, UCSF Weill Institute for Neurosciences, San Francisco, California [1, 5, 24, 25, 28, 422, 424, 441, 442, 444, 445, 447, S9]

Thomas R. Hawn, MD, PhD
Professor, Department of Medicine, Division of Allergy & Infectious Diseases, University of Washington, Seattle, Washington [159]

Daniel F. Hayes, MD, FASCO, FACP
Stuart B. Padnos Professor of Breast Cancer Research, University of Michigan Rogel Cancer Center, Ann Arbor, Michigan [79]

Barton F. Haynes, MD
Director, Duke Human Vaccine Institute; Frederic M. Hanes Professor of Medicine; Professor of Immunology, Departments of Medicine and Immunology, Duke University Medical Center, Durham, North Carolina [349, 350]

J. Claude Hemphill, III, MD, MAS
Professor of Neurology and Neurological Surgery, University of California, San Francisco; Chief, Neurology Service, Zuckerberg San Francisco General Hospital, San Francisco, California [307, 426–429]

Dirk M. Hentschel, MD
Assistant Professor of Medicine, Harvard Medical School; Director of Interventional Nephrology, Brigham Health; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts [320]

Katherine A. High, MD
Professor Emerita, Perelman School of Medicine of the University of Pennsylvania; President, Therapeutics, Asklepios BioPharmaceuticals, Philadelphia, Pennsylvania [470]

Christine E. Hill-Kayser, MD
Assistant Professor of Radiation Oncology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [S5]

Ikuo Hirano, MD
Professor of Medicine, Division of Gastroenterology, Northwestern University Feinberg School of Medicine, Chicago, Illinois [44, 323]

Martin S. Hirsch, MD
Professor of Medicine, Harvard Medical School; Senior Physician, Massachusetts General Hospital, Boston, Massachusetts [195]

Dieter Hoelzer, PhD, MD
Emeritus Director of Internal Medicine, University of Frankfurt, Frankfurt, Germany [106]

A. Victor Hoffbrand, DM
Emeritus Professor of Haematology, University College, London, United Kingdom [99]

L. John Hoffer, MD, PhD
Professor, Faculty of Medicine, McGill University; Senior Physician, Divisions of Internal Medicine and Endocrinology, Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, Quebec, Canada [335]

Charles W. Hoge, MD
Senior Scientist, Center for Psychiatry and Neuroscience, Walter Reed Army Institute of Research, Silver Spring, Maryland [S7]

Steven M. Holland, MD
Scientific Director, National Institute of Allergy and Infectious Diseases; Distinguished NIH Investigator, National Institutes of Health, Bethesda, Maryland [64, 180]

King K. Holmes, MD, PhD
Professor Emeritus, Global Health; Professor Emeritus, Medicine – Allergy and Infectious Diseases; Director, Research and Faculty Development, Department of Global Health; Co-Director, Center for AIDS Research, University of Washington – Fred Hutchinson Cancer Research Center; PI, International Training and Education Center for Health (I-TECH), University of Washington – University of California San Francisco; Director, Center for AIDS and STD, University of Washington; Infectious Disease Section Head, Harborview Medical Center; Member, National Institutes of Health (NIH) Fogarty International Center Council; Member, National Institutes of Health (NIH) Council or Councils, Seattle, Washington [136]

David Hong, MD
Assistant Professor of Medicine, Harvard Medical School; Division of Allergy & Immunology, Brigham and Women's Hospital, Boston, Massachusetts [353]

Jay H. Hoofnagle, MD
Director, Liver Diseases Research Branch, Division of Digestive Diseases and Nutrition, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland [336]

David C. Hooper, MD
Professor of Medicine, Harvard Medical School; Chief, Infection Control Unit, and Associate Chief, Division of Infectious Diseases, Massachusetts General Hospital, Boston, Massachusetts [144, 145]

Robert J. Hopkin, MD
Associate Professor of Clinical Pediatrics,
Cincinnati Children's Hospital Medical Center
Division of Human Genetics, Cincinnati, Ohio [418]

Leora Horn, MD, MSc
Associate Professor, Division of Hematology and Medical Oncology, Vanderbilt University School of Medicine, Nashville, Tennessee [78]

Jonathan C. Horton, MD, PhD
William F. Hoyt Professor of Neuro-ophthalmology, Professor of Ophthalmology, Neurology and Physiology, University of California, San Francisco School of Medicine, San Francisco, California [32, V3]

Howard Hu, MD, MPH, ScD
Professor & Flora L. Thornton Chair, Department of Population and Public Health Sciences, Keck School of Medicine, University of Southern California, Los Angeles, California [458]

Deborah T. Hung, MD, PhD
Professor of Genetics, Harvard Medical School, Brigham and Women's Hospital and Massachusetts General Hospital, Boston, Massachusetts; Co-Director, Infectious Disease and Microbiome Program, Broad Institute of MIT and Harvard, Cambridge, Massachusetts [121]

Gary M. Hunninghake, MD, MPH
Associate Professor of Medicine, Harvard Medical School; Division of Pulmonary & Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts [293]

Stephen C. Hunt, MD, MPH
National Director, VA Post-Deployment Integrated Care Initiative; Clinical Professor of Medicine, Department of Medicine, Division of General Internal Medicine, Occupational and Environmental Medicine Program, University of Washington, Seattle, Washington [S7]

Wade T. Iams, MD, MSCI
Department of Medicine, Division of Hematology/Oncology, Vanderbilt University Medical Center, Nashville, Tennessee [78]

Ashraf S. Ibrahim, PhD
Professor of Medicine, Division of Infectious Diseases, David Geffen School of Medicine at the University of California, Los Angeles; Senior Investigator and Vice Chair, Board of Directors, Director of the Graduate Studies Program, The Lindquist Institute at Harbor–UCLA Medical Center, Torrance, California [216, 218]

David H. Ingbar, MD
Professor, Medicine, Pediatrics and Integrative Biology and Physiology; Director, Pulmonary, Allergy, Critical Care and Sleep Division; CTSI Associate Director, Education, Career Development and Training; Executive Director, Center for Lung Science and Health, University of Minnesota, Minneapolis, Minnesota [305]

Elliot Israel, MD
Professor of Medicine, Harvard Medical School; Gloria M. and Anthony C. Simboli Distinguished Chair in Asthma Research; Director of Clinical Research, Pulmonary and Critical Care Division, Allergy and Immunology Division, Brigham and Women's Hospital, Boston, Massachusetts [287]

Elias Jabbour, MD
Professor, Section Chief, Acute Lymphocytic Leukemia, Department of Leukemia, Division of Cancer Medicine, MD Anderson Cancer Center, Houston, Texas [105]

Alan C. Jackson, MD
Professor of Medicine (Neurology), University of Manitoba, Winnipeg, Manitoba, Canada [208]

Yves Jackson, MD, PhD
Assistant Professor, Division of Primary Care Medicine, Geneva University Hospitals, Geneva, Switzerland [227]

Danny O. Jacobs, MD, MPH, FACS
President, Oregon Health and Science University, Portland, Oregon [15, 330, 331]

Caron A. Jacobson, MD
Assistant Professor of Medicine, Harvard Medical School; Dana-Farber Cancer Institute, Boston, Massachusetts [108, 109]

Rajesh K. Jain, MD
Assistant Professor, Department of Medicine, Section of Endocrinology, University of Chicago, Chicago, Illinois [412]

J. Larry Jameson, MD, PhD
Robert G. Dunlop Professor of Medicine; Dean, Raymond and Ruth Perelman School of Medicine; Executive Vice President, University of Pennsylvania for the Health System, Philadelphia, Pennsylvania [1, 5, 47, 93, 376–380, 382–385, 390, 391, 466, 467, A15]

Gordon L. Jensen, MD, PhD
Senior Associate Dean for Research; Professor of Medicine and Nutrition, University of Vermont Larner College of Medicine, Burlington, Vermont [334]

Savio John, MD
Chief of Gastroenterology, State University of New York Upstate Medical University, Syracuse, New York [49]

James R. Johnson, MD
Professor of Medicine, Division of Infectious Diseases and International Medicine, University of Minnesota, Minneapolis, Minnesota [161]

Stuart Johnson, MD
Professor of Medicine, Loyola University Chicago Stritch School of Medicine, Maywood, Illinois; Staff Physician, Edward Hines Jr. VA Hospital, Hines, Illinois [134]

S. Claiborne Johnston, MD, PhD
Professor of Neurology, Dell Medical School, University of Texas at Austin, Austin, Texas [426–428]

S. Andrew Josephson, MD
Professor and Chairman, Department of Neurology, University of California, San Francisco, San Francisco, California [27, 28, 307, 422, V4]

Sandeep S. Jubbal, MD
Assistant Professor of Medicine, Division of Infectious Diseases and Immunology, University of Massachusetts Chan Medical School, Worcester, Massachusetts [141]

Harald Jüppner, MD
Professor of Pediatrics, Endocrine Unit and Pediatric Nephrology Unit, Harvard Medical School; Massachusetts General Hospital, Boston, Massachusetts [410]

Joseph Kado, MBBS, DCH, MMed
University of Western Australia, Crawley, Western Australia; Clinical Research Officer, Telethon Kids Institute, Nedlands, Western Australia [359]

Peter J. Kahrilas, MD
Gilbert H. Marquardt Professor of Medicine, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [44, 323]

Stephen G. Kaler, MD
CAPT, US Public Health Service (Ret); Professor of Pediatrics and Genetics, The Ohio State University College of Medicine; Principal Investigator, Center for Gene Therapy, Abigail Wexner Research Institute, Nationwide Children's Hospital, Columbus, Ohio [415]

Gail Kang, MD
Private Practice, Berkeley, California [V1]

Hagop Kantarjian, MD
Chairman, Leukemia Department; Professor of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas [105]

Hemanta K. Kar, MBBS, MD, MAMS
Professor and Head, Department of Dermatology, STD and Leprosy, Kalinga Institute of Medical Sciences, Bhubaneswar, Odisha, India [179]

Adolf W. Karchmer, MD
Professor of Medicine, Harvard Medical School; Emeritus Chief, Division of Infectious Diseases, Beth Israel Deaconess Medical Center, Boston, Massachusetts [128]

Dennis L. Kasper, MD
William Ellery Channing Professor of Medicine and Professor of Immunology, Department of Immunology, Harvard Medical School; Division of Infectious Diseases, Brigham and Women's Hospital, Boston, Massachusetts [1, 5, 119, 132, 177, 471]

Daniel L. Kastner, MD, PhD
Scientific Director, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland [369]

Carol A. Kauffman, MD
Chief, Infectious Diseases Section, VA Ann Arbor Healthcare System; Professor of Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan [219]

Elaine T. Kaye, MD
Assistant Professor of Dermatology, Harvard Medical School, Boston Children's Hospital, Boston, Massachusetts [19, A1]

Kenneth M. Kaye, MD
Professor of Medicine, Harvard Medical School; Senior Physician, Division of Infectious Diseases, Brigham and Women's Hospital, Boston, Massachusetts [19, A1]

John F. Keaney, Jr., MD
Professor of Medicine, Harvard Medical School; Chief, Division of Cardiovascular Medicine; Co-Executive Director, Heart and Vascular Center, Brigham and Women's Hospital, Boston, Massachusetts [237]

David Kelsen, MD
Professor of Medicine, Weill Cornell Medical College; Edward S. Gordon Chair in Medical Oncology, Memorial Sloan Kettering Cancer Center, New York, New York [80]

John A. Kessler, MD
Davee Professor of Stem Cell Biology, Davee Department of Neurology; Director, Northwestern University Stem Cell Institute, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [484]

Maryam Ali Khan, MD
Research Scholar, Division of Vascular and Endovascular Surgery, University of California, San Diego, San Diego, California [329]

Sundeep Khosla, MD
Dr. Francis Chucker and Nathan Landow Research Professor; Mayo Foundation Distinguished Investigator, Mayo Clinic College of Medicine, Rochester, Minnesota [54]

Kiran K. Khush, MD, MAS
Professor of Medicine (Cardiovascular Medicine), Stanford University School of Medicine, Stanford, California [490]

Anthony A. Killeen, MD, PhD
Professor, Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, Minnesota [S10]

Kami Kim, MD
Andor Szentivanyi Professor of Medicine; Director, Division of Infectious Diseases and International Medicine, Morsani College of Medicine, University of South Florida, Tampa, Florida [228]

Priya S. Kishnani, MD
C.L. and Su Chen Professor of Pediatrics; Medical Director, YT and Alice Chen Pediatrics Genetics and Genomics Center; Division Chief, Medical Genetics; Professor of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, North Carolina [419]

Bruce S. Klein, MD
Gerard B. Odell Professor and Shirley S. Matchette Professor; Chief, Division of Pediatric Infectious Disease, Departments of Pediatrics, Medicine and Medical Microbiology and Immunology, University of Wisconsin, Madison, Madison, Wisconsin [214]

Christine Klein, MD
Professor of Neurology and Neurogenetics, Institute of Neurogenetics and Department of Neurology, University of Lübeck and University Hospital Schleswig-Holstein, Lübeck, Germany [436]

David M. Knipe, PhD
Higgins Professor of Microbiology and Molecular Genetics; Head, Program in Virology, Department of Microbiology, Blavatnik Institute, Harvard Medical School, Boston, Massachusetts [190]

Isaac S. Kohane, MD, PhD
Marion V. Nelson Professor and Chair, Biomedical Informatics; Harvard Medical School; Faculty Member, Informatics Program, Boston Children's Hospital, Boston, Massachusetts [488]

Barbara A. Konkle, MD
Professor of Medicine/Hematology, University of Washington; Scientific Director, Washington Center for Bleeding Disorders, Seattle, Washington [65, 115]

Bruce A. Koplan, MD, MPH
Assistant Professor of Medicine, Harvard Medical School; Director, Electrophysiology Laboratory, Brigham and Women's Hospital, Boston, Massachusetts [243–245]

Peter Kopp, MD
Professor of Medicine/Médecin Chef, Division of Endocrinology, Diabetology and Metabolism, University of Lausanne, Lausanne, Switzerland; Adjunct Professor, Division of Endocrinology, Metabolism and Molecular Medicine, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [466]

Walter J. Koroshetz, MD
National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland [139]

Thomas R. Kosten, MD
J. H. Waggoner Professor of Psychiatry, Pharmacology, Immunology, Neuroscience, Baylor College of Medicine, Houston, Texas [456]

Theodore A. Kotchen, MD‡
Professor Emeritus, Associate Dean for Clinical Research, Medical College of Wisconsin, Milwaukee, Wisconsin [277]

Camille Nelson Kotton, MD, FIDSA, FAST
Clinical Director, Transplant and Immunocompromised Host Infectious Diseases, Infectious Diseases Division, Massachusetts General Hospital, Boston, Massachusetts [195]

Barnett S. Kramer, MD, MPH, FACP
Director, Division of Cancer Prevention, National Cancer Institute, Bethesda, Maryland [70]

Joel Kramer, PsyD
John Douglas French Alzheimer's Foundation Endowed Professor of Neuropsychology in Neurology; Director of Neuropsychology, Memory and Aging Center, University of California, San Francisco, San Francisco, California [V2]

Arnold R. Kriegstein, MD, PhD
Professor of Neurology, University of California, San Francisco, San Francisco, California [424]

Somashekar G. Krishna, MD, MPH
Professor of Medicine, Division of Gastroenterology, Hepatology, & Nutrition, The Ohio State University Wexner Medical Center, Columbus, Ohio [347, 348]

Henry M. Kronenberg, MD
Professor of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts [409]

Jens H. Kuhn, MD, PhD, MS
Principal Scientist and Director of Virology, NIH/NIAID/DCR/Integrated Research Facility at Fort Detrick, Frederick, Maryland [209, 210]

Matthew H. Kulke, MD
Zoltan Kohn Professor of Medicine, Boston University School of Medicine; Chief, Section of Hematology and Medical Oncology, Boston Medical Center; Co-Director, Boston University–Boston Medical Cancer Center, Boston, Massachusetts [84]

Sebastian G. Kurz, MD
Associate Professor of Medicine, Division of Pulmonary, Critical Care and Sleep Medicine, The Mount Sinai Hospital, New York, New York [181]

Robert F. Kushner, MD
Professor of Medicine and Medical Education, Northwestern University Feinberg School of Medicine, Chicago, Illinois [402]

Raymond Y. Kwong, MD, MPH, FACC
Professor of Medicine, Harvard Medical School; Director of Cardiac Magnetic Resonance Imaging, Cardiovascular Division, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [241, A9]

Loren Laine, MD
Professor of Medicine; Chief, Section of Digestive Diseases, Yale School of Medicine, New Haven, Connecticut; VA Connecticut Healthcare System, West Haven, Connecticut [48]

Neal K. Lakdawala, MD, MSc
Assistant Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts [259]

Anil K. Lalwani, MD
Associate Dean for Student Research, Columbia University Vagelos College of Physicians and Surgeons; Professor and Vice Chair for Research; Co-Director, Columbia Cochlear Implant Center, Columbia University Vagelos College of Physicians and Surgeons; Medical Director of Perioperative Services, New York Presbyterian–Columbia University Irving Medical Center, New York, New York [34]

Michael J. Landzberg, MD
Associate Professor of Medicine, Harvard Medical School; Boston Adult Congenital Heart Disease and Pulmonary Hypertension Program, Boston Children's Hospital, Brigham and Women's Hospital, Boston, Massachusetts [269]

H. Clifford Lane, MD
Clinical Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [202, S3]

Helene M. Langevin, MD
Director, National Center for Complementary and Integrative Health, National Institutes of Health, Bethesda, Maryland [482]

Carol A. Langford, MD, MHS
Harold C. Schott Endowed Chair; Director, Center for Vasculitis Care and Research, Department of Rheumatic and Immunologic Diseases, Cleveland Clinic, Cleveland, Ohio [363, 366, 374, 375, A14]

‡Deceased

Regina C. LaRocque, MD, MPH
Associate Professor of Medicine, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts [133]

Leslie P. Lawley, MD
Associate Professor, Department of Dermatology, School of Medicine, Emory University, Atlanta, Georgia [57]

Thomas J. Lawley, MD
William Patterson Timmie Professor of Dermatology, Former Dean, Emory University School of Medicine, Atlanta, Georgia [56, 59, A5]

David G. Le Couteur, MD, PhD
Professor of Geriatric Medicine, University of Sydney; Senior Staff Geriatrician, Concord Hospital, Sydney, Australia [476]

Sancy A. Leachman, MD, PhD
John D. Gray Endowed Chair in Melanoma Research; Professor & Chair, Department of Dermatology, Oregon Health & Science University, Center for Health & Healing, Portland, Oregon [76]

William M. Lee, MD
Professor of Internal Medicine; Meredith Mosle Chair in Liver Diseases, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas [340]

Charles Lei, MD
Assistant Professor, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee [460]

Jane A. Leopold, MD
Associate Professor of Medicine, Harvard Medical School; Director, Women's Interventional Cardiology Health Initiative, Brigham and Women's Hospital, Boston, Massachusetts [242, A11]

Jessica Leung, MPH
Epidemiologist, Viral Vaccine Preventable Diseases Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [207]

Nelson Leung, MD
Professor of Medicine, Division of Nephrology and Hypertension, Division of Hematology, Mayo Clinic Rochester, Rochester, Minnesota [317]

Jonathan S. Leventhal, MD
Assistant Professor of Dermatology, Yale University School of Medicine, New Haven, Connecticut [58]

Bruce D. Levy, MD
Professor of Medicine, Harvard Medical School; Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts [284, 301]

Julia B. Lewis, MD
Professor of Medicine, Division of Nephrology and Hypertension, Vanderbilt University Medical Center, Nashville, Tennessee [314]

Peter Libby, MD
Mallinckrodt Professor of Medicine, Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts [A10]

Richard W. Light, MD, FCCP‡
Professor of Medicine, Division of Allergy, Pulmonary, and Critical Care Medicine, Vanderbilt University Medical Center, Nashville, Tennessee [294, 295]

Jin-Mann S. Lin, PhD
Division of High-Consequence Pathogens and Pathology, National Center for Zoonotic and Emerging Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [450]

Jeffrey A. Linder, MD, MPH, FACP
Michael A. Gertz Professor of Medicine and Chief, Division of General Internal Medicine and Geriatrics, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois [35]

Robert Lindsay, MD, PhD
Professor of Medicine, College of Physicians and Surgeons, Columbia University, New York, New York; Chief, Internal Medicine; Attending Physician, Helen Hayes Hospital, West Haverstraw, New York [411]

Michail S. Lionakis, MD, ScD
Chief, Fungal Pathogenesis Section, Laboratory of Clinical Immunology & Microbiology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [211, 216]

Marc E. Lippman, MD, MACP, FRCP
Professor of Oncology and Internal Medicine, Georgetown University, Washington, DC [79]

Peter E. Lipsky, MD
Charlottesville, Virginia [355]

Irene Litvan, MD, MSc, FAAN, FANA
Tasch Endowed Professor in Parkinson Disease Research; Director of the Parkinson and Other Movement Disorders Center, University of California, San Diego, La Jolla, California [434]

Eva S. Liu, MD
Assistant Professor of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts [409]

Kathleen D. Liu, MD, PhD, MAS
Professor, Division of Nephrology, Department of Medicine, Division of Critical Care Medicine, Department of Anesthesiology, University of California, San Francisco, San Francisco, California [312]

Josep M. Llovet, MD, PhD
Liver Cancer Program, Division of Liver Diseases, Tisch Cancer Institute, Department of Medicine, Icahn School of Medicine at Mount Sinai, New York; Liver Cancer Translational Research Laboratory, Barcelona Clínic Liver Cancer Group (BCLC), Liver Unit, IDIBAPS-Hospital Clínic, CIBERehd, University of Barcelona, Catalonia, Spain; Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Catalonia, Spain [82]

Donald M. Lloyd-Jones, MD, ScM, FACC, FAHA
Eileen M. Foell Professor of Heart Research; Professor of Preventive Medicine, Medicine, and Pediatrics; Chair, Department of Preventive Medicine, Northwestern University Feinberg School of Medicine; President, American Heart Association 2021–22, Chicago, Illinois [2]

Bernard Lo, MD
Professor of Medicine Emeritus and Director Emeritus of the Program in Medical Ethics, University of California, San Francisco, San Francisco, California; President Emeritus, The Greenwall Foundation, New York, New York [11]

George Loewenstein, PhD
Herbert A. Simon Professor of Economics and Psychology, Carnegie Mellon University, Pittsburgh, Pennsylvania [481]

Dan L. Longo, MD
Professor of Medicine, Harvard Medical School; Senior Physician, Brigham and Women's Hospital; Deputy Editor, *New England Journal of Medicine,* Boston, Massachusetts [1, 5, 62, 63, 66, 69, 72, 73, 93, 95, 96, 101, 108–111, 201, A6]

Nicola Longo, MD, PhD
Professor and Chief, Division of Medical Genetics, Departments of Pediatrics, Pathology, Nutrition, and Integrated Physiology; Medical Co-Director, Biochemical Genetics Laboratory, ARUP Laboratories, University of Utah, Salt Lake City, Utah [420, 421]

Lenny López, MD, MPH, MDiv
Professor of Medicine, University of California San Francisco; San Francisco VA Medical Center, San Francisco, California [10]

Joseph Loscalzo, MD, PhD
Hersey Professor of the Theory and Practice of Medicine, Harvard Medical School; Chairman, Department of Medicine, Soma Weiss MD Distinguished Chair in Medicine, Physician-in-Chief, Brigham and Women's Hospital, Boston, Massachusetts [1, 5, 40–43, 117, 236, 237, 239, 259, 261–268, 270, 273, 275, 280–283, 486, 492]

‡Deceased

Daniel H. Lowenstein, MD
Dr. Robert B. and Mrs. Ellinor Aird Professor of Neurology; Executive Vice Chancellor and Provost, University of California, San Francisco, San Francisco, California [422, 425, V6]

Elyse E. Lower, MD
Department of Internal Medicine, Division of Hematology-Oncology, University of Cincinnati, Cincinnati, Ohio [367]

Franklin D. Lowy, MD
Clyde '56 and Helen Wu Professor Emeritus of Medicine and Professor Emeritus of Pathology and Cell Biology (in Epidemiology), Columbia University College of Physicians and Surgeons, New York, New York [147]

Sheila A. Lukehart, PhD
Professor of Medicine, Division of Allergy & Infectious Diseases and Global Health, University of Washington, Seattle, Washington [182, 183]

Carolina Lúquez, PhD
Team Lead, National Botulism and Enteric Toxins Team, Enteric Diseases Laboratory Branch, Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [153]

Lucio Luzzatto, MD, FRCP, FRCPath
Professor of Haematology, Muhimbili University of Health and Allied Sciences, Dar-es-Salaam, Tanzania; Honorary Professor of Hematology, University of Florence, Firenze, Italy [100]

Calum A. MacRae, MD, PhD
Professor of Medicine, Harvard Medical School; Vice Chair for Scientific Innovation, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [237]

Lawrence C. Madoff, MD
Professor of Medicine, University of Massachusetts Chan Medical School, Worcester, Massachusetts; Medical Director, Bureau of Infectious Disease and Laboratory Sciences, Massachusetts Department of Public Health, Hinton State Laboratory Institute, Jamaica Plain, Massachusetts [130, 141]

Barry J. Make, MD
Co-Director, COPD Program; Professor, Department of Medicine, Division of Pulmonary, Critical Care and Sleep Medicine, National Jewish Health, University of Colorado Denver School of Medicine, Denver, Colorado [292]

Mahmoud Malas, MD, MHS, RPVI, FACS
Professor in Residence; Vice Chair of Surgery for Clinical Research; Chief Division Vascular and Endovascular Surgery, University of California, San Diego, Health System, La Jolla, California [329]

Fransiska Malfait, MD, PhD
Associate Professor, Center for Medical Genetics, Ghent University Hospital and Department for Biomolecular Medicine, Ghent University, Ghent, Belgium [413]

Hari R. Mallidi, MD
Associate Professor of Surgery, Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts [298]

Susan J. Mandel, MD, MPH
Professor of Medicine; Chief, Division of Endocrinology, Diabetes and Metabolism, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [382–385]

Brian F. Mandell, MD, PhD
Professor and Chairman of Medicine, Cleveland Clinic Lerner College of Medicine, Department of Rheumatic and Immunologic Disease, Cleveland Clinic, Cleveland, Ohio [374]

Lionel A. Mandell, MD, FRCPC
Professor Emeritus of Medicine, McMaster University, Hamilton, Ontario, Canada [126]

Geoffrey T. Manley, MD, PhD
Professor and Vice Chairman of Neurological Surgery, University of California, San Francisco; Chief of Neurosurgery, Zuckerberg San Francisco General Hospital and Trauma Center; Co-Director, Brain and Spinal Injury Center, University of California, San Francisco, San Francisco, California [443]

Arjun K. Manrai, PhD
Assistant Professor, Harvard Medical School; Computational Health Informatics Program, Boston Children's Hospital, Boston, Massachusetts [488]

JoAnn E. Manson, MD, DrPH
Professor of Medicine and the Michael and Lee Bell Professor of Women's Health, Harvard Medical School; Chief, Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts [395]

Joan C. Marini, MD, PhD
Senior Investigator; Head, Section on Heritable Disorders of Bone and Extracellular Matrix, National Institute of Child Health and Human Development (NICHD), National Institutes of Health, Bethesda, Maryland [413]

Daniel B. Mark, MD, MPH
Professor of Medicine, Duke University Medical Center; Director, Outcomes Research, Duke Clinical Research Institute, Durham, North Carolina [4]

Mariel Marlow, PhD, MPH
Mumps Program Lead, Viral Vaccine Preventable Diseases Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [207]

Alexander G. Marneros, MD, PhD
Associate Professor, Department of Dermatology, Harvard Medical School; Cutaneous Biology Research Center, Massachusetts General Hospital, Boston, Massachusetts [61]

Bradley A. Maron, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts [283]

Jeanne M. Marrazzo, MD, MPH
Professor of Medicine; Director, Division of Infectious Diseases, University of Alabama at Birmingham, Birmingham, Alabama [136]

Gary J. Martin, MD
Raymond J. Langenbach, MD Professor of Medicine; Senior Vice Chairman, Department of Medicine, Northwestern University Medical School, Chicago, Illinois [6]

Anthony F. Massaro, MD
Instructor, Harvard Medical School; Director, Medical Intensive Care Unit, Division of Pulmonary and Critical Care, Brigham and Women's Hospital, Boston, Massachusetts [300, 303]

Henry Masur, MD
Chief, Critical Care Medicine Department, National Institutes of Health Clinical Center, Bethesda, Maryland [220]

Max Maurin, MD, PhD
Professor of Bacteriology, Université Grenoble Alpes; Centre Hospitalier Universitaire, Institut de Biologie et Pathologie, Grenoble, France [170]

Marcela V. Maus, MD, PhD
Director, Cell Therapy Program; Paula O'Keefe Endowed Chair, Massachusetts General Hospital Cancer Center; Associate Professor of Medicine, Harvard Medical School; Attending Physician, Hematopoietic Cell Transplant & Cell Therapy Program, Massachusetts General Hospital; Associate Member, Broad Institute of MIT and Harvard; Associate Member, Ragon Institute of MGH, MIT, and Harvard, Charlestown, Massachusetts [470]

Clio P. Mavragani, MD
Rheumatologist, Associate Professor, Department of Physiology, National and Kapodistrian University of Athens, Athens, Greece [357, 361]

Robert J. Mayer, MD
Faculty Vice President for Academic Affairs, Dana-Farber Cancer Institute; Stephen B. Kay Family Professor of Medicine, Harvard Medical School, Boston, Massachusetts [81]

Jared R. Mayers, MD, PhD
Research Fellow in Medicine, Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts [489]

Sarah Mbaeyi, MD, MPH
Medical Officer, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [123]

Alexander J. McAdam, MD, PhD
Associate Professor of Pathology, Harvard Medical School; Medical Director, Infectious Diseases Diagnostic Laboratory, Boston Children's Hospital, Boston, Massachusetts [S11]

Calvin O. McCall, MD
Dermatology Section, Hunter Holmes McGuire Veterans Affairs Medical Center, Richmond, Virginia [A5]

Zachary B. R. McClain, MD
Attending Physician, Gender and Sexuality Development Clinic; Medical Director, Young Men's Clinic, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania [400]

John F. McConville, MD
Associate Professor of Medicine; Director, Internal Medicine Residency Program, Vice Chair for Education, University of Chicago, Chicago, Illinois [296]

Michael McCrea, PhD, ABPP
Professor and Eminent Scholar; Vice Chair of Research; Co-Director, Center for Neurotrauma Research (CNTR), Department of Neurosurgery, Medical College of Wisconsin, Milwaukee, Wisconsin [443]

Kathleen M. McKibbin, MD
Staff Physician, Northwestern University Health Services, Evanston, Illinois [2]

Maureen McMahon, MD, MCR
Associate Chief; Associate Professor, Division of Rheumatology, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, California [356]

Kevin T. McVary, MD, FACS
Director of the Center for Male Health; Professor of Urology, Department of Urology, Stritch School of Medicine, Loyola University Medical Center, Maywood, Illinois [397]

John N. Mecchella, DO, MPH
Assistant Professor of Medicine, Geisel School of Medicine at Dartmouth, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire [417]

Mandeep R. Mehra, MD, MSc, FRCP (London)
Professor of Medicine, Harvard Medical School; The William Harvey Distinguished Chair in Advanced Cardiovascular Medicine; Executive Director, Center for Advanced Heart Disease, Brigham and Women's Hospital, Boston, Massachusetts [257, 258, 260]

Sanjay R. Mehta, MD, DTM&H, D(ABMM)
Associate Professor of Medicine and Pathology, University of California, San Diego School of Medicine, San Diego, California [S12]

Shlomo Melmed, MBChB, MACP, FRCP
Executive Vice President and Dean of the Medical Faculty; Professor of Medicine, Cedars-Sinai Medical Center, Los Angeles, California [378–380]

Robert O. Messing, MD
Professor and Chair of Neuroscience; Professor of Neurology; Director, Waggoner Center for Alcohol and Addiction Research, University of Texas at Austin, Austin, Texas [451]

Nancy Messonnier, MD
Executive Director for Pandemic Prevention and Health Systems, Skoll Foundation, Palo Alto, California [123]

M.-Marsel Mesulam, MD
Ruth Dunbar Davee Professor of Neuroscience and Neurology, Mesulam Center for Cognitive Neurology and Alzheimer's Disease, Northwestern University Feinberg School of Medicine, Chicago, Illinois [30]

Robert G. Micheletti, MD
Associate Professor of Dermatology and Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [60]

Aaron W. Michels, MD
Associate Professor of Pediatrics, Medicine, and Immunology, Barbara Davis Center for Childhood Diabetes, University of Colorado School of Medicine, Aurora, Colorado [389]

Susan Miesfeldt, MD
Associate Professor of Medicine, Tufts University School of Medicine; Medical Oncology, Medical Director, Cancer Risk and Prevention Program, Maine Medical Center Cancer Institute, Scarborough, Maine [467]

Bruce L. Miller, MD
A. W. and Mary Margaret Clausen Distinguished Professor of Neurology, Memory and Aging Center, Global Brain Health Institute, University of California, San Francisco School of Medicine, San Francisco, California [27, 29, 431, 432, 434, V2]

Samuel I. Miller, MD
Professor of Medicine, Microbiology and Genome Sciences, University of Washington, Seattle, Washington [165]

William R. Miller, MD
Assistant Professor of Medicine, Division of Infectious Diseases, Houston Methodist Hospital, Center for Infectious Diseases Research, Houston Methodist Research Institute, Houston, Texas [149]

Jyoti Mishra, PhD
Department of Psychiatry, University of California, San Diego, La Jolla, California [487]

Hana Mitchell, MD, MSC
Clinical Assistant Professor, Division of Pediatric Infectious Diseases, Department of Pediatrics, The University of British Columbia, BC Children's Hospital, Vancouver, British Columbia, Canada [3]

Simon J. Mitchell, MBChB, PhD, FUHM, FANZCA
Professor, Department of Anaesthesiology, University of Auckland and Auckland City Hospital, Auckland, New Zealand [463]

Babak Mokhlesi, MD, MSc
The J. Bailey Carter, MD Professor of Medicine; Chief, Division of Pulmonary, Critical Care, and Sleep Medicine; Co-Director, Rush Lung Center, Rush University Medical Center, Chicago, Illinois [296]

Thomas A. Moore, MD, FACP, FIDSA
Clinical Professor of Medicine, University of Kansas School of Medicine-Wichita Campus, Wichita, Kansas [222]

Richard I. Morimoto, PhD
Bill and Gayle Cook Professor of Biology, Department of Molecular Biosciences, Rice Institute for Biomedical Research, Northwestern University, Evanston, Illinois [491]

Alison Morris, MD, MS
Chief, Pulmonary, Allergy and Critical Care Medicine; Professor of Medicine; UPMC Chair of Translational Pulmonary and Critical Care Medicine; Director, University of Pittsburgh Center for Medicine and the Microbiome, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania [220]

David A. Morrow, MD, MPH
Professor of Medicine, Harvard Medical School; Director, Samuel A. Levine Cardiac Intensive Care Unit, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts [14]

William J. Moss, MD, MPH
Professor, Departments of Epidemiology, International Health, and Molecular Microbiology and Immunology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, Maryland [205]

Robert J. Motzer, MD
Jack and Dorothy Byrne Chair in Clinical Oncology, Kidney Cancer Section Head; Attending Physician, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, New York [85]

David B. Mount, MD, FRCPC
Assistant Professor of Medicine, Harvard Medical School; Clinical Chief and Director, Dialysis Services Renal Divisions, Brigham and Women's Hospital and VA Boston Healthcare System; Boston, Massachusetts [52, 53, S1]

Haralampos M. Moutsopoulos, MD, FACP, FRCP(hc), Master ACR
Professor, Chair Medical Sciences-Immunology, Academy of Athens, Athens, Greece [357, 361]

Catharina M. Mulders-Manders, MD, PhD
Department of Internal Medicine, Radboud University Medical Center, Nijmegen, The Netherlands [20]

L. Silvia Munoz-Price, MD, PhD
Chief Quality and Safety Officer, Virginia Commonwealth University Health System, Richmond, Virginia [162]

Nikhil C. Munshi, MD
Professor of Medicine, Harvard Medical School; Boston VA Healthcare System; Director of Basic and Correlative Sciences; Associate Director, Jerome Lipper Myeloma Center, Dana-Farber Cancer Institute, Boston, Massachusetts [111]

Naoka Murakami, MD, PhD
Instructor in Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts [313]

John R. Murphy, PhD
Professor of Medicine, Division of Infectious Diseases, Johns Hopkins School of Medicine, Baltimore, Maryland [150]

Timothy F. Murphy, MD
SUNY Distinguished Professor; Director, UB Clinical and Translational Science Institute; Senior Associate Dean for Clinical and Translational Research, Jacobs School of Medicine and Biomedical Sciences, University at Buffalo, The State University of New York, Buffalo, New York [157]

Barbara E. Murray, MD
J. Ralph Meadows Professor of Medicine, Division of Infectious Diseases; Professor, Microbiology and Molecular Genetics, University of Texas Medical School, Houston, Texas [149]

Joseph A. Murray, MD
Professor of Medicine, Departments of Internal Medicine and Immunology, Mayo Clinic School of Medicine, Rochester, Minnesota [46]

Mark B. Mycyk, MD
Associate Professor, Department of Emergency Medicine, Northwestern University Feinberg School of Medicine; Chair of Research, Department of Emergency Medicine, Cook County Health, Chicago, Illinois [459]

Avindra Nath, MD
Chief, Section of Infections of the Nervous System; Clinical Director, National Institute of Neurological Disorders and Stroke (NINDS), National Institutes of Health, Bethesda, Maryland [139]

Edward T. Naureckas, MD
Professor of Medicine, Section of Pulmonary and Critical Care Medicine, University of Chicago, Chicago, Illinois [285]

Eric G. Neilson, MD
Vice President for Medical Affairs; Lewis Landsberg Dean Professor of Medicine and Cell and Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [309, 314, A4]

Tuhina Neogi, MD, PhD
Professor of Medicine and Chief of Rheumatology, Section of Rheumatology, Department of Medicine; Professor of Epidemiology, Department of Epidemiology, Boston University School of Public Health, Boston, Massachusetts [371]

Eric J. Nestler, MD, PhD
Nash Family Professor, Department of Neuroscience; Director, Friedman Brain Institute; Dean for Academic and Scientific Affairs, Ichan School of Medicine at Mount Sinai, New York, New York [451]

Hartmut P. H. Neumann, MD
Unit for Preventive Medicine, Department of Nephrology and General Medicine, Albert-Ludwigs University of Freiburg, Freiburg, Germany [387]

Kathleen M. Neuzil, MD, MPH
Director, Center for Vaccine Development & Global Health, University of Maryland School of Medicine, Baltimore, Maryland [200]

Jonathan Newmark, MD, MM
Colonel (Retired), Medical Corps, US Army; Adjunct Professor, Neurology, F. Edward Hebert School of Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Clinical Assistant Professor, Neurology, School of Medicine and Health Sciences, George Washington University, Washington, DC; Department of Neurology, Washington DC Veterans' Affairs Medical Center, Washington, DC; Senior Medical Advisor, Office of Biodefense Research and Surety, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Rockville, Maryland [S4]

J. Curtis Nickel, MD, FRCS(C)
Professor, Department of Urology, Queen's University at Kingston; Staff Urologist, Kingston Health Sciences Centre, Kingston, Ontario, Canada [51]

Michael S. Niederman, MD
Professor of Clinical Medicine, Weill Cornell Medical College; Division of Pulmonary and Critical Care Medicine, New York Presbyterian/Weill Cornell Medical Center, New York, New York [126]

Kevin D. Niswender, MD, PhD
Associate Professor of Medicine, Vanderbilt University Medical Center, Nashville, Tennessee [403]

Scott A. Norton, MD, MPH, MSc
Professor of Dermatology and Pediatrics, George Washington University School of Medicine and Health Sciences; Chief of Dermatology, Division of Dermatology, Children's National Health System, Washington, DC [461]

Emily Nosova, MD
Assistant Professor of Medicine, Division of Endocrinology, Diabetes and Bone Disease, Icahn School of Medicine and Mount Sinai Health System, New York, New York [398]

Thomas B. Nutman, MD
Head, Helminth Immunology Section; Head, Clinical Parasitology Section; Chief, Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland [232, 233]

Katherine L. O'Brien, MD, MPH
Director, IVB, World Health Organization, Geneva, Switzerland [146]

Max R. O'Donnell, MD, MPH
Associate Professor of Medicine & Epidemiology, Division of Pulmonary, Allergy, and Critical Care Medicine & Department of Epidemiology, Columbia University Irving Medical Center, New York, New York [181]

Nigel O'Farrell, MD, FRCP
Pasteur Suite Ealing Hospital, London, United Kingdom [173]

Jennifer Ogar, MS, CCC-SLP
Speech-Language Pathologist, Memory and Aging Center, University of California, San Francisco, San Francisco, California [V2]

Patrick T. O'Gara, MD
Professor of Medicine, Harvard Medical School; Watkins Family Distinguished Chair in Cardiology, Brigham and Women's Hospital, Boston, Massachusetts [42, 239, 261–268]

C. Warren Olanow, MD, FRCPC, FRCP(hon)
Professor and Chairman Emeritus, Department of Neurology; Professor Emeritus, Department of Neuroscience, Mount Sinai School of Medicine, New York, New York; CEO, Clintrex, LLC [435, 436]

Stephen O'Rahilly, MD, FRS, FMedSci
Professor of Clinical Biochemistry and Medicine and Director of the MRC Metabolic Disease Unit, University of Cambridge, Addenbrookes Hospital, Cambridge, United Kingdom [401]

Joseph G. Ouslander, MD
Charles E. Schmidt College of Medicine, Florida Atlantic University, Boca Raton, Florida [477]

Chung Owyang, MD
H. Marvin Pollard Professor of Internal Medicine; Professor of Molecular and Integrative Physiology; Chief, Division of Gastroenterology and Hepatology; Director, Pollard Institute for Medical Research; University of Michigan Health System, Ann Arbor, Michigan [321, 327]

Umesh D. Parashar, MBBS, MPH
Chief, Viral Gastroenteritis Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [203]

Shreyaskumar R. Patel, MD
Robert R. Herring Distinguished Professor of Medicine; Center Medical Director, Sarcoma Center, The University of Texas MD Anderson Cancer Center, Houston, Texas [91]

Gustav Paumgartner, MD
Professor Emeritus of Medicine, University of Munich, Munich, Germany [346]

David A. Pegues, MD
Professor of Medicine, Division of Infectious Diseases, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania [165]

Steven A. Pergam, MD, MPH
Associate Professor, Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Research Center; Associate Professor, Department of Medicine, Division of Allery & Infectious Diseases, University of Washington; Medical Director, Infection Prevention, Seattle Cancer Care Alliance, Seattle, Washington [159]

Karran A. Phillips, MD, MSc
Clinical Director, National Institute on Drug Abuse, National Institutes of Health, Baltimore, Maryland [457]

Richard J. Pollack, PhD
Senior Environmental Public Health Officer, Department of Environmental Health and Safety, Harvard University, Cambridge, Massachusetts [461]

Martin R. Pollak, MD
George C. Reisman Professor of Medicine, Harvard Medical School; Beth Israel Deaconess Medical Center, Boston, Massachusetts [315]

Sir Andrew J. Pollard, BSc, MA, MBBS, MRCP(UK), FRCPCH, PhD, DIC, FHEA, FIDSA, FMedSci
Professor of Paediatric Infection and Immunity, Department of Paediatrics, University of Oxford; Children's Hospital, Oxford, United Kingdom [155]

Nongnooch Poowanawittayakom, MD, MPH
Assistant Professor, Division of Infectious Diseases, Allergy, and Immunology, St. Louis University, St. Louis, Missouri [130]

Reuven Porat, MD
Professor of Medicine, Department of Internal Medicine, Tel Aviv Souarsky Medical Center; Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel [18]

John T. Potts, Jr., MD
Jackson Distinguished Professor of Clinical Medicine, Harvard Medical School; Director of Research and Physician-in-Chief Emeritus, Massachusetts General Hospital, Boston, Massachusetts [410]

Lawrie W. Powell, AC, MD, PhD
Professor Emeritus, The University of Queensland and the Royal Brisbane and Women's Hospital, Queensland, Australia [414]

Alvin C. Powers, MD
Joe C. Davis Chair in Biomedical Science; Professor of Medicine, Molecular Physiology and Biophysics; Director, Vanderbilt Diabetes Center; Chief, Division of Diabetes, Endocrinology, and Metabolism, Vanderbilt University Medical Center, Nashville, Tennessee [403–405]

Daniel S. Pratt, MD
Assistant Professor of Medicine, Harvard Medical School; Clinical Director, Liver Transplantation; Director, Autoimmune and Cholestatic Liver Center, Massachusetts General Hospital, Boston, Massachusetts [49, 337, 346]

Michael B. Prentice, MBChB, PhD, FRCP(UK), FRCPath, FFPRCPI
Professor of Medical Microbiology, School of Microbiology, University College Cork, Cork, Ireland [171]

Stanley B. Prusiner, MD
Director, Institute for Neurodegenerative Diseases; Professor, Department of Neurology, UCSF Weill Institute for Neurosciences, University of California, San Francisco; Professor, Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, California [424, 438]

Thomas C. Quinn, MD, MSc
Professor of Medicine and Pathology, Johns Hopkins University School of Medicine; Director, Johns Hopkins Center for Global Health, Baltimore, Maryland [189]

Gil D. Rabinovici, MD
Ed Fein and Pearl Landrith Distinguished Professor, Memory and Aging Center, Department of Neurology, Department of Radiology and Biomedical Imaging, Weill Institute for Neurosciences, University of California, San Francisco, San Francisco, California [29, 431, V2]

Daniel J. Rader, MD
Seymour Gray Professor of Molecular Medicine; Chair, Department of Genetics; Chief, Division of Translational Medicine and Human Genetics, Department of Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Pennsylvania [407]

Kanwal Raghav, MBBS, MD
Associate Professor, GI Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, Texas [92]

Kaitlin Rainwater-Lovett, PhD, MPH
Senior Staff Scientist, Asymmetric Operations Sector, Johns Hopkins Applied Physics Laboratory, Laurel, Maryland [205]

Sanjay Ram, MBBS
Professor of Medicine, Division of Infectious Diseases & Immunology, University of Massachusetts Chan Medical School, Worcester, Massachusetts [156]

Prashanth S. Ramachandran, MBBS
Weill Institute for Neurosciences, Department of Neurology, University of California, San Francisco, San Francisco, California [S2]

Reuben Ramphal, MD
Courtesy Professor, Department of Medicine, University of Florida College of Medicine, Gainesville, Florida [164]

Kathryn Moynihan Ramsey, PhD
Research Assistant Professor, Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Feinberg School of Medicine, Northwestern University, Chicago, Illinois [485]

Vikram R. Rao, MD, PhD
Distinguished Professor in Neurology; Associate Professor of Clinical Neurology; Chief, Epilepsy Division, Department of Neurology, University of California, San Francisco, San Francisco, California [425]

Didier Raoult, MD, PhD
Emeritus Professor, IHU Méditerranée Infection, Marseille, France. Aix-Marseille Université, Marseille, France [170]

Kumanan Rasanathan, MBChB, MPH, FAFPHM
Unit Head, Equity and Health (EQH), Department of Social Determinants of Health (SDH), World Health Organization, Phnom Penh, Cambodia [474]

James P. Rathmell, MD
Leroy D. Vandam Professor of Anaesthesia, Harvard Medical School; Chair, Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Boston, Massachusetts [13]

Mario C. Raviglione, MD, FRCP (UK), FERS, Hon RSP (RF)
Full Professor of Global Health; Co-Director, Centre for Multidisciplinary Research in Health Science (MACH), University of Milan, Milan, Italy [178]

Divya Reddy, MBBS, MPH
Associate Professor of Medicine; Program Director, Pulmonary and Critical Care Fellowship; Medical Director, Bronchiectasis and Nontuberculous Mycobacterial (NTM) Disease Program, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York [181]

Susan Redline, MD, MPH
Peter C. Farrell Professor of Sleep Medicine, Harvard Medical School; Brigham and Women's Hospital; Boston, Massachusetts [297]

Sharon L. Reed, MD, MScCTM
Professor of Pathology and Medicine, University of California, San Diego School of Medicine, La Jolla, California [221, 223, S12]

Susan E. Reef, MD
Medical Epidemiologist, Centers for Disease Control and Prevention, Atlanta, Georgia [206]

Michael Regner, MD
Neuroradiology Clinical Instructor, Department of Radiology & Biomedical Imaging, University of California, San Francisco, San Francisco, California [A16]

Victor I. Reus, MD
Distinguished Professor Emeritus, Department of Psychiatry and Behavioral Sciences, University of California, San Francisco School of Medicine; UCSF Weill Institute for Neurosciences, San Francisco, California [452]

Bernardo Reyes, MD
Charles E. Schmidt College of Medicine, Florida Atlantic University, Boca Raton, Florida [477]

Joseph J. Rhatigan, MD
Associate Chief, Division of Global Health Equity, Brigham and Women's Hospital; Associate Professor, Harvard Medical School and Harvard T.H. Chan School of Public Health, Boston, Massachusetts [472]

Peter A. Rice, MD
Professor of Medicine, Division of Infectious Diseases & Immunology, University of Massachusetts Chan Medical School, Worcester, Massachusetts [156]

Eugene T. Richardson, MD, PhD
Assistant Professor of Global Health and Social Medicine, Harvard Medical School, Boston, Massachusetts [475]

Jan H. Richardus, MD, PhD
Professor of Infectious Diseases and Public Health, Department of Public Health, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands [179]

Michael R. Rickels, MD, MS
Willard and Rhoda Ware Professor in Diabetes and Metabolic Diseases, Department of Medicine, Division of Endocrinology, Diabetes and Metabolism, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania [404, 405]

Elizabeth Robbins, MD
Clinical Professor, Pediatrics, Emeritus, University of California, San Francisco, San Francisco, California [S9]

Gary L. Robertson, MD
Emeritus Professor of Medicine, Northwestern University School of Medicine, Chicago, Illinois [381]

Dan M. Roden, MD
Professor of Medicine, Pharmacology, and Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, Tennessee [67, 68]

James A. Romano, Jr., PhD, DABT, ATS
Principal Senior Life Scientist Advisor, Tunnell Government Services, Inc., Rockville, Maryland [S4]

Karen L. Roos, MD
John and Nancy Nelson Professor of Neurology; Professor of Neurological Surgery, Indiana University School of Medicine, Indianapolis, Indiana [137, 138, 140]

Allan H. Ropper, MD, FRCP, FACP
Professor of Neurology, Harvard Medical School; Deputy Editor, *New England Journal of Medicine*, Boston, Massachusetts [28]

Rossana Rosa, MD
Infectious Diseases Consultant, UnityPoint Clinic, Des Moines, Iowa [162]

Ivan O. Rosas, MD
Professor and Section Chief, Pulmonary, Critical Care, and Sleep Medicine, Baylor College of Medicine, Houston, Texas [293]

Mark Roschewski, MD
Clinical Director, Lymphoid Malignancies Branch, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland [95]

Misha Rosenbach, MD
Associate Professor, Perelman School of Medicine at the University of Pennsylvania, Departments of Dermatology and Internal Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania [60]

Roger N. Rosenberg, MD
Zale Distinguished Chair and Professor of Neurology, Department of Neurology, University of Texas Southwestern Medical Center, Dallas, Texas [439]

Myrna R. Rosenfeld, MD, PhD
Institut d'Investigacions Biomèdiques August Pi i Sunyer, Fundació Clínic per a la Recerca Biomèdica, Spain; Adjunct Professor, University of Pennsylvania, Philadelphia, Pennsylvania [94]

Deborah C. Rubin, MD
Professor of Medicine and of Developmental Biology; Associate Chair for Faculty Affairs and Director, Womens' GI Committee, Washington University School of Medicine, St. Louis, Missouri [325]

Thomas A. Russo, MD, CM
SUNY Distinguished Professor of Medicine and Microbiology & Immunology, Chief, Division of Infectious Diseases, Jacobs School of Medicine and the Biomedical Sciences, University at Buffalo, State University of New York, Buffalo, New York
[161, 175, 176]

George W. Rutherford, MD
Professor of Epidemiology, Preventive Medicine, Pediatrics and History, and Head, Division of Infectious Disease and Global Epidemiology, Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, California [473]

Edward T. Ryan, MD
Professor of Medicine, Harvard Medical School; Professor of Immunology and Infectious Diseases, Harvard T.H. Chan School of Public Health; Director, Global Infectious Diseases, Massachusetts General Hospital, Boston, Massachusetts [168]

Manish Sadarangani, MA, BM, BCh, DPhil
Associate Professor, Department of Pediatrics, University of British Columbia; Director, Vaccine Evaluation Center, BC Children's Hospital Research Institute, Vancouver, British Columbia, Canada [155]

David J. Salant, MD
Professor of Medicine, Boston University School of Medicine; Chief, Renal Section, Boston University Medical Center, Boston, Massachusetts [316]

Richard B. Saltman, PhD
Professor of Health Policy and Management, Rollins School of Public Health, Emory University, Atlanta, Georgia [7]

Blossom Samuels, MD
Attending, Westchester Medical Center; Clinical Assistant Professor, New York Medical College, Valhalla, New York [411]

Martin A. Samuels, MD, DSc (hon), FACP, FAAN, FRCP, FANA
Miriam Sydney Joseph Distinguished Professor of Neurology, Harvard Medical School; Founding Chair Emeritus, Department of Neurology, Brigham and Women's Hospital, Boston, Massachusetts [V7]

Vaishali Sanchorawala, MD
Professor of Medicine; Director, Amyloidosis Center; Director, Autologous Stem Cell Transplantation Program, Boston University School of Medicine and Boston Medical Center, Boston, Massachusetts [112]

Philippe J. Sansonetti, MD
Professor, Collège de France; Emeritus Professor, Institut Pasteur, Paris, France [166]

Clifford B. Saper, MD, PhD
James Jackson Putnam Professor of Neurology and Neuroscience, Harvard Medical School; Department of Neurology, Beth Israel Deaconess Medical Center, Boston, Massachusetts [31]

William H. Sauer, MD
Associate Professor of Medicine, Harvard Medical School; Section Chief, Cardiac Arrhythmia Service, Brigham and Women's Hospital, Boston, Massachusetts [243–256, 306]

Edward A. Sausville, MD, PhD
National Cancer Institute, Bethesda, Maryland (Retired); Marlene & Stewart Greenebaum Comprehensive Cancer Center, University of Maryland, Baltimore, Maryland [73]

David T. Scadden, MD
Gerald and Darlene Jordan Professor of Medicine; Chair Emeritus and Professor, Department of Stem Cell and Regenerative Biology, Harvard University; Director, Center for Regenerative Medicine; Massachusetts General Hospital, Co-director, Harvard Stem Cell Institute, Cambridge, Massachusetts [96]

Thomas E. Scammell, MD
Professor, Harvard Medical School; Beth Israel Deaconess Medical Center; Boston Children's Hospital, Boston, Massachusetts [31]

Anthony H. V. Schapira, MD, DSc, FRCP, FMedSci
Head and Professor, Department of Clinical and Movement Neurosciences, UCL Queen Square Institute of Neurology; Director of UCL Royal Free Campus; Vice-Dean UCL, London, United Kingdom [435]

Howard I. Scher, MD, FASCO
Professor of Medicine, Weill Cornell Medicine College; D. Wayne Calloway Chair in Urologic Oncology; Head, Biomarker Development Program, Office of the Physician in Chief; Member and Attending Physician, Genitourinary Oncology Service, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, New York [87]

Gordon Schiff, MD
Associate Professor of Medicine, Harvard Medical School; Associate Director, Brigham and Women's Hospital Center Patient Safety Research; Quality and Safety Director, HMS Center for Primary Care, Boston, Massachusetts [9]

Scott Schissel, MD, PhD
Chief of Medicine, Department of Medicine, Brigham and Women's Faulkner Hospital, Jamaica Plain, Massachusetts [302]

Bernd Schnabl, MD
Professor of Medicine, Department of Medicine, Division of Gastroenterology, University of California San Diego, La Jolla, California [342]

Marc A. Schuckit, MD
Distinguished Professor of Psychiatry, University of California, San Diego Medical School, La Jolla, California [453]

William W. Seeley, MD
Professor of Neurology and Pathology, UCSF Weill Institute for Neurosciences, University of California, San Francisco, San Francisco, California [29, 431–434]

Florencia Pereyra Segal, MD
Assistant Professor of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [141]

Julian L. Seifter, MD
Associate Professor of Medicine, Harvard Medical School; Distinguished Nephrologist, Brigham and Women's Hospital, Boston, Massachusetts [308, 319]

Jaime Sepúlveda, MD, MPH, MSc, DrSc
Haile T. Debas Distinguished Professor of Global Health; Executive Director, Institute for Global Health Sciences, University of California, San Francisco, San Francisco, California [473]

Christopher W. Seymour, MD, MSc
Associate Professor of Critical Care and Emergency Medicine, Department of Critical Care and Emergency Medicine, The CRISMA Center, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania [304]

Majid Shafiq, MD, MPH
Medical Director, Interventional Pulmonology, Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts [286]

Ankoor Shah, MD
Associate Professor, Department of Medicine, Division of Rheumatology and Immunology, Duke University Medical Center, Durham, North Carolina [358]

Erica S. Shenoy, MD, PhD
Associate Professor of Medicine, Harvard Medical School; Associate Chief, Infection Control Unit, Massachusetts General Hospital, Boston, Massachusetts [144]

Kanade Shinkai, MD, PhD
Professor, Department of Dermatology, University of California, San Francisco, San Francisco, California [60]

Edwin K. Silverman, MD, PhD
Professor of Medicine, Harvard Medical School; Chief, Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [292]

Shakti Singh, MSc, PhD
Research Scientist, The Lundquist Institute at Harbor-UCLA Medical Center, Torrance, California [216]

Karl Skorecki, MD, FCRPC, FASN
Dean, Azrieli Faculty of Medicine, Bar-Ilan University, Safed, Israel [311, 468]

Wade S. Smith, MD, PhD
Professor of Neurology, Department of Neurology, University of California, San Francisco, San Francisco, California [307, 426–429]

Jeremy Sobel, MD, MPH
Associate Director for Epidemiologic Science, Division of Foodborne, Waterborne, and Environmental Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [153]

Kelly A. Soderberg, PhD
Chief of Staff, Duke Human Vaccine Institute, Department of Medicine, Duke University School of Medicine; Duke University Medical Center, Durham, North Carolina [349, 350]

Scott D. Solomon, MD
The Edward D. Frohlich Distinguished Chair; Professor of Medicine, Harvard Medical School; Senior Physician, Brigham and Women's Hospital, Boston, Massachusetts [241, A9]

Julian Solway, MD
Walter L. Palmer Distinguished Service Professor of Medicine and Pediatrics; Dean for Translational Medicine, Biological Sciences Division; Vice Chair for Research, Department of Medicine; Chair, Committee on Molecular Medicine, University of Chicago, Chicago, Illinois [285, 296]

Eric J. Sorscher, MD
Hertz Endowed Professorship, Emory University School of Medicine, Children's Healthcare of Atlanta, Atlanta, Georgia [291]

Brad Spellberg, MD
Professor of Clinical Medicine, Division of Infectious Diseases, Keck School of Medicine at the University of Southern California; Chief Medical Officer, Los Angeles County + University of Southern California (LAC + USC) Medical Center, Los Angeles, California [218]

Jerry L. Spivak, MD
Professor of Medicine and Oncology, Hematology Division, Johns Hopkins University School of Medicine, Baltimore, Maryland [103]

David Spriggs, MD, FACP, FASCO
Faculty Member, Harvard Medical School; Program Director of Gynecologic Oncology, Massachusetts General Hospital Cancer Center, Boston, Massachusetts [89]

E. William St. Clair, MD
W. Lester Brooks, Jr. Professor of Medicine; Professor of Immunology, Department of Medicine, Duke University Medical Center, Durham, North Carolina [358]

John M. Stafford, MD, PhD
Associate Professor of Medicine, Diabetes and Endocrinology, Vanderbilt University School of Medicine; Tennessee Valley Health System, Veterans Affairs, Nashville, Tennessee [405]

Matthew W. State, MD, PhD
Oberndorf Family Distinguished Professor; Chair, Department of Psychiatry and Behavioral Sciences; President, Langley Porter Psychiatric Hospital and Clinics, Weill Institute for Neurosciences, University of California, San Francisco, San Francisco, California [451]

Allen C. Steere, MD
Professor of Medicine, Harvard Medical School and Massachusetts General Hospital, Boston, Massachusetts [186]

Martin H. Steinberg, MD
Professor of Medicine, Pediatrics, Pathology and Laboratory Medicine, Boston University School of Medicine, Boston, Massachusetts [98]

Dennis L. Stevens, MD, PhD
Professor of Medicine, University of Washington School of Medicine, Seattle, Washington; Director, Center of Biomedical Research Excellence in Emerging/Reemerging Infectious Diseases, Boise Veterans Affairs Medical Center, Boise, Idaho [129, 154]

Lynne Warner Stevenson, MD
Professor of Medicine; Program Director, Advanced Heart Failure Fellowship Program, Vanderbilt University Medical Center, Nashville, Tennessee [259]

Benjamin K. Stoff, MD, MAB
Associate Professor of Dermatology, Emory University School of Medicine; Senior Faculty Fellow, Emory Center for Ethics, Atlanta, Georgia [A5]

John H. Stone, MD, MPH
Professor of Medicine, Harvard Medical School; The Edward Fox Chair in Medicine, Massachusetts General Hospital, Boston, Massachusetts [368]

Shyam Sundar, MD
Distinguished Professor, Department of Medicine, Institute of Medical Sciences, Banaras Hindu University, Varanasi, India [226]

Neeraj K. Surana, MD, PhD
Assistant Professor of Pediatrics, Molecular Genetics and Microbiology, and Immunology, Duke University, Durham, North Carolina [18, 119, 177, 471]

Paolo M. Suter, MD, MS
Department of Endocrinology, Diabetology, and Clinical Nutrition, University Hospital, Zurich, Switzerland [333]

Robert A. Swerlick, MD
Department of Dermatology, Emory University School of Medicine, Atlanta, Georgia [57]

Geoffrey Tabin, MD
Director, Department of Ophthalmology, Stanford University, Stanford, California [462]

Maria Carmela Tartaglia, MD
Associate Professor, Tanz Centre for Research in Neurodegenerative Diseases, University of Toronto, Toronto, Ontario, Canada [V2]

Joel D. Taurog, MD
Professor of Internal Medicine (Retired), Rheumatic Diseases Division, University of Texas Southwestern Medical Center, Dallas, Texas [362]

Usha B. Tedrow, MD, MSc
Associate Professor of Medicine, Harvard Medical School; Director, Clinical Cardiac Electrophysiology Fellowship; Clinical Director, Ventricular Arrhythmia Program, Brigham and Women's Hospital, Boston, Massachusetts [252–256]

Ayalew Tefferi, MD
Barbara Woodward Lips Professor of Medicine and Hematology, Mayo Clinic, Rochester, Minnesota [110]

Stephen C. Textor, MD
Professor of Medicine, Division of Nephrology and Hypertension, Mayo Clinic School of Medicine, Rochester, Minnesota [278]

R. V. Thakker, MD, ScD, FRCP, FRCPath, FRS, FMedSci
May Professor of Medicine, Academic Endocrine Unit, University of Oxford; O.C.D.E.M., Churchill Hospital, Headington, Oxford, United Kingdom [388]

Holger Thiele, MD
Full Professor of Internal Medicine/Cardiology; Director, Heart Center, Department of Internal Medicine/Cardiology, University of Leipzig, Leipzig, Germany [305]

C. Louise Thwaites, MBBS, BSc, MD
Clinical Research Fellow, Oxford University Clinical Research Unit, Ho Chi Minh City, Vietnam; Clinical Lecturer, Centre for Tropical Medicine and Global Health, University of Oxford, Oxford, United Kingdom [152]

Pierre Tiberghien, MD, PhD
Professor of Medicine, Bourgogne Franche-Comté University, Besançon; Senior Advisor, Etablissement Français du Sang, Paris, France [113]

Zelig A. Tochner, MD
Professor Emeritus of Radiation Oncology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania [S5]

Karina A. Top, MD, MSc
Associate Professor of Pediatrics and Community Health & Epidemiology, Dalhousie University, Halifax, Nova Scotia, Canada [160]

Mark Topazian, MD
Professor of Medicine, Mayo Clinic, Rochester, Minnesota [322, V5]

Camilo Toro, MD
Director, Adult NIH Undiagnosed Diseases Program, National Institutes of Health, Bethesda, Maryland [492]

Barbara W. Trautner, MD, PhD
Professor, Section of Infectious Diseases, Department of Medicine, Baylor College of Medicine; Investigator, Houston VA Center for Innovations in Quality, Effectiveness and Safety (IQuESt), Houston, Texas [135]

Katherine L. Tuttle, MD
Assistant Professor, Department of Pediatrics, Pediatric Allergy/Immunology; Assistant Professor, Department of Medicine, Allergy/Immunology and Rheumatology (SMD), University of Rochester Medical Center, Rochester, New York [352]

Kenneth L. Tyler, MD
Louise Baum Endowed Chair and Chairman of Neurology; Professor of Medicine and Immunology-Microbiology, University of Colorado School of Medicine, Aurora, Colorado; Neurologist, Rocky Mountain VA Medical Center, Aurora, Colorado [137, 138, 140]

Elizabeth R. Unger, PhD, MD
Division of High-Consequence Pathogens and Pathology, National Center for Zoonotic and Emerging Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia [450]

Prashant Vaishnava, MD
Assistant Professor of Medicine; Director of Quality Assurance and Inpatient Services, Mount Sinai Heart, Mount Sinai Hospital, Icahn School of Medicine at Mount Sinai, New York, New York [480]

Anne Marie Valente, MD
Associate Professor of Medicine and Pediatrics, Harvard Medical School; Director, Boston Adult Congenital Heart Disease and Pulmonary Hypertension Program, Boston Children's Hospital, Brigham and Women's Hospital, Boston, Massachusetts [269]

Wim H. van Brakel, MD, MSc, PhD
Medical Director, NLR, Amsterdam, The Netherlands [179]

Jos W. M. van der Meer, MD, PhD
Emeritus Professor of Medicine, Department of Internal Medicine, Radboud University Medical Center, Nijmegen, The Netherlands [20]

Mathew G. Vander Heiden, MD, PhD
Professor and Director, Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, Massachusetts [489]

Edouard Vannier, PharmD, PhD
Assistant Professor of Medicine, Division of Geographic Medicine and Infectious Diseases, Department of Medicine, Tufts Medical Center and Tufts University School of Medicine, Boston, Massachusetts [225]

Gauri R. Varadhachary, MD
Professor, GI Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, Texas [92]

John Varga, MD
Frederick Huetwell Professor; Chief, Division of Rheumatology, University of Michigan, Ann Arbor, Michigan [360]

David J. Vaughn, MD
Genitourinary Medical Oncology Professor, Perelman School of Medicine at the University of Pennsylvania, Perelman Center for Advanced Medicine, Philadelphia, Pennsylvania [88]

Birgitte Jyding Vennervald, MD, MSA
Professor, Section for Parasitology and Aquatic Pathobiology, Faculty of Health and Medical Sciences, University of Copenhagen, Frederiksberg, Denmark [234]

John T. Vetto, MD, FACS
Professor of Surgery, Division of Surgical Oncology; Director, Cutaneous Oncology Program, Department of Surgery, Oregon Health & Science University; Program Leader, Melanoma Disease Site Team, OHSU Knight Cancer Institute, Portland, Oregon [76]

Luciano Villarinho, MD
Neuroradiologist, South County Hospital, Wakefield, Rhode Island [A16]

Bert Vogelstein, MD
Professor, Ludwig Center for Cancer Genetics and Therapeutics, Johns Hopkins University School of Medicine; Investigator, Howard Hughes Medical Institute, Baltimore, Maryland [71]

Everett E. Vokes, MD
John E. Ultmann Professor; Chairman, Department of Medicine; Physician-in-Chief, University of Chicago Medicine and Biological Sciences, Chicago, Illinois [77]

Tamara J. Vokes, MD
Professor, Department of Medicine, Section of Endocrinology, University of Chicago, Chicago, Illinois [412]

Nora D. Volkow, MD
Director, National Institute on Drug Abuse (NIDA), National Institutes of Health, Rockville, Maryland [455]

Kevin G. Volpp, MD, PhD
Director, Penn Center for Health Incentives and Behavioral Economics; Founders Presidential Distinguished Professor, Perelman School of Medicine and the Wharton School, University of Pennsylvania, Philadelphia, Pennsylvania [481]

Daniel D. Von Hoff, MD, FACP, FASCO, FAACR
Distinguished Professor, Translational Genomics Research Institute (TGEN), Phoenix, Arizona; Virginia G. Piper Distinguished Chair for Innovative Cancer Research and Chief Scientific Officer, Honor Health Research Institute; Senior Consultant-Clinical Investigations, City of Hope; Professor of Medicine, Mayo Clinic, Scottsdale, Arizona [83]

Martin H. Voss, MD
Clinical Director, Genitourinary Oncology Service, Memorial Sloan Kettering Cancer Center, New York, New York [85]

Jiři F. P. Wagenaar, MD, PhD
Internist and Infectious Disease Specialist, Northwest Clinics, Alkmaar, The Netherlands [184]

Jesse Waggoner, MD
Assistant Professor, Department of Medicine, Division of Infectious Diseases, Emory University, Atlanta, Georgia [124]

Sushrut S. Waikar, MD, MPH
Chief, Section of Nephrology; Norman G. Lewinsky Professor of Medicine, Boston University School of Medicine, Boston, Massachusetts [310]

Matthew K. Waldor, MD, PhD
Edward H. Kass Professor of Medicine, Harvard Medical School, Division of Infectious Diseases, Brigham and Women's Hospital, Boston, Massachusetts [168]

David H. Walker, MD
The Carmage and Martha Walls Distinguished University Chair in Tropical Diseases; Professor, Department of Pathology; Executive Director, Center for Biodefense and Emerging Infectious Diseases, University of Texas Medical Branch, Galveston, Texas [187]

Mark F. Walker, MD
Associate Professor, Neurology, Case Western Reserve University; Director, Daroff-Dell'Osso Ocular Motility Laboratory, VA Northeast Ohio Healthcare System, Cleveland, Ohio [22]

George R. Washko, MD, MMSc
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts [286, A12]

Michael E. Wechsler, MD, MMSc
Professor of Medicine; Director, Asthma Program, Department of Medicine, National Jewish Health, Denver, Colorado [288]

Anthony P. Weetman, MD, DSc
University of Sheffield, School of Medicine, Sheffield, United Kingdom [382–385]

Robert A. Weinstein, MD
The C. Anderson Hedberg MD Professor of Internal Medicine, Rush University Medical Center; Chairman of Medicine, Emeritus, Cook County Health, Chicago, Illinois [142]

Jeffrey I. Weitz, MD, FRCP(C), FRSC, FACP
Professor of Medicine and Biochemistry and Biomedical Sciences, McMaster University; Executive Director, Thrombosis and Atherosclerosis Research Institute, Hamilton, Ontario, Canada [118]

Peter F. Weller, MD
William Bosworth Castle Professor of Medicine, Harvard Medical School; Professor of Immunology and Infectious Diseases, Harvard T.H. Chan School of Public Health; Chief Emeritus, Infectious Diseases Division and Vice Chair of Research, Department of Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts [229–233, 235]

Andrew Wellman, MD, PhD
Associate Professor of Medicine, Harvard Medical School; Director, Sleep Disordered Breathing Lab, Brigham and Women's Hospital, Boston, Massachusetts [297]

Patrick Y. Wen, MD
Professor of Neurology, Harvard Medical School; Director, Center for Neuro-Oncology, Dana-Farber Cancer Institute; Director, Division of Neuro-Oncology, Department of Neurology, Brigham and Women's Hospital, Boston, Massachusetts [90]

Michael R. Wessels, MD
John F. Enders Professor of Pediatrics and Professor of Medicine, Harvard Medical School; Senior Physician, Division of Infectious Diseases, Boston Children's Hospital, Boston, Massachusetts [148]

L. Joseph Wheat, MD
Medical Director, MiraVista Diagnostics, Indianapolis, Indiana [212]

A. Clinton White, Jr., MD, FACP, FIDSA, FASTMH
Professor, Infectious Disease Division, Department of Internal Medicine, University of Texas Medical Branch, Galveston, Texas [235]

Nicholas J. White, DSc, MD, FRCP, F Med Sci, FRS
Professor of Tropical Medicine, Mahidol and Oxford Universities, Bangkok, Thailand [224, A2]

Richard J. Whitley, MD
Loeb Eminent Scholar in Pediatrics; Professor of Pediatrics, Microbiology and Neurosurgery, The University of Alabama at Birmingham, Birmingham, Alabama [193]

Eleanor Wilson, MD, MHS
Associate Professor of Medicine, Associate Director of Clinical Research, Division of Clinical Care and Research, Institute of Human Virology, University of Maryland School of Medicine, Baltimore, Maryland [191]

Michael R. Wilson, MD, MAS
Rachleff Family Distinguished Associate Professor in Neurology, University of California San Francisco Weill Institute for Neurosciences; Staff Physician, University of California San Francisco Medical Center and Zuckerberg San Francisco General Hospital, San Francisco, California [137, 139, S2]

Bruce U. Wintroub, MD
Professor and Chair, Department of Dermatology, University of California, San Francisco, San Francisco, California [60]

Allan W. Wolkoff, MD
The Herman Lopata Chair in Liver Disease Research; Professor of Medicine and Anatomy and Structural Biology; Associate Chair of Medicine for Research; Chief, Division of Hepatology; Director, Marion Bessin Liver Research Center, Albert Einstein College of Medicine and Montefiore Medical Center, Bronx, New York [338]

Louis Michel Wong Kee Song, MD
Professor of Medicine, Division of Gastroenterology and Hepatology, Mayo Clinic College of Medicine, Rochester, Minnesota [322, V5]

John B. Wong, MD
Professor of Medicine, Tufts University School of Medicine; Interim Chief Scientific Officer, Tufts Medical Center, Boston, Massachusetts [4]

Thomas E. Wood, PhD
Research Fellow, Department of Medicine, Division of Infectious Diseases, Massachusetts General Hospital; Department of Microbiology, Harvard Medical School, Boston, Massachusetts [120]

Jennifer A. Woyach, MD
Professor of Medicine, Division of Hematology, The Ohio State University, Columbus, Ohio [107]

Peter F. Wright, MD
Professor of Pediatrics, Geisel School of Medicine, Dartmouth College, Hanover, New Hampshire [200]

Henry M. Wu, MD, DTM&H, FIDSA
Associate Professor of Medicine, Division of Infectious Diseases, Emory University; Director, Emory TravelWell Center, Atlanta, Georgia [124]

Kim B. Yancey, MD
Professor and Chair, Department of Dermatology, University of Texas Southwestern Medical Center in Dallas, Dallas, Texas [56, 59]

Lonny Yarmus, DO, MBA
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland [299]

Yusuf Yazici, MD
Clinical Associate Professor of Medicine, New York University Grossman School of Medicine, New York, New York [364]

Baligh R. Yehia, MD, MPP, MSc
Ascension Health, St. Louis, Missouri [400]

Janet A. Yellowitz, DMD, MPH
Associate Professor; Director, Special Care and Geriatric Dentistry, University of Maryland School of Dentistry, Baltimore, Maryland [A3]

Lam Minh Yen, MD
Senior Clinical Researcher, Oxford University Clinical Research Unit, Ho Chi Minh City, Vietnam [152]

Neal S. Young, MD
Chief, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland [102, 469]

Paul C. Zei, MD, PhD
Associate Professor of Medicine, Harvard Medical School; Director, Clinical Atrial Fibrillation Program, Brigham and Women's Hospital, Boston, Massachusetts [243, 246–251]

Jing Zhou, MD, PhD, FASN
Professor of Medicine, Harvard Medical School; Director, Laboratory of Molecular Genetics and Developmental Biology of Disease, Renal Division; Director, Center for Polycystic Kidney Disease Research, Brigham and Women's Hospital; Boston, Massachusetts [315]

Werner Zimmerli, MD
Professor of Medicine, Basel University, Interdisciplinary Unit of Orthopaedic Infections, Kantonsspital Baselland, Liestal, Switzerland [131]

Laura A. Zimmerman, MPH
Epidemiologist, Centers for Disease Control and Prevention, Atlanta, Georgia [206]

The Editors are pleased to present the 21st edition of *Harrison's Principles of Internal Medicine*. This 21st edition is a true landmark in medicine, spanning 71 years and multiple generations of trainees and practicing clinicians. While medicine and medical education have evolved, readers will appreciate how this classic textbook has retained enduring features that have distinguished it among medical texts—a sharp focus on the clinical presentation of disease, expert in-depth summaries of pathophysiology and treatment, and highlights of emerging frontiers of science and medicine. Indeed, *Harrison's* retains its conviction that, in the profession of medicine, we are all perpetual students with lifelong learning as our common goal.

Harrison's is intended for learners throughout their careers. For *students*, Part 1, Chapter 1 begins with an overview of "The Practice of Medicine." In this introductory chapter, the editors continue the tradition of orienting clinicians to the *science* and the *art* of medicine, emphasizing the values of our profession while incorporating new advances in technology, science, and clinical care. Part 2, "Cardinal Manifestations and Presentation of Diseases," is a signature feature of *Harrison's*. These chapters eloquently describe how patients present with common clinical conditions, such as headache, fever, cough, palpitations, or anemia, and provide an overview of typical symptoms, physical findings, and differential diagnosis. Mastery of these topics prepares students for subsequent chapters on specific diseases they will encounter in courses on pathophysiology and in clinical clerkships. For *residents* and *fellows* caring for patients and preparing for board examinations, *Harrison's* remains a definitive source of trusted content written by internationally renowned experts. Trainees will be reassured by the depth of content, comprehensive tables, and illuminating figures and clinical algorithms. Many examination questions are based on key testing points derived from *Harrison's* chapters. A useful companion book, *Harrison's Self-Assessment and Board Review*, includes over 1000 questions, offers comprehensive explanations of the correct answer, and provides links to the relevant chapters in the textbook. *Practicing clinicians* must keep up with an ever-changing knowledge base and clinical guidelines as part of lifelong learning. Clinicians can trust that chapters are updated extensively with each edition of *Harrison's*. The text is an excellent point-of-care reference for clinical questions, differential diagnosis, and patient management. In addition to the expanded and detailed Treatment sections, *Harrison's* continues its tradition of including "Approach to the Patient" sections, which provide an expert's overview of the practical management of common but often complex clinical conditions.

This edition has been modified extensively in its structure as well as its content and offers a more consistently standardized format for each disease chapter. The authors and editors have curated rigorously and synthesized the vast amount of information that comprises general internal medicine—and each of the major specialties—into a highly readable and informative two-volume book. Readers will appreciate the concise writing style and substantive quality that have always characterized *Harrison's*. This book has a sharp focus on essential information with a goal of providing clear and definitive answers to clinical questions.

In the 21st edition, examples of new chapters include "Precision Medicine and Clinical Care," focusing on the ever-growing pool of "big data" used to provide individualized genotype-phenotype correlations; "Mechanisms of Regulation and Dysregulation of the Immune System," focusing on the extraordinary advances made over the past 5 years in understanding the complex and subtle mechanisms whereby the immune system is regulated and how perturbations in this regulation lead to disease states as well as targets for therapeutic intervention; new chapters on Alzheimer's disease and related conditions, with a special focus on vascular dementia, a common and treatable cause of cognitive loss; and a new chapter on marijuana and marijuana use disorders, as well as updated management guidelines for multiple sclerosis and the expanding array of other autoimmune nervous system diseases that can now be identified and treated.

Other new chapters include "Vaccine Opposition and Hesitancy," "Precision Medicine and Clinical Care," "Diagnosis: Reducing Errors and Improving Quality," "Approach to the Patient with Renal or Urinary Tract Disease," "Interventional Nephrology," "Health Effects of Climate Change," and "Circulating Nucleic Acids as Liquid Biopsies and Noninvasive Disease Biomarkers." In addition, many chapters have new authors.

The chapter, "Vaccine Opposition and Hesitancy," provides an overview of the current antivaccination crisis, the issues involved, and specific strategies to utilize within the clinical setting to address the lack of confidence that many patients feel toward the health care system. The chapter, "Metabolomics," outlines an emerging and important new and sensitive approach to measuring perturbations within a system or patient that will likely become a routine part of the clinical armamentarium for diagnosing, monitoring, and treating disease.

In addition to these and other new topics, the 21st edition presents important updates in the established chapters, such as the microbiology and clinical management of SARS-CoV-2 infection, the use of gene editing for sickle cell anemia and thalassemia, gene therapy for hemophilia, new immunotherapies for autoimmune diseases and cancers, and novel approaches to vaccine development, among many others. Our focus on forwarding-looking issues of emerging clinical importance continues with the series of chapters entitled "Frontiers," which foreshadows cutting-edge science that will change medical practice in the near term. Examples of new Frontier chapters include "Machine Learning and Augmented Intelligence," "Metabolomics," "Protein Folding Disorders," and "Novel Approaches to Disease of Unknown Etiology."

Harrison's content is available in a variety of print and digital formats, including eBooks, apps, and a popular, widely used online platform available at *www.accessmedicine.com*.

We have many people to thank for their efforts in producing this book. First, the authors have done a superb job of producing authoritative chapters that synthesize vast amounts of scientific and clinical data to create informative and practical approaches to managing patients. In today's information-rich, rapidly evolving environment, they have ensured that this information is current. We are most grateful to our colleagues who work closely with each editor to facilitate communication with the authors and help us keep *Harrison's* content current. In particular, we wish to acknowledge the expert support of Lauren Bauer, Patricia Conrad, Patricia L. Duffey, Gregory K. Folkers, Julie B. McCoy, Elizabeth Robbins, Marie Scurti, and Stephanie C. Tribuna. Scott Grillo and James Shanahan, our long-standing partners at McGraw Hill's Professional Publishing group, have inspired the creative and dynamic evolution of *Harrison's*, guiding the development of the book and its related products in new formats. Kim Davis, as Managing Editor, has adeptly ensured that the complex production of this multi-authored textbook proceeded smoothly and efficiently. Priscilla Beer oversaw the production of our videos and animations; Jeffrey Herzich, Elleanore Waka, and Rachel Norton, along with other members of the McGraw Hill staff; and Revathi Viswanathan of KnowledgeWorks Global Ltd., shepherded the production of this new edition.

We are privileged to have compiled this 21st edition and are enthusiastic about all that it offers our readers. We learned much in the process of editing *Harrison's* and hope that you will find this edition uniquely valuable as a clinical and educational resource.

Related Harrison's Resources

A complete collection to meet your educational, clinical, and board prep needs.

Harrison's Online

The online edition of *Harrison's* is available at *www.accessmedicine.com*. It requires an institutional or individual subscription separate from the purchase of the print book. The online edition of *Harrison's* features all the chapters from the print edition, plus more than two dozen supplementary chapters in print, atlas, and video formats. *Harrison's Online* includes numerous monthly updates, from the editors of *Harrison's*, on important new developments in medical research and practice. Easily search across the entire *Harrison's* content set, download images and tables for presentations and lectures, view step-by-step videos on common clinical procedures, access the text of the *Harrison's Manual of Medicine*, set up a personalized test exam for board prep, get access to chapters from new editions of *Harrison's* months before book publication, and more.

The Harrison's Manual of Medicine

The *Harrison's Manual of Medicine* provides high-yield, rapid-access clinical summaries of *Harrison's* content, suitable for use at the bedside. Chapters in the *Manual* reflect those likely to be encountered in both the inpatient and outpatient setting. The format is built for ease of use. The *Manual* is available in print, eBook, and app. In addition, the full text of the *Manual* is available to subscribers at *accessmedicine.com*. This format provides flexibility of format to customers, who can move back and forth between the full scope of *Harrison's Principles of Internal Medicine* and the high-yield clinical essentials of the *Manual.*

The *Manual* includes more than 200 chapters in 17 sections and covers presenting signs and symptoms and major conditions seen in both inpatient and outpatient settings. The full table of contents is available at *www.accessmedicine.com.*

The Harrison's Self-Assessment and Board Review

This practical resource provides more than 1000 self-assessment questions, most in board-style clinical vignette format with multiple choice answers. The explanations for the questions are comprehensive and provide detailed guidance on correct and incorrect answers. Question-and-answer sets include references to related chapters in *Harrison's Principles of Internal Medicine* for more comprehensive understanding. Use this very handy resource for primary and recertification exam prep, for rotational shelf exams, and for general assessment of understanding of the principles of clinical medicine. This resource is available as a print book, an eBook, an app, and on *accessmedicine.com*, where users can create personalized testing experiences and receive instant scores on practice tests.

Harrison's Podclass

Our podcast presents bi-weekly episodes covering clinical vignettes across internal medicine, with two expert discussants reviewing common and challenging patient presentations and a series of self-assessment Q&A choices tied to each case. The hosts work through correct and incorrect answer choices and summarize cases with practical pearls that all students and clinicians will find helpful and interesting. *Harrison's Podclass* is available in most of the common podcast outlets and on *www.accessmedicine.com.*

1 The Practice of Medicine

The Editors

ENDURING VALUES OF THE MEDICAL PROFESSION

No greater opportunity, responsibility, or obligation can fall to the lot of a human being than to become a physician. In the care of the suffering, [the physician] needs technical skill, scientific knowledge, and human understanding. Tact, sympathy, and understanding are expected of the physician, for the patient is no mere collection of symptoms, signs, disordered functions, damaged organs, and disturbed emotions. [The patient] is human, fearful, and hopeful, seeking relief, help, and reassurance.

—*Harrison's Principles of Internal Medicine,* 1950

The practice of medicine has changed in significant ways since the first edition of this book was published in 1950. The advent of molecular genetics, sophisticated new imaging techniques, robotics, and advances in bioinformatics and information technology have contributed to an explosion of scientific information that has changed fundamentally the way physicians define, diagnose, treat, and attempt to prevent disease. This growth of scientific knowledge continues to evolve at an accelerated pace.

The widespread use of electronic medical records and the Internet have altered the way physicians and other health care providers access and exchange information as a routine part of medical education and practice **(Fig. 1-1)**. As today's physicians strive to integrate an ever-expanding body of scientific knowledge into everyday practice, it is critically important to remember two key principles: first, the ultimate goal of medicine is to prevent disease and, when it occurs, to diagnose it early and provide effective treatment; and second, despite 70 years of scientific advances since the first edition of this text, a trusting relationship between physician and patient still lies at the heart of effective patient care.

THE SCIENCE AND ART OF MEDICINE

Deductive reasoning and applied technology form the foundation for the approach and solution to many clinical problems. Extraordinary advances in biochemistry, cell biology, immunology, and genomics, coupled with newly developed imaging techniques, provide a window into the most remote recesses of the body and allow access to the innermost parts of the cell. Revelations about the nature of genes and single cells have opened a portal for formulating a new molecular basis for the physiology of systems. Researchers are deciphering the complex mechanisms by which genes are regulated, and increasingly, physicians are learning how subtle changes in many different genes, acting in an integrative contextual way, can affect the function of cells and organisms. Clinicians have developed a new appreciation of the role of stem cells in normal tissue function, in the development of cancer and other disorders, and in the treatment of certain diseases. Entirely new areas of research, including studies of the human microbiome, epigenetics, and noncoding RNAs as regulatory features of the genome, have become important for understanding both health and disease. Information technology enables the interrogation of medical records from millions of individuals, yielding new insights into the etiology, characteristics, prognosis, and stratification of many diseases. With the increasing availability of very large data sets ("big data") from omic analyses and the electronic medical record, there is now a growing need for machine learning and artificial intelligence for unbiased analyses that enhance clinical predictive accuracy. The knowledge gleaned from the ***science of medicine*** continues to enhance the understanding by physicians of complex pathologic processes and to provide new approaches to disease prevention, diagnosis, and treatment. With continued refinement of unique omic signatures coupled with nuanced clinical pathophenotypes, the profession moves ever closer to practical precision medicine. Yet, skill in the most sophisticated applications of laboratory technology and in the use of the latest therapeutic modality alone does not make a good physician. Extraordinary advances in vaccine platform technology and the use of cryo-electron microscopy for the structure-based design of vaccine immunogens have transformed the field of vaccinology, resulting in the unprecedented speed and success with which COVID-19 vaccines were developed.

When a patient poses challenging clinical problems, an effective physician must be able to identify the crucial elements in a complex history and physical examination; order the appropriate laboratory, imaging, and diagnostic tests; and extract the key results from densely populated computer screens to determine whether to treat or to "watch." As the number of tests increases, so does the likelihood that some incidental finding, completely unrelated to the clinical problem at hand, will be uncovered. Deciding whether a clinical clue is worth pursuing or should be dismissed as a "red herring" and weighing whether a proposed test, preventive measure, or treatment entails a greater risk than the disease itself are essential judgments that a skilled clinician must make many times each day. This combination of medical knowledge, intuition, experience, and judgment defines the ***art of medicine***, which is as necessary to the practice of medicine and the precision medicine of the future as is a sound scientific base, and as important for contemporary medical practice as it has been in earlier eras.

FIGURE 1-1 *The Doctor* by Luke Fildes depicts the caring relationship between this Victorian physician and a very ill child. Painted in 1891, the painting reflects the death of the painter's young son from typhoid fever and was intended to reflect the compassionate care provided by the physician even when his tools were not able to influence the course of disease. *(Source: History and Art Collection/Alamy Stock Photo.)*

CLINICAL SKILLS

History-Taking The recorded history of an illness should include all the facts of medical significance in the life of the patient. Recent events should be given the most attention. Patients should, at some early point, have the opportunity to tell their own story of the illness without frequent interruption and, when appropriate, should receive expressions of interest, encouragement, and empathy from the physician. Any event related by a patient, however trivial or seemingly irrelevant, may provide the key to solving the medical problem. A methodical review of systems is important to elicit features of an underlying disease that might not be mentioned in the patient's narrative. In general, patients who feel comfortable with the physician will offer more complete information; thus, putting the patient at ease contributes substantially to obtaining an adequate history.

An informative history is more than eliciting an orderly listing of symptoms. By listening to patients and noting the ways in which they describe their symptoms, physicians can gain valuable insight. Inflections of voice, facial expression, gestures, and attitude (i.e., "body language") may offer important clues to patients' perception of and reaction to their symptoms. Because patients vary considerably in their medical sophistication and ability to recall facts, the reported medical history should be corroborated whenever possible. The social history also can provide important insights into the types of diseases that should be considered and can identify practical considerations for subsequent management. The family history not only identifies rare genetic disorders or common exposures, but often reveals risk factors for common disorders, such as coronary heart disease, hypertension, autoimmunity, and asthma. A thorough family history may require input from multiple relatives to ensure completeness and accuracy. An experienced clinician can usually formulate a relevant differential diagnosis from the history alone, using the physical examination and diagnostic tests to narrow the list or reveal unexpected findings that lead to more focused inquiry.

The very act of eliciting the history provides the physician with an opportunity to establish or enhance a unique bond that can form the basis for a good patient–physician relationship. This process helps the physician develop an appreciation of the patient's view of the illness, the patient's expectations of the physician and the health care system, and the financial and social implications of the illness for the patient. Although current health care settings may impose time constraints on patient visits, it is important not to rush the encounter. A hurried approach may lead patients to believe that what they are relating is not of importance to the physician, and, as a result, they may withhold relevant information. The confidentiality of the patient–physician relationship cannot be overemphasized.

Physical Examination The purpose of the physical examination is to identify physical signs of disease. The significance of these objective indications of disease is enhanced when they confirm a functional or structural change already suggested by the patient's history. At times, however, physical signs may be the only evidence of disease and may not have been suggested by the history.

The physical examination should be methodical and thorough, with consideration given to the patient's comfort and modesty. Although attention is often directed by the history to the diseased organ or part of the body, the examination of a new patient must extend from head to toe in an objective search for abnormalities. The results of the examination, like the details of the history, should be recorded at the time they are elicited—not hours later, when they are subject to the distortions of memory. Physical examination skills should be learned under direct observation of experienced clinicians. Even highly experienced clinicians can benefit from ongoing coaching and feedback. Simulation laboratories and standardized patients play an increasingly important role in the development of clinical skills. Although the skills of physical diagnosis are acquired with experience, it is not merely technique that determines success in identifying signs of disease. The detection of a few scattered petechiae, a faint diastolic murmur, or a small mass in the abdomen is not a question of keener eyes and ears or more sensitive fingers, but of a mind alert to those findings. Because physical findings can change with time, the physical examination should be repeated as frequently as the clinical situation warrants.

Given the many highly sensitive diagnostic tests now available (particularly imaging techniques), it may be tempting to place less emphasis on the physical examination. Some are critical of physical diagnosis based on perceived low levels of specificity and sensitivity. Indeed, many patients are seen by consultants only after a series of diagnostic tests have been performed and the results are known. This fact should not deter the physician from performing a thorough physical examination since important clinical findings may have escaped detection by diagnostic tests. Especially important, a thorough and thoughtful physical examination may render a laboratory finding unimportant (i.e., certain echocardiographic regurgitant lesions). The act of a hands-on examination of the patient also offers an opportunity for communication and may have reassuring effects that foster the patient–physician relationship.

Diagnostic Studies Physicians rely increasingly on a wide array of laboratory and imaging tests to make diagnoses and ultimately to solve clinical problems; however, such information does not relieve the physician from the responsibility of carefully observing and examining the patient. It is also essential to appreciate the limitations of diagnostic tests. By virtue of their apparent precision, these tests often gain an aura of certainty regardless of the fallibility of the tests themselves, the instruments used in the tests, and the individuals performing or interpreting the tests. Physicians must weigh the expense involved in laboratory procedures against the value of the information these procedures are likely to provide.

Single laboratory tests are rarely ordered. Instead, physicians generally request "batteries" of multiple tests, which often prove useful and can be performed with a single specimen at relatively low cost. For example, abnormalities of hepatic function may provide the clue to nonspecific symptoms such as generalized weakness and increased fatigability, suggesting a diagnosis of chronic liver disease. Sometimes a single abnormality, such as an elevated serum calcium level, points to a particular disease, such as hyperparathyroidism.

The thoughtful use of screening tests (e.g., measurement of low-density lipoprotein cholesterol) may allow early intervention to prevent disease (Chap. 6). Screening tests are most informative when they are directed toward common diseases and when their results indicate whether other potentially useful—but often costly—tests or interventions are needed. On the one hand, biochemical measurements, together with simple laboratory determinations such as routine serum chemistries, blood counts, and urinalysis, often provide a major clue to the presence of a pathologic process. On the other hand, the physician must learn to evaluate occasional screening-test abnormalities that do not necessarily connote significant disease. An in-depth workup after the report of an isolated laboratory abnormality in a person who is otherwise well is often wasteful and unproductive. Because so many tests are performed routinely for screening purposes, it is not unusual for one or two values to be slightly abnormal. Nevertheless, even if there is no reason to suspect an underlying illness, tests yielding abnormal results ordinarily are repeated to rule out laboratory error. If an abnormality is confirmed, it is important to consider its potential significance in the context of the patient's condition and other test results.

There is almost continual development of technically improved imaging studies with greater sensitivity and specificity. These tests provide remarkably detailed anatomic information that can be pivotal in informing medical decision-making. MRI, CT, ultrasonography, a variety of isotopic scans, and positron emission tomography (PET) have supplanted older, more invasive approaches and opened new diagnostic vistas. In light of their capabilities and the rapidity with which they can lead to a diagnosis, it is tempting to order a battery of imaging studies. All physicians have had experiences in which imaging studies revealed findings that led to an unexpected diagnosis. Nonetheless, patients must endure each of these tests, and the added cost of unnecessary testing is substantial. Furthermore, investigation of an unexpected abnormal finding may lead to an iatrogenic complication or to the diagnosis of an irrelevant or incidental problem. A skilled physician must learn to use these powerful diagnostic tools judiciously, always considering whether the results will alter management and benefit the patient.

MANAGEMENT OF PATIENT CARE

Team-Based Care Medical practice has long involved teams, particularly physicians working with nurses and, more recently, with physician assistants and nurse practitioners. Advances in medicine have increased our ability to manage very complex clinical situations (e.g., intensive care units [ICUs], bone marrow transplantation) and have shifted the burden of disease toward chronic illnesses. Because an individual patient may have multiple chronic diseases, he or she may be cared for by several specialists as well as a primary care physician. In the inpatient setting, care may involve multiple consultants along with

the primary admitting physician. Communication through the medical record is necessary but not sufficient, particularly when patients have complex medical problems or when difficult decisions need to be made about the optimal management plan. Physicians should optimally meet face-to-face or by phone to ensure clear communication and thoughtful planning. It is important to note that patients often receive or perceive different messages from various care providers; thus, attempts should be made to provide consistency among these messages to the patient. Management plans and treatment options should be outlined succinctly and clearly for the patient.

Another dimension of team-based care involves allied health professions. It is not unusual for a hospitalized patient to encounter physical therapists, pharmacists, respiratory therapists, radiology technicians, social workers, dieticians, and transport personnel (among others) in addition to physicians and nurses. Each of these individuals contributes to clinical care as well as to the patient's experience with the health care system. In the outpatient setting, disease screening and chronic disease management are often carried out by nurses, physician assistants, or other allied health professionals.

The growth of team-based care has important implications for medical culture, student and resident training, and the organization of health care systems. Despite diversity in training, skills, and responsibilities among health care professionals, common values need to be espoused and reinforced. Many medical schools have incorporated interprofessional teamwork into their curricula. Effective communication is inevitably the most challenging aspect of implementing team-based care. While communication can be aided by electronic devices, including medical records, apps, or text messages, it is vitally important to balance efficiency with taking the necessary time to speak directly with colleagues.

The Dichotomy of Inpatient and Outpatient Internal Medicine The hospital environment has undergone sweeping changes over the past few decades. Emergency departments and critical care units have evolved to manage critically ill patients, allowing them to survive formerly fatal conditions. In parallel, there is increasing pressure to reduce the length of stay in the hospital and to manage complex disorders in the outpatient setting. This transition has been driven not only by efforts to reduce costs but also by the availability of new outpatient technologies, such as imaging and percutaneous infusion catheters for long-term antibiotics or nutrition, minimally invasive surgical procedures, and evidence that outcomes often are improved by reducing inpatient hospitalization.

In addition to traditional medical beds, hospitals now encompass multiple distinct levels of care, such as the emergency department, procedure rooms, overnight observation units, critical care units, and palliative care units. A consequence of this differentiation has been the emergence of new specialties (e.g., emergency medicine and end-of-life care) and the provision of in-hospital care by hospitalists and intensivists. Most *hospitalists* are board-certified internists who bear primary responsibility for the care of hospitalized patients and whose work is limited entirely to the hospital setting. The shortened length of hospital stay means that most patients receive only acute care while hospitalized; the increased complexities of inpatient medicine make the presence of an internist with specific training, skills, and experience in the hospital environment extremely beneficial. *Intensivists* are board-certified physicians who are further certified in critical care medicine and who direct and provide care for very ill patients in critical care units. Clearly, an important challenge in internal medicine today is to ensure the continuity of communication and information flow between a patient's primary care physician and those who are in charge of the patient's hospital care. Maintaining these channels of communication is frequently complicated by patient "handoffs"—i.e., transitions from the outpatient to the inpatient environment, from the critical care unit to a general medicine floor, from a medical to a surgical service and vice versa, from the hospital environment to the recently developed "home hospital" setting (for select patients with adequate home support), and from the hospital or home hospital to the outpatient environment.

The involvement of many care providers in conjunction with these transitions can threaten the traditional one-to-one relationship between patient and primary care physician. Of course, patients can benefit greatly from effective collaboration among a number of health care professionals; however, *it is the duty of the patient's principal or primary physician to provide cohesive guidance through an illness*. To meet this challenge, primary care physicians must be familiar with the techniques, skills, and objectives of specialist physicians and allied health professionals who care for their patients in the hospital. In addition, primary care physicians must ensure that their patients benefit from scientific advances and the expertise of specialists, both in and out of the hospital. Primary care physicians should explain the role of these specialists to reassure patients that they are in the hands of physicians best trained to manage their current illness. However, the primary care physician should assure patients and their families that decisions are being made in consultation with these specialists. The evolving concept of the "medical home" incorporates team-based primary care with subspecialty care in a cohesive environment that ensures smooth transitions of care.

Mitigating the Stress of Acute Illness Few people are prepared for a new diagnosis of cancer or anticipate the occurrence of a myocardial infarction, stroke, or major accident. The care of a frightened or distraught patient is confounded by these understandable responses to life-threatening events. The physician and other health providers can reduce the shock of life-changing events by providing information in a clear, calm, consistent, and reassuring manner. Often, information and reassurance need to be repeated. Caregivers should also recognize that, for the typical patient, hospital emergency rooms, operating rooms, ICUs, and general medical floors represent an intimidating environment. Hospitalized patients find themselves surrounded by air jets, buttons, and glaring lights; invaded by tubes and wires; and beset by the numerous members of the health care team—hospitalists, specialists, nurses, nurses' aides, physician assistants, social workers, technologists, physical therapists, medical students, house officers, attending and consulting physicians, and many others. They may be transported to special laboratories and imaging facilities replete with blinking lights, strange sounds, and unfamiliar personnel; they may be left unattended at times; and they may be obligated to share a room with other patients who have their own health problems. It is little wonder that patients may find this environment bewildering and stressful. The additive effects of an acute illness, unfamiliar environment, multiple medications, and sleep deprivation can lead to confusion or delirium, especially in older hospitalized patients. Physicians who appreciate the hospital experience from the patient's perspective and who make an effort to guide the patient through this experience may make a stressful situation more tolerable and enhance the patient's chances for an optimal recovery.

Medical Decision-Making Medical decision-making is a fundamental responsibility of the physician and occurs at each stage of the diagnostic and therapeutic process. The decision-making process involves the ordering of additional tests, requests for consultations, decisions about treatment, and predictions concerning prognosis. This process requires an in-depth understanding of the pathophysiology and natural history of disease. Formulating a differential diagnosis requires not only a broad knowledge base but also the ability to assess the relative probabilities of various diseases for a given patient. Application of the scientific method, including hypothesis formulation and data collection, is essential to the process of accepting or rejecting a particular diagnosis. Analysis of the differential diagnosis is an iterative process. As new information or test results are acquired, the group of disease processes being considered can be contracted or expanded appropriately. Whenever possible, decisions should be evidence-based, taking advantage of rigorously designed clinical trials or objective comparisons of different diagnostic tests. *Evidence-based medicine* stands in sharp contrast to anecdotal experience, which is often biased. Unless attuned to the importance of using larger, objective studies for making decisions, even the most experienced physicians can be influenced

to an undue extent by recent encounters with selected patients. Evidence-based medicine has become an increasingly important part of routine medical practice and has led to the publication of many useful practice guidelines. It is important to remember, however, that only a small fraction of the many decisions made in clinical practice are based on rigorous clinical trial evidence; other guideline recommendations are, therefore, predicated on expert consensus and weaker evidentiary support.

Thus, the importance of evidence-based medicine notwithstanding, much medical decision-making still relies on good clinical judgment, an attribute that is difficult to quantify or even to assess qualitatively. Physicians must use their knowledge and experience as a basis for weighing known factors, along with the inevitable uncertainties, and then making a sound judgment; this synthesis of information is particularly important when a relevant evidence base is not available. Several quantitative tools may be invaluable in synthesizing the available information, including diagnostic tests, Bayes' theorem (the probability of an event predicated on prior knowledge of conditions possibly related to the event), and multivariate statistical models **(Chap. 4)**. Diagnostic tests serve to reduce uncertainty about an individual's diagnosis or prognosis and help the physician decide how best to manage that individual's condition. The battery of diagnostic tests complements the history and physical examination. The accuracy of a particular test is ascertained by determining its sensitivity (true-positive rate) and specificity (true-negative rate), as well as the predictive value of a positive and a negative result. **See Chap. 4 for a more thorough discussion of decision-making in clinical medicine.**

Practice Guidelines Many professional organizations and government agencies have developed formal clinical-practice guidelines to aid physicians and other caregivers in making diagnostic and therapeutic decisions that are evidence-based, cost-effective, and most appropriate to a particular patient and clinical situation. As the evidence base of medicine increases, guidelines can provide a useful framework for managing patients with particular diagnoses or symptoms. Clinical guidelines can protect patients—particularly those with inadequate health care benefits—from receiving substandard care. These guidelines also can protect conscientious caregivers from inappropriate charges of malpractice and society from the excessive costs associated with the overuse of medical resources. There are, however, caveats associated with clinical-practice guidelines since they tend to oversimplify the complexities of medicine. Furthermore, groups with different perspectives may develop divergent recommendations regarding issues as basic as the need for screening of women by mammography or of men with serum prostate-specific antigen (PSA) measurements. Finally, guidelines, as the term implies, do not—and cannot be expected to—account for the uniqueness of each individual and his or her illness. The physician's challenge is to integrate into clinical practice the useful recommendations offered by experts without accepting them blindly or being inappropriately constrained by them.

Precision Medicine The concept of *precision* or *personalized medicine* reflects the growing recognition that diseases once lumped together can be further stratified on the basis of genetic, biomarker, phenotypic, and/or psychosocial characteristics that distinguish a given patient from other patients with similar clinical presentations. Inherent in this concept is the goal of targeting therapies in a more specific way to improve clinical outcomes for the individual patient and minimize unnecessary side effects for those less likely to respond to a particular treatment. In some respects, precision medicine represents the evolution of clinical practice guidelines, which are usually developed for populations of patients or a particular diagnosis (e.g., hypertension, thyroid nodule). As the pathobiology, prognosis, and treatment responses of subgroups within these diagnoses become better understood (i.e., through refined genomic analysis or enhanced deep phenotyping), the relevant clinical guidelines incorporate progressively more refined recommendations for individuals within these subgroups. The role of precision medicine is best illustrated for cancers in which genetic testing is able to predict responses (or the lack thereof) to targeted therapies **(Chap. 73)**. One can anticipate similar applications of precision medicine in pharmacogenomics, immunologic disorders, and diseases in which biomarkers can predict treatment responses. **See Chap. 5 for a more thorough discussion of precision medicine.**

Evaluation of Outcomes Clinicians generally use *objective* and readily measurable parameters to judge the outcome of a therapeutic intervention. These measures may oversimplify the complexity of a clinical condition as patients often present with a major clinical problem in the context of multiple complicating background illnesses. For example, a patient may present with chest pain and cardiac ischemia, but with a background of chronic obstructive pulmonary disease and renal insufficiency. For this reason, outcome measures, such as mortality, length of hospital stay, or readmission rates, are typically risk-adjusted. An important point to remember is that patients usually seek medical attention for *subjective* reasons; they wish to obtain relief from pain, to preserve or regain function, and to enjoy life. The components of a patient's health status or quality of life can include bodily comfort, capacity for physical activity, personal and professional function, sexual function, cognitive function, and overall perception of health. Each of these important domains can be assessed through structured interviews or specially designed questionnaires. Such assessments provide useful parameters by which a physician can judge patients' subjective views of their disabilities and responses to treatment, particularly in chronic illness. The practice of medicine requires consideration and integration of both objective and subjective outcomes.

Many health systems use survey and patient feedback data to assess qualitative features such as patient satisfaction, access to care, and communication with nurses and physicians. In the United States, HCAHPS (Hospital Consumer Assessment of Healthcare Providers and Systems) surveys are used by many systems and are publicly reported. Social media is also being used to assess feedback in real time as well as to share patient experiences with health care systems, potentially enriching the information available for use in medical decisions.

Errors in the Delivery of Health Care A series of reports from the Institute of Medicine (now the National Academy of Medicine [NAM]) called for an ambitious agenda to reduce medical error rates and improve patient safety by designing and implementing fundamental changes in health care systems **(Chap. 8)**. It is the responsibility of hospitals and health care organizations to develop systems to reduce risk and ensure patient safety. Medication errors can be reduced through the use of ordering systems that rely on electronic processes or, when electronic options are not available, that eliminate misreading of handwriting. Whatever the clinical situation, it is the physician's responsibility to use powerful therapeutic measures wisely, with due regard for their beneficial actions, potential dangers, and cost. Implementation of infection control systems, enforcement of hand-washing protocols, and careful oversight of antibiotic use can minimize the complications of nosocomial infections. Central-line infection rates and catheter-associated urinary tract infections have been dramatically reduced at many centers by careful adherence of trained personnel to standardized protocols for introducing and maintaining central lines and urinary catheters, respectively. Rates of surgical infection and wrong-site surgery can likewise be reduced by the use of standardized protocols and checklists. Falls by patients can be minimized by judicious use of sedatives and appropriate assistance with bed-to-chair and bed-to-bathroom transitions. Taken together, these and other measures are saving thousands of lives each year.

Electronic Medical Records Both the growing reliance on computers and the strength of information technology now play central roles in medicine, including efforts to reduce medical errors. Laboratory data are accessed almost universally through computers. Many medical centers now have electronic medical records (EMRs), computerized order entry, and bar-coded tracking of medications. Some of these systems are interactive, sending reminders or warning of potential medical errors.

EMRs offer rapid access to information that is invaluable in enhancing health care quality and patient safety, including relevant data,

historical and clinical information, imaging studies, laboratory results, and medication records. These data can be used to monitor and reduce unnecessary variations in care and to provide real-time information about processes of care and clinical outcomes. Ideally, patient records are easily transferred across the health care system; however, technological limitations and concerns about privacy and cost continue to limit broad-based use of EMRs in many clinical settings.

For all of the advantages of EMRs, they can create distance between the physician and patient if care is not taken to preserve face-to-face contact. EMRs also require training and time for data entry. Many providers spend significant time entering information to generate structured data and to meet billing requirements. They may feel pressured to take short cuts, such as "cutting and pasting" parts of earlier notes into the daily record, thereby increasing the risk of errors. EMRs also structure information in a manner that disrupts the traditional narrative flow across time and among providers. These features, which may be frustrating for some providers, must be weighed against the advantages of ready access to past medical history, imaging, laboratory data, and consultant notes. Furthermore, the effort, time, and attention needed to maintain and utilize the EMR have led to a growing sense of dissatisfaction among physicians, lessening professional and personal well-being as a result. Clearly, this is an area of daily practice that requires improvement both for the delivery of safe and optimal care and physician wellness.

It is important to emphasize that information technology is merely a tool and can never replace the clinical decisions that are best made by the physician. Clinical knowledge and an understanding of a patient's needs, supplemented by quantitative tools, still represent the best approach to decision-making in the practice of medicine.

THE PATIENT–PHYSICIAN RELATIONSHIP

The significance of the intimate personal relationship between physician and patient cannot be too strongly emphasized, for in an extraordinarily large number of cases both the diagnosis and treatment are directly dependent on it. One of the essential qualities of the clinician is interest in humanity, ***for the secret of the care of the patient is in caring for the patient****.*

—Francis W. Peabody, October 21, 1925,
Lecture at Harvard Medical School

Physicians must never forget that patients are individuals with problems that all too often transcend their physical complaints. They are not "cases" or "admissions" or "diseases." Patients do not fail treatments; treatments fail to benefit patients. This point is particularly important in this era of high technology in clinical medicine. Most patients are anxious and fearful. Physicians should instill confidence and offer reassurance, but they must never come across as arrogant, patronizing, impatient, or hurried. A professional attitude, coupled with warmth and openness, can do much to alleviate anxiety and to encourage patients to share all aspects of their medical history. Empathy and compassion are the essential features of a caring physician. The physician needs to consider the setting in which an illness occurs—in terms not only of patients themselves but also of their familial, social, and cultural backgrounds. The ideal patient–physician relationship is based on thorough knowledge of the patient, mutual trust, and the ability to communicate.

Informed Consent The fundamental principles of medical ethics require physicians to act in the patient's best interest and to respect the patient's autonomy. Both principles are reflected in the process of informed consent. Patients are required to sign consent forms for most diagnostic or therapeutic procedures. Many patients possess limited medical knowledge and must rely on their physicians for advice. Communicating in a clear and understandable manner, physicians must fully discuss the alternatives for care and explain the risks, benefits, and likely consequences of each alternative. The physician is responsible for ensuring that the patient thoroughly understands these risks and benefits; encouraging questions is an important part of this process. It may be necessary to go over certain issues with the patient more than once. This is the very definition of *informed consent*. Complete, clear explanation and discussion of the proposed procedures and treatment can greatly mitigate the fear of the unknown that commonly accompanies hospitalization. Often the patient's understanding is enhanced by repeatedly discussing the issues in an unthreatening and supportive way, answering new questions that occur to the patient as they arise. Continuing efforts to educate the patient are essential. Patients are frequently inhibited from understanding by the fear of an uncertain future and potential impact of the illness on themselves and their families. Clear communication can also help alleviate misunderstandings in situations where complications of intervention occur. Special care should also be taken to ensure that a physician seeking a patient's informed consent has no real or apparent conflict of interest.

Approach to Grave Prognoses and Death No circumstance is more distressing than the diagnosis of an incurable disease, particularly when premature death is inevitable. What should the patient and family be told? What measures should be taken to maintain life? What can be done to optimize quality of life?

Transparency of information, delivered in an appropriate manner, is essential in the face of a terminal illness. Even patients who seem unaware of their medical circumstances, or whose family members have protected them from diagnoses or prognoses, often have keen insights into their condition. They may also have misunderstandings that can lead to additional anxiety. The patient must be given an opportunity to speak with the physician and ask questions. A wise and insightful physician uses such open communication as the basis for assessing what the patient wants to know and when he or she wants to know it. On the basis of the patient's responses, the physician can assess the most appropriate time and pace for sharing information. Ultimately, the patient must understand the expected course of the disease so that appropriate plans and preparations can be made. The patient should participate in decision-making with an understanding of the goal of treatment (palliation) and its likely effects. The patient's religious beliefs should be taken into consideration. Some patients may find it easier to share their feelings about death with their physician, nurses, or members of the clergy than with family members or friends.

The physician should provide or arrange for emotional, physical, and spiritual support, and must be compassionate, unhurried, and open. In many instances, there is much to be gained by the laying on of hands. Pain should be controlled adequately, human dignity maintained, and isolation from family and close friends avoided. These aspects of care tend to be overlooked in hospitals, where the intrusion of life-sustaining equipment can detract from attention to the individual person and encourage concentration instead on the life-threatening disease, against which the battle ultimately will be lost in any case. In the face of terminal illness, the goal of medicine must shift from *cure* to *care* in the broadest sense of the term. *Primum succurrere*, first to help, is a guiding principle. In offering care to a dying patient, a physician should be prepared to provide information to family members and deal with their grief and sometimes their feelings of guilt or even anger. It is important for the physician to assure the family that everything reasonable is being done. A substantial challenge in these discussions is that the physician often does not know exactly how to gauge the prognosis. In addition, various members of the health care team may offer different opinions. Good communication among providers is essential so that consistent information is provided to patients. This is especially important when the best path forward is uncertain. Advice from experts in palliative and terminal care should be sought whenever appropriate to ensure that clinicians are not providing patients with unrealistic expectations. **For a more complete discussion of end-of-life care, see Chap. 12.**

Maintaining Humanism and Professionalism Many trends in the delivery of health care tend to make medical care impersonal. These trends, some of which have been mentioned already, include (1) vigorous efforts to reduce the escalating costs of health care; (2) the growing number of managed-care programs, which are intended to reduce costs but where the patient may have little choice in selecting a physician; (3) increasing reliance on technological advances and

computerization; and (4) the need for numerous physicians and other health professionals to be involved in the care of most patients who are seriously ill.

In light of these changes in the medical care system, it is a major challenge for physicians to maintain the *humane* aspects of medical care. The American Board of Internal Medicine, working together with the American College of Physicians–American Society of Internal Medicine and the European Federation of Internal Medicine, has published a *Charter on Medical Professionalism* that underscores three main principles in physicians' contract with society: (1) the primacy of patient welfare, (2) patient autonomy, and (3) social justice. While medical schools appropriately place substantial emphasis on professionalism, a physician's personal attributes, including integrity, respect, and compassion, also are extremely important. In the United States, the Gold Humanism Society recognizes individuals who are exemplars of humanistic patient care and serve as role models for medical education and training.

Availability to the patient, expression of sincere concern, willingness to take the time to explain all aspects of the illness, and a nonjudgmental attitude when dealing with patients whose cultures, lifestyles, attitudes, and values differ from those of the physician are just a few of the characteristics of a humane physician. Every physician will, at times, be challenged by patients who evoke strongly negative or positive emotional responses. Physicians should be alert to their own reactions to such situations and should consciously monitor and control their behavior so that the patient's best interest remains the principal motivation for their actions at all times.

Another important aspect of patient care involves an appreciation of the patient's "quality of life," a subjective assessment of what each patient values most. This assessment requires detailed, sometimes intimate knowledge of the patient, which usually can be obtained only through deliberate, unhurried, and often repeated conversations. Time pressures will always threaten these interactions, but they should not diminish the importance of understanding and seeking to fulfill the priorities of the patient.

EXPANDING FRONTIERS IN MEDICAL PRACTICE

The Era of "Omics" In the spring of 2003, announcement of the complete sequencing of the human genome officially ushered in the genomic era. However, even before that landmark accomplishment, the practice of medicine had been evolving as a result of insights into both the human genome and the genomes of a wide variety of microbes. The clinical implications of these insights are illustrated by the complete genome sequencing of H1N1 influenza virus in 2009 and even faster sequencing of COVID-19 in early 2020, leading to the swift development and dissemination of effective vaccines. Today, gene expression profiles are being used to guide therapy and inform prognosis for a number of diseases, and genotyping is providing a new means to assess the risk of certain diseases as well as variations in response to a number of drugs. Despite these advances, the use of complex genomics in the diagnosis, prevention, and treatment of disease is still in its early stages. The task of physicians is complicated by the fact that phenotypes generally are determined not by genes alone but by the complex interactions among genes and gene products, and by the interplay of genetic and environmental factors.

Rapid progress is also being made in other areas of molecular medicine. *Epigenetics* is the study of alterations in chromatin and histone proteins and methylation of DNA sequences that influence gene expression **(Chap. 483)**. Every cell of the body has identical DNA sequences; the diverse phenotypes a person's cells manifest are, in part, the result of epigenetic regulation of gene expression. Epigenetic alterations are associated with a number of cancers and other diseases. *Proteomics*, the study of the entire library of proteins made in a cell or organ and the complex relationship of these proteins to disease, is enhancing the repertoire of the 23,000 genes in the human genome through alternate splicing, posttranslational processing, and posttranslational modifications that often have unique functional consequences. The presence or absence of particular proteins in the circulation or in cells is being explored for many diagnostic and disease-screening applications. *Microbiomics* is the study of the resident microbes in humans and other mammals, which together compose the microbiome. The human haploid genome has ~23,000 genes, whereas the microbes residing on and in the human body encompass more than 3–4 million genes; these resident microbes are likely to be of great significance with regard to health status. Ongoing research is demonstrating that the microbes inhabiting human mucosal and skin surfaces play a critical role in maturation of the immune system, in metabolic balance, in brain function, and in disease susceptibility. A variety of environmental factors, including the use and overuse of antibiotics, have been tied experimentally to substantial increases in disorders such as obesity, metabolic syndrome, atherosclerosis, and immune-mediated diseases in both adults and children. *Metagenomics*, of which microbiomics is a part, is the genomic study of environmental species that have the potential to influence human biology directly or indirectly. An example is the study of exposures to microorganisms in farm environments that may be responsible for the lower incidence of asthma among children raised on farms. *Metabolomics* is the study of the range of metabolites in cells or organs and the ways they are altered in disease states. The aging process itself may leave telltale metabolic footprints that allow the prediction (and possibly the prevention) of organ dysfunction and disease. It seems likely that disease-associated patterns will be found in lipids, carbohydrates, membranes, mitochondria and mitochondrial function, and other vital components of cells and tissues. *Exposomics* is the study of the exposome—i.e., the environmental exposures such as smoking, sunlight, diet, exercise, education, and violence that together have an enormous impact on health. All of this new information represents a challenge to the traditional reductionist approach to medical thinking. The variability of results in different patients, together with the large number of variables that can be assessed, creates challenges in identifying preclinical disease and defining disease states unequivocally. Accordingly, the tools of *systems biology* and *network medicine* are being applied to the enormous body of information ("big data") now obtainable for every patient and may eventually provide new approaches to classifying disease. **For a more complete discussion of a complex systems and network science approach to human disease, see Chap. 486.**

The rapidity of these advances may seem overwhelming to practicing physicians; however, physicians have an important role to play in ensuring that these powerful technologies and sources of new information are applied judiciously to patient care. Since omics are evolving so rapidly, physicians and other health care professionals must engage in continuous learning so that they can apply this new knowledge to the benefit of their patients' health and well-being. Genetic testing requires wise counsel based on an understanding of the value and limitations of the tests as well as the implications of their results for specific individuals. **For a more complete discussion of genetic testing, see Chap. 467.**

The Globalization of Medicine Physicians should be cognizant of diseases and health care services beyond local boundaries. Global travel has critical implications for disease spread, and it is not uncommon for diseases endemic to certain regions to be seen in other regions after a patient has traveled to and returned from those regions. The outbreak of Zika virus infections in the Americas is a cogent example of this phenomenon. In addition, factors such as wars, the migration of refugees, and increasing climate extremes are contributing to changing disease profiles worldwide. Patients have broader access to unique expertise or clinical trials at distant medical centers, even those in other countries, and the cost of travel may be offset by the quality of care at those distant locations. As much as any other factor influencing global aspects of medicine, the Internet has transformed the transfer of medical information throughout the world. This change has been accompanied by the transfer of technological skills through telemedicine and international consultation—for example, interpretation of radiologic images and pathologic specimens. **For a complete discussion of global issues, see Chap. 472.**

Medicine on the Internet On the whole, the Internet has had a positive effect on the practice of medicine; through personal computers, a wide range of information is available to physicians and patients

almost instantaneously at any time and from anywhere in the world. This medium holds enormous potential for the delivery of current information, practice guidelines, state-of-the-art conferences, journal content, textbooks (including this text), and direct communications with other physicians and specialists, expanding the depth and breadth of information available to the physician regarding the diagnosis and care of patients. Medical journals are now accessible online, providing rapid sources of new information. By bringing them into direct and timely contact with the latest developments in medical care, this medium also serves to lessen the information gap that has hampered physicians and health care providers in remote areas.

Patients, too, are turning to the Internet in increasing numbers to acquire information about their illnesses and therapies and to join Internet-based support groups. Patients often arrive at a clinic visit with sophisticated information about their illnesses. In this regard, physicians are challenged in a positive way to keep abreast of the latest relevant information while serving as an "editor" as patients navigate this seemingly endless source of information, the accuracy and validity of which are not uniform.

A critically important caveat is that virtually anything can be published on the Internet, with easy circumvention of the peer-review process that is an essential feature of academic publications. Both physicians and patients who search the Internet for medical information must be aware of this danger. Notwithstanding this limitation, appropriate use of the Internet is revolutionizing information access for physicians and patients, and in this regard represents a remarkable resource that was not available to practitioners a generation ago.

Public Expectations and Accountability The general public's level of knowledge and sophistication regarding health issues has grown rapidly over the past few decades. As a result, expectations of the health care system in general and of physicians in particular have risen. Physicians are expected to master rapidly advancing fields (the *science* of medicine) while considering their patients' unique needs (the *art* of medicine). Thus, physicians are held accountable not only for the technical aspects of the care they provide but also for their patients' satisfaction with the delivery and costs of care.

In many parts of the world, physicians increasingly are expected to account for the way in which they practice medicine by meeting certain standards prescribed by federal and local governments. The hospitalization of patients whose health care costs are reimbursed by the government and other third parties is subjected to utilization review. Thus, a physician must defend the cause for and duration of a patient's hospitalization if it falls outside certain "average" standards. Authorization for reimbursement increasingly is based on documentation of the nature and complexity of an illness, as reflected by recorded elements of the history and physical examination. A growing "pay-for-performance" movement seeks to link reimbursement to quality of care. The goal of this movement is to improve standards of health care and contain spiraling health care costs. In many parts of the United States, managed (capitated) care contracts with insurers have replaced traditional fee-for-service care, placing the onus of managing the cost of all care directly on the providers and increasing the emphasis on preventive strategies. In addition, physicians are expected to give evidence of their current competence through mandatory continuing education, patient record audits, maintenance of certification, and relicensing.

Medical Ethics and New Technologies The rapid pace of technological advances has profound implications for medical applications that go far beyond the traditional goals of disease prevention, treatment, and cure. Cloning, genetic engineering, gene therapy, human–computer interfaces, nanotechnology, and use of targeted therapies have the potential to modify inherited predispositions to disease, select desired characteristics in embryos, augment "normal" human performance, replace failing tissues, and substantially prolong life span. Given their unique training, physicians have a responsibility to help shape the debate on the appropriate uses of and limits placed on these new technologies and to consider carefully the ethical issues associated with the implementation of such interventions. As medicine becomes more complex, shared decision-making is increasingly important, not only in areas such as genetic counseling and end-of-life care, but also in diagnostic and treatment options.

Learning Medicine More than a century has passed since the publication of the Flexner Report, a seminal study that transformed medical education and emphasized the scientific foundations of medicine as well as the acquisition of clinical skills. In an era of burgeoning information and access to medical simulation and informatics, many schools are implementing new curricula that emphasize lifelong learning and the acquisition of competencies in teamwork, communication skills, system-based practice, and professionalism. The tools of medicine also change continuously, necessitating formal training in the use of EMRs, large datasets, ultrasound, robotics, and new imaging techniques. These and other features of the medical school curriculum provide the foundation for many of the themes highlighted in this chapter and are expected to allow physicians to progress, with experience and learning over time, from competency to proficiency to mastery.

At a time when the amount of information that must be mastered to practice medicine continues to expand, increasing pressures both within and outside of medicine have led to the implementation of restrictions on the amount of time a physician-in-training can spend in the hospital and in clinics. Because the benefits associated with continuity of medical care and observation of a patient's progress over time were thought to be outstripped by the stresses imposed on trainees by long hours and by fatigue-related errors, strict limits were set on the number of patients that trainees could be responsible for at one time, the number of new patients they could evaluate in a day on call, and the number of hours they could spend in the hospital. In 1980, residents in medicine worked in the hospital more than 90 hours per week on average. In 1989, their hours were restricted to no more than 80 per week. Resident physicians' hours further decreased by ~10% between 1996 and 2008, and in 2010, the Accreditation Council for Graduate Medical Education further restricted (i.e., to 16 hours per shift) consecutive in-hospital duty hours for first-year residents. The impact of these changes is still being assessed, but the evidence that medical errors have decreased as a consequence is sparse. An unavoidable by-product of fewer hours at the bedside is an increase in the number of "handoffs" of patient responsibility from one physician to another. These transfers often involve a transition from a physician who knows the patient well, having evaluated that individual on admission, to a physician who knows the patient less well. It is imperative that these transitions of responsibility be handled with care and thoroughness, with all relevant information exchanged and acknowledged. These issues highlight the challenge our profession has in establishing a reliable measure of physician effectiveness.

The Physician as Perpetual Student From the time physicians graduate from medical school, it becomes all too apparent that this milestone is symbolic and that they must embrace the role of a "perpetual student." This realization is at the same time exhilarating and anxiety-provoking. It is exhilarating because physicians can apply constantly expanding knowledge to the treatment of their patients; it is anxiety-provoking because physicians realize that they will never know as much as they want or need to know. Ideally, physicians will translate the latter feeling into energy through which they can continue to improve and reach their potential. It is the physician's responsibility to pursue new knowledge continually by reading, attending conferences and courses, and consulting colleagues and the Internet. This is often a difficult task for a busy practitioner; however, a commitment to continued learning is an integral part of being a physician and must be given the highest priority.

The Physician as Citizen Being a physician is a privilege. The capacity to apply one's skills for the benefit of fellow human beings is a noble calling. The physician–patient relationship is inherently unbalanced in the distribution of power. In light of their influence, physicians must always be aware of the potential impact of what they do and say, and must always strive to strip away individual biases and preferences to find what is best for their patients. To the extent possible, physicians should also act within their communities to promote health

and alleviate suffering. Meeting these goals begins by setting a healthy example and continues in taking action to deliver needed care even when personal financial compensation may not be available.

Research, Teaching, and the Practice of Medicine The word *doctor* is derived from the Latin *docere*, "to teach." As teachers, physicians should share information and medical knowledge with colleagues, students of medicine and related professions, and their patients. The practice of medicine is dependent on the sum total of medical knowledge, which in turn is based on an unending chain of scientific discovery, clinical observation, analysis, and interpretation. Advances in medicine depend on the acquisition of new information through research, and improved medical care requires the transmission of that information. As part of their broader societal responsibilities, physicians should encourage patients to participate in ethical and properly approved clinical investigations if these studies do not impose undue hazard, discomfort, or inconvenience. Physicians engaged in clinical research must be alert to potential conflicts of interest between their research goals and their obligations to individual patients. The best interests of the patient must always take priority.

To wrest from nature the secrets which have perplexed philosophers in all ages, to track to their sources the causes of disease, to correlate the vast stores of knowledge, that they may be quickly available for the prevention and cure of disease—these are our ambitions.

—William Osler, 1849–1919

2 Promoting Good Health

Donald M. Lloyd-Jones, Kathleen M. McKibbin

GOALS AND APPROACHES TO PREVENTION

Prevention of acute and chronic diseases before their onset has been recognized as one of the hallmarks of excellent medical practice for centuries and is now used as a metric for highly functioning health care systems. The ultimate goal of preventive strategies is to avoid premature death. However, as longevity has increased dramatically worldwide over the last century (largely as a result of public health practices), increasing emphasis is placed on prevention for the purpose of preserving quality of life and extending the health span, not just the life span. Given that all patients will eventually die, the goal of prevention ultimately becomes compression of morbidity toward the end of the life span; that is, reduction of the amount of burden and time spent with disease prior to dying. As shown in **Fig. 2-1**, normative aging tends to involve a steady decline in the stock of health, with accelerating decline over time. Successful prevention offers the opportunity both to extend life and to extend healthy life, thus "squaring the curve" of health loss during aging.

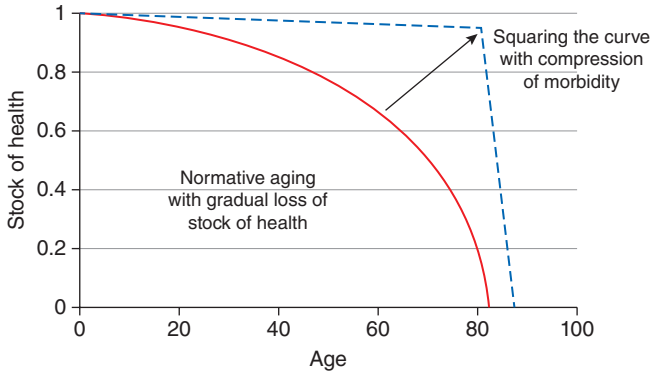

FIGURE 2-1 Loss of health with aging. Representation of normative aging with loss of the full stock of health with which individuals are born (indicating gain of morbidity), contrasted with a squared curve with greater longevity and fuller stock of health (less morbidity) until shortly before death. The "squared curve" represents the likely ideal situation for most patients.

Prevention strategies have been characterized as tertiary, secondary, primary, and primordial. *Tertiary prevention* requires rapid action to prevent imminent death in the setting of acute illness, such as through percutaneous coronary intervention in the setting of ST-segment elevation myocardial infarction. *Secondary prevention* strategies focus on avoiding the recurrence of disease and death in an individual who is already affected. For example, tamoxifen is recommended for women with surgically treated early-stage, estrogen receptor–positive breast cancer, because it reduces the risk of recurrent breast cancer (including in the contralateral breast) and death. *Primary prevention* attempts to reduce the risk of incident disease among individuals with one or more risk factors. Treatment of elevated blood pressure in individuals who have not yet experienced cardiovascular disease represents one example of primary prevention that has proven effective in reducing the incidence of stroke, heart failure, and coronary heart disease.

Primordial prevention is a more recent concept (first introduced in 1979) that focuses on prevention of the development of *risk factors* for disease, not just prevention of disease. Primordial prevention strategies emphasize upstream determinants of risk for chronic diseases, such as eating patterns, physical activity, and environmental and social determinants of health. It therefore encompasses medical treatment strategies for some individuals as well as a strong reliance on public health and social policy. It is increasingly clear that primordial prevention represents the ultimate means for reducing the burden of chronic diseases of aging. Once risk factors develop, it is difficult to restore risk to the low level of someone who never developed the risk factor. The time spent with adverse levels of the risk factor often causes irreversible damage that precludes complete restoration of low risk. For example, individuals with hypertension who are treated back to optimal levels (<120/<80 mmHg) do have a lower risk compared with untreated patients with hypertension, but they still have twice the risk of cardiovascular events as those who maintained optimal blood pressure without medications. Patients with elevated blood pressure that is subsequently treated have greater left ventricular mass index, worse renal function, and more evidence of atherosclerosis and other target organ damage as a result of the time spent with elevated blood pressure; such damage cannot be fully reversed despite efficacious therapy with antihypertensive medications. Conversely, as described below in greater detail, individuals who maintain optimal levels of all major

cardiovascular risk factors into middle age through primordial prevention essentially abolish their lifetime risk of developing cardiovascular disease while also living substantially longer and having a lower burden and later onset of other comorbid illnesses (compression of morbidity).

Prevention strategies should be distinguished from disease screening strategies. Screening attempts to detect evidence of disease at its earliest stages, when treatment is likely to be more efficacious than for advanced disease **(Chap. 6)**. Screening can be performed in service of prevention, especially if it aids in identifying preclinical markers, such as dyslipidemia or hyperglycemia, associated with elevated disease risk.

HEALTH PROMOTION

In recent decades, medical practice has increasingly focused on clinical and public health approaches to promote health, and not just prevent disease. Prevention of disease is a worthy individual and societal goal in and of itself, but it does not necessarily guarantee health. Health is a broader construct encompassing more than just absence of disease. It includes biologic, physiologic, and psychological domains (among others) in a continuum, rather than occurring as a dichotomous trait. Health is therefore somewhat subjective, but attempts have been made to use more objective criteria to define health in order to raise awareness, prevent disease, and promote healthy longevity.

For example, in 2010, the American Heart Association (AHA) defined a new construct of "cardiovascular health" based on evidence of associations with longevity, disease avoidance, healthy longevity, and quality of life. The definition of cardiovascular health is based on seven health behaviors and health factors (eating pattern, physical activity, smoking status, body mass index [BMI], and levels of blood pressure, blood cholesterol, and blood glucose) and includes a spectrum from poor to ideal. Individuals with optimal levels of all seven metrics simultaneously are considered to have ideal cardiovascular health. The state of cardiovascular health for an individual or a population can be assessed with simple scoring by counting the number of ideal metrics (out of seven) or applying 0 points for each poor metric, 1 point for each intermediate metric, and 2 points for each ideal metric, thus creating a composite cardiovascular health score ranging from 0 to 14 points. Higher cardiovascular health scores in younger and middle ages have been associated with greater longevity, lower incidence of cardiovascular disease, lower incidence of other chronic diseases of aging (including dementia, cancer, and more), compression of morbidity, greater quality of life, and lower health care costs, achieving both individual and societal goals for healthy aging and further establishing the critical importance of primordial prevention and cardiovascular health promotion.

Focusing on health promotion, rather than just disease prevention, may also provide greater motivation for patients to pursue lifestyle changes or adhere to clinician recommendations. Extensive literature suggests that providing patients solely with information regarding disease risk, or risk reduction with treatment, is unlikely to motivate desired behavior change. Empowering patients with strategies to achieve positive health goals after discussing risks can provide more effective adherence and better long-term outcomes. In the case of smoking cessation, enumerating only the risks of smoking can lead to patient inertia and therapeutic nihilism and has proven to be an ineffective approach, whereas strategies that incorporate positive health messaging, support, and feedback, with appropriate use of evidence-based therapies, have proven far more effective.

PRIORITIZING PREVENTION STRATEGIES

In secondary prevention, the patient already has manifest clinical disease and is therefore at high risk for progression. The approach should be to work with the patient to implement all evidence-based strategies that will help to prevent recurrence or progression. This will typically include drug therapy as well as therapeutic lifestyle changes to control ongoing risk factors that may have caused disease in the first place. Juggling priorities can be difficult, and barriers to implementation are many, including costs, time, patient health literacy, and patient and caregiver capacity to organize the regimen. Addressing these potential barriers with the patient can help to forge a therapeutic bond and may improve adherence; ignoring them will likely lead to therapeutic failure. Numerous studies demonstrate that, even in high-functioning health systems, only ~50% of patients are taking recommended, evidence-based secondary prevention medications, such as statins, by 1 year after a myocardial infarction.

In patients who are eligible for primary prevention strategies, it is important to frame the discussion around the overall evidence base as well as an individual patient's likelihood of benefit from a given preventive intervention. A first step is to understand the patient's estimated absolute risk for disease in the foreseeable future or during their remaining life span. However, absolute risk estimation and presentation of those risks are generally insufficient to motivate behavior change. It is critical to assess the patient's understanding and tolerance of the risk, their readiness to implement lifestyle changes or adhere to drug therapy, and their overall preferences regarding use of drug therapy to prevent an event (e.g., cancer, myocardial infarction, stroke). The clinician can help the patient by informing them of the risks for disease and potential for absolute benefits (and harms) from the available evidence-based choices. This may take more than one conversation, but given that diseases, such as cancer and cardiovascular disease, are the leading causes of premature death and disability, the time is well spent.

Partnering with the patient through motivational interviewing may assist in the process of selecting initial approaches to prevention. Selecting an area that the patient feels they are ready to change can lead to better adherence and greater achievement of success in the short and longer term. If the patient is uncertain what course to choose, prudence would dictate focusing on control of risk factors that may lead to the most rapid reduction in risk for acute events. For example, blood pressure is both a chronic risk factor and an acute trigger for cardiovascular events. Thus, if a patient has both significant elevations in blood pressure and dyslipidemia, it would be appropriate to focus initial efforts on blood pressure control. Likewise, a focus on smoking cessation can lead to more rapid reductions in risk for acute events than some other lifestyle interventions.

PREVENTION AND HEALTH PROMOTION ACROSS THE LIFE COURSE

Periodic Health Evaluations The "routine annual physical" has in many ways become an expected part of the patient-physician relationship in primary care practice. However, evidence for the efficacy of the periodic health evaluation in asymptomatic adults unselected for risk factors or disease is mixed and depends on the outcome. Systematic reviews and meta-analyses of published trials have consistently observed lack of benefit (and also lack of harm) in terms of total mortality in association with periodic health evaluations. Data are more heterogeneous but overall suggest no benefit for cancer- or cardiovascular-specific mortality, with the potential for either benefit or harm depending on number of evaluations and patient-level factors. Well-designed studies on nonfatal clinical events and morbidity have been sparsely reported, but there appear to be no large effects.

Periodic health evaluations do appear to lead to greater diagnosis of certain conditions such as hypertension and dyslipidemia, as expected. Likewise, periodic health examinations also improve the delivery of recommended preventive services, such as gynecologic examinations and Papanicolaou smears, fecal occult blood testing, and cholesterol screening. The benefits and risks associated with screening tests are discussed in detail in **Chap. 6**. Risks of routine evaluations include inappropriate testing or overtesting or false-positive findings that require follow-up and induce patients to worry. Periodic health examinations appear to be associated with less patient worry. On balance, given the lack of convincing evidence of harm and the potential for better delivery of appropriate screening, counseling, and preventive services, periodic health evaluations appear reasonable for general populations at average risk for chronic conditions.

It is important to note that routine annual comprehensive physical examinations of asymptomatic adult patients have very low yield and may take an inordinate amount of time in a wellness visit. Such time

TABLE 2-1 Guidelines and Key Recommendations from the *Dietary Guidelines for Americans*, 2020–2025

GUIDELINES	KEY RECOMMENDATIONS
1. Follow a healthy dietary pattern at every life stage. For the first 6 months of life, infants should exclusively be fed human milk, or iron-fortified formula if human milk is unavailable. From 6 to 12 months, infants should be introduced to a variety of complementary nutrient-dense foods. From 12 months to older adulthood, the dietary pattern should meet nutrient needs, help achieve a healthy body weight, and reduce the risk of chronic disease. **2. Customize and enjoy nutrient-dense food and beverage choices to reflect personal preferences, cultural traditions, and budgetary considerations.** The Dietary Guidelines provide a framework of several dietary patterns intended to be customized to individual needs and preferences, as well as the foodways of the diverse cultures in the United States. **3. Focus on meeting food group needs with nutrient-dense foods and beverages, and stay within calorie limits.** Nutrient-dense foods provide vitamins, minerals, and other health-promoting components and have no or little added sugars, saturated fat, and sodium. A healthy dietary pattern consists of nutrient-dense forms of foods and beverages across all food groups, in recommended amounts, and within calorie limits. **4. Limit foods and beverages higher in added sugars, saturated fat, and sodium, and limit alcoholic beverages.** At every life stage, meeting food group recommendations, even with nutrient-dense choices, fulfills most of a person's daily calorie needs and sodium limits, with little room for extra added sugars, saturated fat, or sodium, or for alcoholic beverages.	**The Dietary Guidelines' Key Recommendations for healthy eating patterns should be applied in their entirety, given the interconnected relationship that each dietary component can have with others. They are also intended as a framework to accommodate personal preferences, cultural traditions, and budgetary considerations.** **Focus on meeting food group needs with nutrient-dense foods and beverages, and stay within calorie limits to achieve a healthy weight and reduce the risk of chronic disease.** **The core elements that make up a healthy dietary pattern include:** • Vegetables of all types—dark green; red and orange; beans, peas, and lentils; starchy; and other vegetables • Fruits, especially whole fruit • Grains, at least half of which are whole grain • Dairy, including fat-free or low-fat milk, yogurt, and cheese, and/or lactose-free versions and fortified soy beverages and yogurt as alternatives • Protein foods, including lean meats, poultry, and eggs; seafood; beans, peas, and lentils; and nuts, seeds, and soy products • Oils, including vegetable oils and oils in food, such as seafood and nuts **A healthy eating pattern limits:** • Added sugars—Less than 10% of calories per day starting at age 2. Avoid foods and beverages with added sugars for those younger than age 2. • Saturated fat—Less than 10% of calories per day starting at age 2. • Sodium—Less than 2300 mg per day—and even less for children younger than age 14. • Alcoholic beverages—Adults of legal drinking age can choose not to drink or to drink in moderation by limiting intake to 2 drinks or less in a day for men and 1 drink or less in a day for women, when alcohol is consumed. Drinking less is better for health than drinking more. There are some adults who should not drink alcohol, such as women who are pregnant. **Meet the U.S. Department of Health and Human Services' *Physical Activity Guidelines for Americans*** In tandem with the recommendations above, Americans of all ages—children, adolescents, adults, and older adults—should meet the *Physical Activity Guidelines for Americans* to help promote health and reduce the risk of chronic disease. Americans should aim to achieve and maintain a healthy body weight. The relationship between diet and physical activity contributes to calorie balance and managing body weight.

Source: Adapted from the *Dietary Guidelines for Americans, 2020-2025.* Washington, DC: U.S. Department of Agriculture and U.S. Department of Health and Human Services; 2020. Available at *https://www.dietaryguidelines.gov/sites/default/files/2020-12/Dietary_Guidelines_for_Americans_2020-2025.pdf.*

may be better spent on assessing and counseling the patient on other aspects of their health, as discussed below. Evidence-based components that should be included in periodic evaluations focused on health and prevention include a number of age-appropriate screening tests for chronic disease and risk factors, preventive interventions including immunizations and chemoprevention for at-risk individuals, and preventive counseling. The U.S. Preventive Services Task Force publishes its *Guide to Clinical Preventive Services,* which contains evidence-based recommendations from the Task Force on preventive services for which there is a high degree of certainty that the service provides at least moderate net clinical benefit (i.e., benefits outweigh harms significantly and to a reasonable magnitude).

Healthy Behaviors and Lifestyles Owing to the paucity of evidence, the heterogeneity of study designs, and the diverse nature of interventions studied, many clinicians are uncertain as to how to deliver advice regarding healthy behaviors and lifestyles. Nevertheless, adverse behaviors and lifestyles contribute to >75% of premature, preventable deaths and disability. Estimates from the U.S. National Health and Nutrition Examination Survey indicate that fewer than 1% of Americans achieve an optimal heart-healthy eating pattern. Thus, whereas there are many demands on time during a typical patient-clinician encounter, few things may have more impact on longevity, health, and quality of life for asymptomatic patients than an efficient approach to assessing, documenting, and improving patients' health behaviors. Indeed, the mere act of assessing health behaviors has been shown to affect patients' health behaviors. Facility with tools for assessment of lifestyle and with strategies for counseling are therefore of paramount importance.

Healthy Eating Patterns (see Chap. 332) Despite the existence of numerous "fad" diets and seemingly inconsistent recommendations on dietary composition, there is remarkable agreement about what should constitute a healthy eating pattern for the broad population to avoid nutritional deficits (i.e., vitamin deficiency) and excesses (i.e., excessive caloric intake) and to maximize potential health (Table 2-1). Optimal eating patterns consist of whole fruits and vegetables, whole grains, lean proteins, and healthy oils, and allow for nonfat or low-fat dairy intake. They tend to exclude frequent ingestion of foods high in refined sugars and starches, saturated fat, and sodium. Since sodium and refined sugars and starches are the hallmark of much of the processed/packaged food supply, a simple rule of thumb is to provide or cook the majority of one's own meals starting from whole foods and emphasizing fruits and vegetables. Likewise, foods prepared outside of the home tend to have higher fat and sodium content, so special attention to menu choices focused on fruits, vegetables, lean proteins, and whole grains, while minimizing sauces and dressings, can help most individuals follow healthier eating patterns when eating food prepared outside the home. In all cases, sugar-sweetened beverages and nonnutritious snack foods should be minimized. If snacks are included, small amounts of healthy nuts and seeds or more fruits and vegetables should be encouraged.

Specific conditions and diseases, such as diabetes, other metabolic disorders, allergies, and gastrointestinal disorders, may require tailored approaches to diet. In counseling most patients, the general approach should focus on whole foods, eating patterns, and appropriate calorie balance, rather than on specific micronutrients such as electrolytes or selected vitamins. It should be remembered that most patients have difficulty understanding nutritional labels on packaged foods, with the attendant demands on numeracy and health literacy.

Dietary guidelines are published by the U.S. Department of Agriculture (USDA) and U.S. Department of Health and Human Services every 5 years, and these guidelines have undergone substantial

evolution over time. The current U.S. Dietary Guidelines and Key Recommendations for 2020–2025 are summarized in Table 2-1 and emphasize the importance of healthy eating patterns for every stage of life, to avoid chronic diseases including obesity, diabetes, cancer, and cardiovascular disease. The core elements include eating patterns with nutrient-dense (rather than calorie-dense) whole foods and appropriate caloric intake to achieve and maintain healthy weight. The USDA guidelines focus on the concept of a healthy plate (rather than the prior food pyramid) for ease of counseling and adoption. Fifty percent of the plate should consist of vegetables and whole fruits, with remaining portions for whole grains and lean protein foods. When using fat for cooking, it should be done by sauteing in healthier oils (e.g., canola oil), and addition of judicious amounts of healthy raw oils (e.g., olive oil, nuts) to dishes is appropriate. Recommendations also focus on limitation of foods and beverages higher in added sugars, saturated fat, and sodium, and moderation or avoidance of alcohol intake.

The USDA guidelines focus on specific healthy eating patterns that adhere to these broad recommendations and are appropriate for ~97% of the general population. They identify a "Healthy U.S.-Style Dietary Pattern" that adheres closely to the evidence-based Dietary Approaches to Stop Hypertension (DASH) eating pattern but is customizable for different cultural or personal preferences. Alternative patterns, which vary more in emphasis than in content, include a "Healthy Mediterranean-Style Dietary Pattern" and a "Healthy Vegetarian Dietary Pattern."

AGE- AND SEX-SPECIFIC RECOMMENDATIONS Current dietary framework recommendations are generally similar for all life stages from ages ≥12 months, but recommended levels of caloric intake (and hence amounts of foods) differ by age, sex, and physical activity level. For example, recommended caloric intake ranges from 1000 calories/d for sedentary 2-year-old children to as high as 3200 calories/d for active 16- to 18-year-old young men. Recommended caloric intakes peak in late adolescence or early adulthood for men and women and gradually decrease over ensuing decades.

As with all lifestyle counseling aimed at behavior change, dietary approaches that partner with the patient and utilize motivational interviewing strategies and shared goals and commitments tend to work best, as described below (see "Approach to the Patient").

Physical Activity Similar to the approach to counseling regarding healthy eating patterns, recommendations on participation in physical activity emphasize the point that any physical activity is better than none. A simple rule of thumb for patients is: "If you are doing nothing, do something; and if you are doing something, do more, every day." The evidence base for physical activity indicates that the marginal benefits from physical activity are greatest in advancing from no activity to low levels of moderate activity. With increasing duration and intensity of activity, there is a continued curvilinear increase in health benefits, but the marginal gains for each additional minute of moderate-to-vigorous activity slowly diminish. Thus, for adults, the recommended amount of physical activity is 150 min of moderate-intensity or 75 min of vigorous-intensity aerobic activity per week, performed in episodes of at least 5 min, and preferably spread throughout the week, plus participation in muscle-strengthening activity at least 2 days per week. Additional health benefits can be realized by engaging in physical activity beyond this amount.

In counseling patients regarding physical activity, it is important to note that sedentary time (e.g., seated at work or at home in front of electronic screens) has adverse health consequences independent of the lack of physical activity during these episodes. Therefore, even modest efforts like standing at the desk and doing gentle stretching for periods during the day may be beneficial. It is also important to emphasize that participating in a variety of aerobic activities (biking, swimming, walking, jogging, rowing, elliptical training, stair-climbing, etc.) can be beneficial and may help to avoid overuse injuries and boredom with the exercise regimen. If patients choose to participate in muscle-strengthening activities for health improvement, emphasis should be placed on weights that allow more repetitions (e.g., 3 sets of 15–20 repetitions that can be performed comfortably, with a rest period in between) and on avoiding breath-holding and straining against a closed glottis.

SUDDEN CARDIAC DEATH RISK Patients may express concerns regarding the risk of sudden cardiac death during exercise. Whereas the risk of sudden death during exercise does increase directly with the amount of time spent exercising, this association is substantially mitigated by training effects. Thus, patients embarking on an exercise program should be encouraged to increase the duration of aerobic exercise gradually as tolerated, aiming for episodes of at least 30 min 5 times a week as an ideal. Once a comfortable duration is reached, incorporating interval training periods of more intensive activity interspersed during the exercise can provide greater fitness gains.

EXTREME ENDURANCE ACTIVITIES As with other forms of exercise, extreme endurance activities such as triathlons and marathons should be undertaken only with appropriate and graded training. Such activities tend to take a greater toll on the musculoskeletal system over time than less extreme activities, and they are also associated with measurable damage to the myocardium and greater risks for other organ damage. Athletes participating in endurance activities routinely have elevations in cardiac troponin (a specific circulating marker of myocardial cell damage and death) at the end of the race, although elevations are lower in those who are well trained. Patients and clinicians should consider the patient's overall health, specific limitations, potential for injury, and ability to train in decision-making regarding participation in endurance events.

AGE-SPECIFIC RECOMMENDATIONS The U.S. Department of Health and Human Services' *Physical Activity Guidelines for Americans*, second edition (2018) **(Table 2-2)**, recommend that preschool-aged children (aged 3–5 years) should be physically active throughout the day in a variety of activity types to enhance growth and development. Children and adolescents aged 6–17 years should participate in ≥60 min of physical activity daily, most of which should be moderate- or vigorous-intensity aerobic activity, including vigorous, muscle-strengthening, and bone-strengthening activities at least 3 days a week each. As noted above, adults aged 18–64 years are recommended to pursue at least 150 min of moderate-intensity or 75 min of vigorous-intensity aerobic activity per week (or equivalent combinations), with at least 2 days of muscle-strengthening activities. Adults aged ≥65 years should follow the adult guidelines or be as active as possible as abilities and conditions allow. For older adults, special emphasis is also placed on multicomponent physical activity that includes balance training as well as aerobic and muscle-strengthening activities.

Sleep Hygiene Sleeping between 7 and 9 h per night appears to be optimal for health in adults aged ≥18 years. Sleeping <7 h is associated with adverse outcomes, including obesity, diabetes, elevated blood pressure, cardiovascular disease, depression, and all-cause mortality, as well as physiologic disturbances such as impaired immune function, increased pain sensitivity, and impaired cognitive performance. Conversely, achieving appropriate levels of sleep is associated with more success in weight loss, better blood pressure control among patients with hypertension, and improved mental health and performance. Regular sleep more than 9 h per night is appropriate for children and adolescents or individuals recovering from sleep deprivation or illness, but for most individuals, the effects on health are uncertain.

Patients often express concerns about the quantity and quality of their sleep. With aging, both aspects of sleep tend to decline, even without overt sleep disorders. Documentation of sleep using a sleep log may assist in understanding different types of insomnia and sleep disorders. Encouraging daily activity to promote fatigue, avoidance of eating and drinking alcohol too close to bedtime, and regular daily sleep habits may help patients achieve better sleep. Regular use of sedative medications should generally be discouraged given the high potential for dependence, addiction, and altered sleep quality.

DISORDERS OF SLEEP The prevalence of sleep-related breathing disorders, including obstructive sleep apnea (OSA), is poorly documented. A recent systematic review suggested that that the prevalence of clinically important OSA in the general adult population may be between 9% and 38%, with higher rates in men versus women, older versus younger adults, and those with higher versus lower BMI.

TABLE 2-2 Recommendations from *Physical Activity Guidelines for Americans*

AGE	RECOMMENDATIONS
3–5 years	• Preschool-aged children (ages 3 through 5 years) should be physically active throughout the day to enhance growth and development. • Adult caregivers of preschool-aged children should encourage active play that includes a variety of activity types.

6–17 years	• It is important to provide young people opportunities and encouragement to participate in physical activities that are appropriate for their age, that are enjoyable, and that offer variety.
	• Children and adolescents ages 6 through 17 years should do 60 min (1 h) or more of moderate-to-vigorous physical activity daily:
	  • Aerobic: Most of the 60 min or more per day should be either moderate- or vigorous-intensity aerobic physical activity and should include vigorous-intensity physical activity on at least 3 days a week.
	  • Muscle-strengthening: As part of their 60 min or more of daily physical activity, children and adolescents should include muscle-strengthening physical activity on at least 3 days a week.
	  • Bone-strengthening: As part of their 60 min or more of daily physical activity, children and adolescents should include bone-strengthening physical activity on at least 3 days a week.

18–64 years	• Adults should move more and sit less throughout the day. Some physical activity is better than none. Adults who sit less and do any amount of moderate-to-vigorous physical activity gain some health benefits. • For substantial health benefits, adults should do at least 150 min (2 h and 30 min) to 300 min (5 hours) a week of moderate-intensity or 75 min (1 h and 15 min) to 150 min (2 h and 30 min) a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. Preferably, aerobic activity should be spread throughout the week. • Additional health benefits are gained by engaging in physical activity beyond the equivalent of 300 min (5 h) of moderate-intensity physical activity a week. • Adults should also do muscle-strengthening activities of moderate or greater intensity and that involve all major muscle groups on 2 or more days a week, as these activities provide additional health benefits.

≥65 years	• The key guidelines for adults also apply to older adults. In addition, the following key guidelines are just for older adults:
	  • As part of their weekly physical activity, older adults should do multicomponent physical activity that includes balance training as well as aerobic and muscle-strengthening activities.
	  • Older adults should determine their level of effort for physical activity relative to their level of fitness.
	  • Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely.
	  • When older adults cannot do 150 min of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.

Moderate-intensity physical activity: Aerobic activity that increases a person's heart rate and breathing to some extent. On a scale relative to a person's capacity, moderate-intensity activity is usually a 5 or 6 on a 0 to 10 scale. Brisk walking, dancing, swimming, or bicycling on a level terrain are examples. Vigorous-intensity physical activity: Aerobic activity that greatly increases a person's heart rate and breathing. On a scale relative to a person's capacity, vigorous-intensity activity is usually a 7 or 8 on a 0 to 10 scale. Jogging, singles tennis, swimming continuous laps, or bicycling uphill are examples. Muscle-strengthening activity: Physical activity, including exercise that increases skeletal muscle strength, power, endurance, and mass. It includes strength training, resistance training, and muscular strength and endurance exercises. Bone-strengthening activity: Physical activity that produces an impact or tension force on bones, which promotes bone growth and strength. Running, jumping rope, and lifting weights are examples.

Source: Adapted from U.S. Department of Health and Human Services. *Physical Activity Guidelines for Americans, 2nd edition.* Washington, DC: U.S. Department of Health and Human Services; 2018. Available at *https://health.gov/sites/default/files/2019-09/Physical_Activity_Guidelines_2nd_edition.pdf.*

Patients with persistent complaints of poor sleep quality or excessive daytime somnolence or with witnessed apneic spells may benefit from screening for sleep disorders, prior to consideration of a formal sleep study. A number of clinical tools have been developed to screen for sleep apnea, including the Epworth Sleepiness Scale, the STOP (*s*noring, *t*iredness, *o*bserved apnea, high blood *p*ressure) Questionnaire, and the STOP-Bang Questionnaire (STOP plus assessment of BMI, age, neck circumference, and gender), among others. The U.S. Preventive Services Task Force found that current evidence is insufficient to assess the balance of benefits and harms of screening for OSA in asymptomatic adults owing to a lack of validation data in primary care settings. Nonetheless, the high prevalence and significant health consequences of sleep apnea suggest that clinicians should be alert for its potential presence, particularly in patients who are obese with symptoms of excessive daytime somnolence or witnessed apnea episodes. Other sleep disorders, such as restless leg syndrome, may be identified with simple history.

Weight Management Overweight and obesity are prevalent in epidemic proportions in the United States and other industrialized nations **(Chaps. 401 and 402)**. Since 1985, the prevalence of obesity in the United States has increased from ~10 to ~35%, and the prevalence of overweight is now ~40%. Overweight and obesity disproportionately affect individuals in lower socioeconomic strata and in many underserved minority populations, including black Americans, Latino Americans, and American Indians. In all race/ethnic groups, both overweight and obesity are associated with adverse health consequences, including diabetes, certain cancers, cardiovascular diseases, and degenerative joint disease. Eating disorders such as anorexia and bulimia are much less common but pose major health consequences for affected patients and should be suspected particularly in younger women with history of rapid weight shifts or underweight status.

Weight loss is one of the most difficult preventive interventions to achieve and sustain over time. However, several key factors can assist the patient and clinician, and early referral to a dietician can be very helpful. The first therapeutic goal is to aim for weight stabilization. Many of the risks of overweight and obesity are driven more strongly by continued weight gain, rather than overweight/obese status per se. Working with the patient to find initial strategies for weight maintenance can be a successful initial step with success for many patients. For those who can progress to considering weight loss, it is critical to help the patient understand that there is no standard solution. Experimentation and documentation are key. Tools to assist patients can include food and weight logs, activity logs, and smart phone apps. Some patients respond best to structured approaches such as intermittent fasting regimens or commercial dietary programs where meals are provided. Any of these approaches can be tried with or without social group supports.

The key construct for weight loss is, of course, negative calorie balance. This is achieved through a combination of reduced caloric intake and increased physical activity. Patients may already understand, from prior weight loss attempts, what combination works best for them to achieve this. Some patients find that they cannot lose weight without increasing their exercise. For many, reduction of caloric intake is most efficient. Encouraging the patient to find what works for them is most important. The same principle holds for dietary content. Well-done feeding studies indicate that weight loss is dependent far more on the reduction of caloric intake than on the relative composition of fat, protein, and carbohydrate in the diet. There may be other medical reasons

to choose one approach over another, but if not, encouraging the patient to pick one approach and document the results is an important start. Once weight loss is achieved, increase in activity is often required for its successful maintenance.

Tobacco Cessation **(see Chap. 454)** Escaping nicotine dependence is another major, but critical, challenge to prevention and wellness efforts. The addictive effects of nicotine have been well documented, with effects that can last for years after successful cessation. Assessing a patient's past history of cessation attempts and current readiness for change are key first steps in forging a successful approach. Frequent follow-up and reinforcement, as well as use of nicotine replacement therapy and other cessation-promoting medications, are additional critical elements. Recidivism is the rule, and patients should expect to resume smoking and attempt again as they journey to tobacco cessation. Electronic cigarettes have some evidence for benefit in adult smoking cessation, but their potential for use by adolescents and young adults who are not smokers represents a major public health threat for a new generation of nicotine addiction, with unknown health consequences as a result of the high doses of nicotine delivered to developing organs, including the brain. Vaping of other substances, often in association with flavoring compounds, has also been associated with pulmonary and cardiovascular damage and should be actively discouraged.

VACCINATION (CHAP. 123)

One of the major advances in public health that has contributed to increases in health and longevity worldwide is the development of safe and effective vaccinations against endemic and epidemic infectious diseases. Patients should be counseled regarding age-appropriate vaccinations for their children and for themselves. Some individuals may be reluctant to receive a vaccination; in these cases, listening to the patient's concerns is important, followed by explanation of the benefits to the individual, their family, and their community and review of the low risk for potential harms. It is true to say that no current vaccines are ever worse than the disease they prevent, although side effects may occur rarely. Thorough knowledge of the data on side effect rates and of efficacy will aid the clinician in helping the patient make a fully informed decision.

MENTAL HEALTH AND ADDICTION

Assessment for depression and cognitive impairment is important to address when patients exhibit symptoms or they or their family members express concerns. Both of these common conditions play a major role in reducing quality of life and are high on patients' lists of concerns, even if not clearly expressed. Screening tools for depression are reviewed in **Chap. 452**. Cognitive function decline with aging or comorbid illness, including depression, should be anticipated. Assessment tools such as the General Practitioner Assessment of Cognition or the Mini-Cog™ test are widely available and effective rapid assessment tools.

Alcohol and Opioids **(see Chaps. 453 and 456)** Alcohol dependence and abuse are common and underdiagnosed. Rapid screening tools have proven efficacy for identifying patients with alcohol problems. In a systematic review, the CAGE (*c*ut down, *a*nnoyed, guilty, *e*ye opener) questionnaire was most effective at identifying alcohol abuse and dependence, with reasonable sensitivity and high specificity. The present opioid epidemic in the United States presents a new and substantial public health challenge given the high potential for dependency and abuse of these drugs. Rapid screening tools are available to assist clinicians in screening for opioid dependence.

ACCIDENTS AND SUICIDE

Regular assessment of patient safety through simple questions about seat belt use, domestic violence, and gun safety in the home continues to be an important part of health promotion and wellness. Longstanding recommendations for assessment of suicidal ideation among patients with depression or a history of suicide attempts also continue to be relevant.

APPROACH TO THE PATIENT

In the context of a clinical visit focused on health assessment, health promotion, and prevention, the basic skills of history-taking are of paramount importance. Much of the evaluation, counseling, and management that focus on health promotion and prevention also require engagement and buy-in from the patient in order to assist with recognition of contributing behaviors and to promote adherence to therapeutic plans. Therefore, in addition to standard history-taking, additional skills such as motivational interviewing and eliciting patient commitments and contracting may prove of significant value. The availability of additional tools to assist with screening, monitoring, and chronic management, both online and through wearable devices and mobile health technologies, is rapidly expanding, with uncertain implications for the future. Major research gaps exist in our understanding of how best to employ these newer technologies to improve health outcomes. Concepts of behavioral economics are being explored to better understand the psychology of decision-making and incentives as a means to improve lifestyle choices and adherence to treatment plans **(Chap. 481)**.

The limited time available to clinicians and patients during a wellness visit or periodic health examination (not driven by specific patient issues) makes it important to prioritize assessment and counseling for factors that affect longevity, health span, and quality of life over approaches that may have low yield, such as the annual comprehensive physical examination in an asymptomatic patient. Setting clear expectations for the content of a wellness visit may be a first step, and scheduling follow-up visits for findings or to continue indicated counseling are important steps to achieving better health outcomes.

3 Vaccine Opposition and Hesitancy

Julie A. Bettinger, Hana Mitchell

Vaccines have been recognized as one of the top public health achievements of the twentieth century. Dramatic declines in the morbidity and mortality of vaccine-preventable diseases have been observed, and the contribution of vaccines to the elimination, control, and prevention of infectious disease cannot be overstated. However, opposition and hesitancy to vaccines exist and are not new. Vaccine hesitancy has existed

since Edward Jenner introduced the first vaccine against smallpox in the eighteenth century. So why did the World Health Organization rank these attitudes as one of the ten greatest threats to public health in 2019? Are current opposition and hesitancy any different from what has been seen before? Many sociologists, public health experts, and health care providers (HCPs) argue yes. Recent social and cultural trends, combined with new communication formats, have converged to create a particularly potent form of hesitancy and what some have labeled a crisis of confidence. This crisis manifests as a lack of trust in specific vaccines, vaccine programs, researchers, HCPs, the health care system, pharmaceutical companies, academics, policymakers, governments, and authority in general. **(See "Focus: COVID-19 Vaccine Hesitancy," below.)**

The roots of modern vaccine hesitancy and opposition—defined as delay or rejection of vaccines in spite of availability—vary depending on the place and the population. For some individuals and communities, pseudoscience and false claims about the safety of existing vaccines (e.g., an unsupported link between measles vaccine and autism) have driven fears, increased hesitancy, and decreased acceptance. For others, real safety events, such as the association of narcolepsy with a specific pandemic influenza vaccine (Pandemrix), have justified concerns. In a few locations (e.g., Ukraine, Pakistan), vaccine hesitancy is the result of failed health systems or even state failures. Finally, for some groups, including some fundamentalist religious groups and alternative-culture communities, vaccine hesitancy and opposition reflect exclusion from and rejection of mainstream society and allopathic health care and manifest as a deep distrust of these institutions and their HCPs. Although the genesis of modern vaccine hesitancy is multifactorial, its outcomes are uniform: a decrease in vaccine demand and uptake, a decrease in coverage by childhood and adult vaccines, and an increase in vaccine-preventable diseases, outbreaks, and epidemics of disease. Addressing this crisis and moving people from vaccine hesitancy and refusal to acceptance and active demand require intervention at multiple levels: the individual, the health system (including public health), and the state.

This chapter will define vaccine hesitancy and briefly describe its determinants and effects in North America (the United States and Canada). Physicians and other HCPs are well positioned to address the crisis of confidence many patients feel toward HCPs and the health care system. Studies demonstrate that an unambiguous, strong recommendation by trusted HCPs is most often the reason that patients, including those who are vaccine hesitant, choose to vaccinate. Strategies for counseling vaccine-hesitant and vaccine-resistant patients will be presented and examples of strong vaccine recommendations provided. Presenting strategies to increase vaccine demand at a system and policy level is beyond the scope of this chapter. While some physicians may have roles that allow them to act at this level, all physicians can act and influence their individual patients. Strategies to create active vaccine demand at the individual level alone will not solve vaccine hesitancy, but vaccine hesitancy cannot be addressed without these efforts. **For further discussion of immunization principles and vaccine use, see Chap. 123.**

VACCINE COVERAGE AND OUTBREAKS

The epidemiologic data from measles outbreaks over the past 10 years provide an interesting illustration of the effects of vaccine opposition and hesitancy. **For further discussion of measles, see Chap. 205.**

North America *Herd immunity* occurs when enough individuals in a population become immune to an infectious disease, usually through vaccination, that transmission of the infection stops. The level of immunity (or level of vaccine coverage) required to confer herd immunity varies with the specific infectious disease. Because measles is a highly contagious virus, a coverage rate of 93–95% must be achieved for vaccination to confer herd immunity and interrupt measles transmission. National coverage estimates place one-dose measles vaccine coverage rates in 2-year-old children at 92% in the United States and 88% in Canada. In spite of these relatively high levels of coverage in young children, numerous measles outbreaks have occurred in both countries since 2010 **(Table 3-1)**.

The vast majority (>80%) of measles cases described in Table 3-1 occurred in under- or completely unvaccinated individuals. Of note, many of these outbreaks highlight pockets of significantly under- or unvaccinated individuals that are not apparent in national vaccine coverage statistics. Moreover, many of the outbreaks listed in Table 3-1 were ignited by unvaccinated returned travelers from areas with existing

TABLE 3-1 Measles Outbreaks in North America

YEAR/PLACE	NO. OF CASES	REASON
2010/Canada	70	An infected traveler to the 2010 Winter Olympics transmitted infection to an under- and unvaccinated local population in British Columbia.
2011/Canada	776	Disease was imported from France by an unvaccinated returned traveler to Quebec. The outbreak spread in a nonvaccinating religious community and outside that community. A majority of cases occurred in under- and unvaccinated persons.
2011/United States	118	Of 118 cases, 46 were in returned travelers from Europe and Asia/Pacific regions; 105 cases (89%) occurred in unvaccinated persons.
2013/United States	58	Disease was imported by a returned unvaccinated traveler from Europe. The outbreak spread in a nonvaccinating religious community in New York.
2014/Canada	433	Disease was imported from the Netherlands. The outbreak spread in a nonvaccinating religious community in British Columbia.
2014/United States	383	The outbreak occurred in nonvaccinating religious communities in Ohio.
2015/United States	147	A multistate/multicountry outbreak was linked to Disneyland amusement park. More than 80% of cases occurred in unvaccinated persons.
2015/Canada	159	Disease was imported from the United States (part of the Disneyland outbreak) by an unvaccinated traveler. The outbreak spread in a nonvaccinating religious community in Quebec.
2017/United States	75	The outbreak occurred in an under-vaccinated community in Minnesota; 95% of patients were unvaccinated.
2018/United States	375	Disease was imported by returned unvaccinated travelers from Israel. The outbreak spread in nonvaccinating religious communities in New York and New Jersey.
2019/Canada	31	Disease was imported from Vietnam by a returned traveler to British Columbia. The outbreak spread throughout local area schools in under- and unvaccinated persons and resulted in a province-wide measles mass immunization campaign for schoolchildren.
2019/United States	1282	Outbreaks occurred in 10 states; 73% of cases (~935) were linked to outbreaks in nonvaccinating religious communities in New York.

Source: Centers for Disease Control and Prevention and Public Health Agency of Canada.

outbreaks or epidemics, who spread disease into an unvaccinated or under-vaccinated community. Many of the outbreaks were contained within the nonvaccinating community, but several spread to other under-vaccinated communities geographically contiguous with the outbreak community. More concerning still are the cases and outbreaks originating in communities that had not previously been identified as nonvaccinating. These cases likely highlight pockets of unvaccinated individuals who object for cultural rather than religious reasons. In the past, these nonvaccinating individuals did not exist in large enough clusters to sustain the spread of measles. Of further concern is the number of individuals included in outbreak statistics who have had one or sometimes even two doses of vaccine and who were thought to be protected but who still end up with the disease. The assumption is that one or two doses provide full disease immunity, but this is not always true. Often, individual level characteristics (age, immune compromise, etc.) affect the individual's response to the vaccine and their level of protection. In other instances, vaccine protection can wane over time, thus leaving fully immunized individuals susceptible to infection. In fact, when herd immunity breaks (i.e., the level of immunity in a community becomes too low to prevent transmission of disease), the occurrence of cases even in fully immunized persons is seen, as reflected in outbreak statistics. As a result of decreased vaccination rates and the resulting disruption of herd immunity, these individuals may become more identifiable as non-immune.

Outside North America Although overall coverage rates may still be high in North America, they are lower in other parts of the world. In Samoa, for example, measles–mumps–rubella (MMR) vaccine coverage before a recent outbreak was 31%; in the Philippines, it was 67%. Twenty years ago, vaccine coverage was sufficiently high in some parts of the world, including Europe, that an unvaccinated traveler from a nonvaccinating community to most regions would have been protected by herd immunity at their destinations. Today that is not the case: such travelers are likely to become infected in a country with active measles transmission and return home to spread the infection into their communities and possibly beyond. Thus active measles transmission, whether at home or abroad, places individuals who rely on herd immunity (e.g., immunocompromised persons and young infants) at increased risk.

FACTORS IN VACCINE HESITANCY

Vaccination coverage rates provide an estimate of the proportion of children or adults in the population who have been vaccinated, but they do not indicate the proportion of individuals who are vaccine hesitant. An individual may be fully vaccinated but still be hesitant about the safety and effectiveness of vaccines, or an individual may be unvaccinated as a result of access issues but may not be hesitant. Therefore, in attempts to understand a patient's lack of vaccination, it is important to distinguish persons who are hesitant and refuse vaccines from those who need assistance to access the health care system and successfully complete vaccination. To this end, an understanding of vaccine hesitancy and its determinants is needed.

Vaccine hesitancy and opposition are defined by the World Health Organization's SAGE Working Group on Vaccine Hesitancy as a "delay in acceptance or refusal of vaccines despite availability of vaccination services." The SAGE group describes vaccine hesitancy as "complex and context specific, varying across time, place, and vaccines."

It is useful to frame vaccine acceptance as a continuum pyramid, with active demand for all vaccines representing the largest group at the bottom of the pyramid and outright refusal of all vaccines depicted in the smallest group at the top. In the middle lies vaccine hesitancy, in which the degree of vaccine demand and acceptance varies. Fortunately, for disease control efforts, most individuals fall within the active-demand category or, if they are hesitant, still accept all vaccines. Hesitancy can be influenced by complacency, convenience, and confidence (Fig. 3-1).

Complacency is self-satisfaction when accompanied by a lack of awareness for real dangers or deficiencies. Complacency exists in communities and individuals when the perceived risks of vaccine-preventable diseases are low and vaccination is not deemed a necessary preventive action. This attitude can apply to vaccination in general or to specific vaccines, such as influenza vaccines. Actual or perceived vaccine efficacy and effectiveness contribute to complacency. Patients who are complacent about vaccine-preventable diseases prioritize other lifestyle or health factors over vaccination. These individuals can be influenced toward vaccination by a strong recommendation from a trusted HCP or a local influenza outbreak. They can be influenced away from vaccination by a vaccine scare or misinformation on social

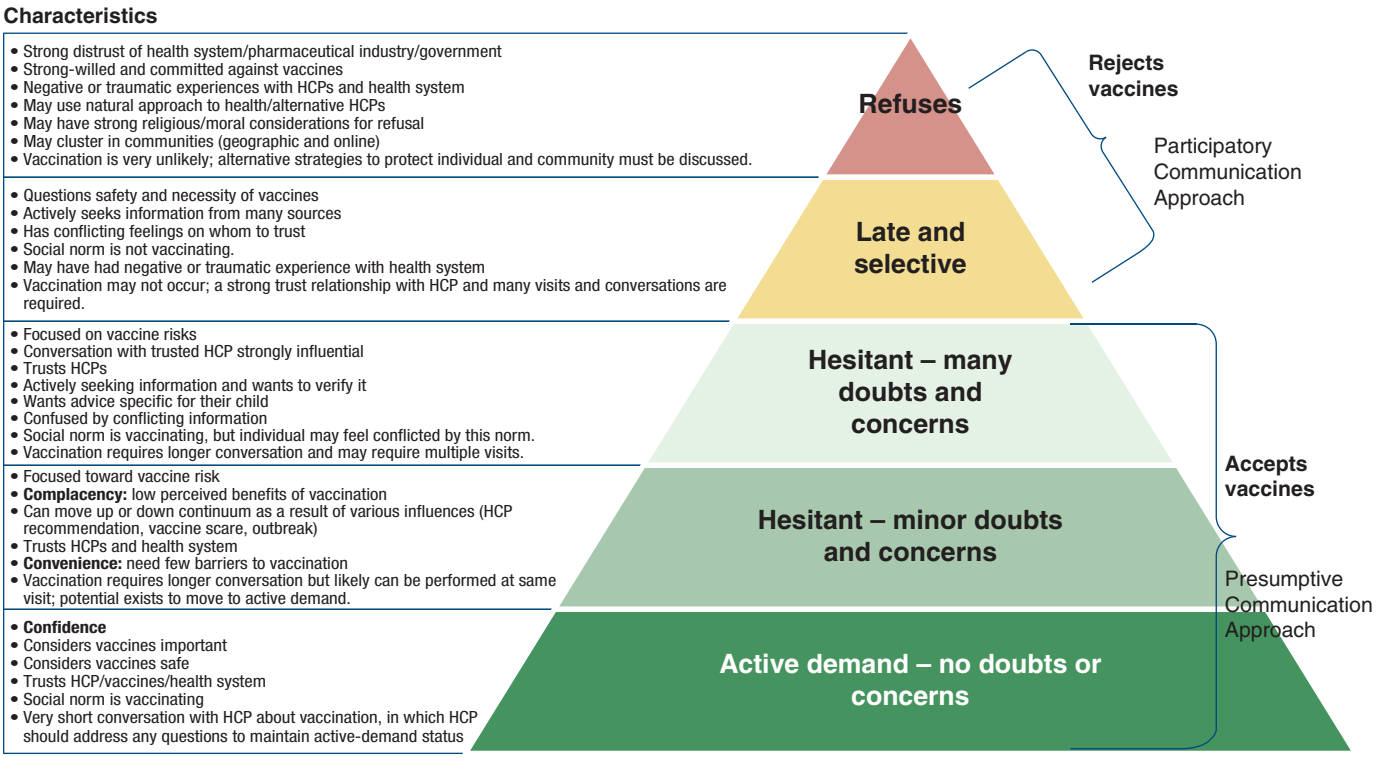

FIGURE 3-1 Vaccine acceptance continuum. HCPs, health care providers. *(Adapted from J Leask et al: BMC Pediatrics 12:154, 2012; AL Benin et al: Pediatrics 117:1532, 2006; and E Dubé, NE MacDonald: The Vaccine Book, 2016, pp. 507-528.)*

media. Finally, the real or perceived ability of patients to take the action required for vaccination (i.e., self-efficacy) influences the role complacency plays in hesitancy and willingness to seek vaccination.

Convenience is determined by the degree to which conversations about vaccination and other services can be provided in culturally safe contexts that are convenient and comfortable for the individual. Clearly, convenience varies by community, health clinic, and even patient. Persons who are criticized or scolded for not vaccinating themselves or their children may not feel comfortable or safe accessing health services. Factors such as affordability, geographic accessibility, language, and health literacy are important considerations when evaluating the convenience of existing clinical care. Any of these factors can affect vaccine acceptance and can push a patient who has some hesitancy toward vaccinating or not vaccinating.

Confidence is based on trust in the safety and efficacy of vaccines, in the health care system that delivers vaccines (including HCPs), and in the policymakers or governments who decide which vaccines are needed and used. A continual erosion of confidence around vaccination, health systems, and governments drives today's hesitancy and has been amplified by larger social and cultural trends in medicine, parenting, and information availability.

SOCIAL AND CULTURAL TRENDS

Individualized Health Care Over the past 30 years, the focus of medicine and health care has shifted to patient-oriented, individualized care, with an increasing emphasis on treatment and prevention options tailored to the individual patient. In vaccination programs, this shift has manifested as requests for individualized vaccine recommendations and customized immunization schedules. The increasing personalization of medicine, while positive overall, has forced public health away from a focus on the community and its common good and has created tension between individual rights and community health.

Parenting Trends The desire for an individualized approach to medicine and vaccination reflects broader cultural trends concerning individual risk management: accordingly, the individual is to blame for bad outcomes, and public institutions cannot be trusted to manage technological (i.e., vaccine-related) risks. This viewpoint is directly linked with cultural shifts in parenting and social norms defining what it means to be a "good parent." The image of a good parent has been reframed to refer to someone whom several investigators have described as "a critical consumer of health services and products, accounting for their own individual situation as they see it with little regard for the implications of their decision on other children." The archetypical good parent no longer unquestioningly trusts HCPs and other authorities and experts. According to this social norm, "good parents" should seek individual medical advice that is tailored for their child and specific to that child's needs. While in essence not a bad thing, this norm can conflict directly with public health vaccine recommendations and schedules that are organized to maximize community health and to facilitate efficient provision of care at a community level.

Traditional Media Newspapers, radio, and television have been criticized for their coverage of vaccines and in particular their coverage of the alleged link between MMR vaccine and autism. By offering equal coverage throughout the early to mid-2000s for both the scientific evidence and unproven claims of MMR vaccine harms, traditional media outlets provided a forum and a megaphone for the spread of pseudoscience. Equal coverage leads to false equivalencies. Celebrity advocates further amplified the message via this channel. The boost that traditional media provided to active vaccine resistance and, less directly, to vaccine hesitancy has not been adequately measured but must be considered in any discussion of vaccine hesitancy. After headlines about multiple outbreaks of measles and other vaccine-preventable diseases and continued direct criticism of the equal-coverage approach, some traditional media now reject and attempt to discredit pseudoscience. The effect this stance will have on increasing vaccine confidence is unknown.

The Internet and Social Media Approximately 90% of Americans and 91% of Canadians use the Internet, and 80% of Americans and 60% of Canadians have a social network profile. Widespread access to social media can be empowering, but it is also problematic. The Internet and social media require users to select their information sources, creating an environment described as an "echo chamber" in which individuals choose information sources harboring beliefs or opinions similar to their own and thereby reinforcing their existing views. This situation has created a new platform for further spread of vaccine *misinformation* (inaccuracies due to error) and *disinformation* (deliberate lies) and has provided a forum for vaccine-resistant individuals, including celebrities, to organize and raise funds to support their efforts. The harmful effects of Internet and social media use on vaccine hesitancy have been well documented. Vaccine hesitancy increases for parents who seek their information from the Internet. Unfortunately, public health and health care institutions have been slow to adapt to this new communication medium and to recognize its influence and impact. In this medium, personal stories and anecdotes are now viewed as data and disproportionately influence vaccine decision-making, while traditional, more authoritative, fact-based information sources are deemphasized. Centralized monitoring by jurisdiction of vaccine misinformation and disinformation, with summaries of the relevant discourses and rebuttals provided to HCPs, has been proposed as a potential way to counter the influence of social media on vaccine hesitancy. While such strategies have been applied in single jurisdictions and appear to have had some success, their applicability to a broader context is unknown. Moreover, the resources for such a coordinated response have not been made available, and individual HCPs have been left to counter popular, shifting, viral communications on their own, patient by patient.

As with traditional media, the social media landscape appears to be shifting. In 2019, the proliferation of anti-vaccination information combined with measles outbreaks in North America and increasing pressure from health leaders led large social media companies (Facebook, Instagram, Pinterest) to deemphasize anti-vaccination information by removing relevant advertisements and recommendations and decreasing their prominence in search results. While it is too soon to determine the effects of these measures, critics are skeptical that they will have the intended result of reducing vaccine misinformation and disinformation. Early evidence shows that misleading content is still widely available, with anti-vaccine advertisements now using the term "vaccine choice" to avoid censorship. More disturbingly, public health advertisements in support of vaccination have been included in social bans and removed from social media sites.

In a more grassroots effort, providers and vaccine supporters have united on social media to provide online support and evidence-based facts to providers and others who support vaccines when they are attacked digitally by anti-vaccine supporters. For example, Shots Heard Round the World (*www.shotsheard.com*) is an effort led by two U.S. pediatricians to provide advice and support for HCPs who speak out about the importance of vaccines. Such efforts harness the power of social media in ways similar to those used by vaccine opponents and may prove successful in combating vaccine hesitancy.

Given these social and cultural trends, no one should be surprised when individuals now question vaccination, express confusion about conflicting information and information sources, and feel unsure whom to trust. Their broader social context is telling them they should question everything and trust no one. This message is reinforced via misinformation and disinformation on social media. Recent vaccine-preventable disease outbreaks illustrate that effective engagement with individuals cannot be accomplished through one-way, top-down information provision (which still is often the de facto choice for health system communication), but rather requires a dialogue that takes into account the social processes surrounding individual vaccination decisions. It is at the interface between the individual and the health system in which conversations between HCPs and their patients can have the greatest impact. It is critical for all HCPs to discuss vaccines and provide strong vaccine recommendations—including HCPs who do not administer vaccines but who have established trust with their patients.

APPROACH TO THE PATIENT

An ideal vaccine-hesitancy intervention would result in full compliance with vaccination, the patient's satisfaction with the health care encounter, and sustained trust in the HCP's recommendations. On a programmatic level, vaccine-hesitancy interventions should be multicomponent, dialogue based, and tailored to specific under-vaccinated populations.

Communicating with vaccine-hesitant individuals can be challenging and time-consuming. HCPs may feel that vaccine-hesitant patients cast doubt on their personal and professional integrity, their authority as medical experts, and their competence as communicators. Some HCPs may be reluctant to initiate conversations about vaccination because of concerns that discussing a sensitive topic may compromise their clinical rapport with their patients. Other HCPs may believe that they have not received sufficient training to confidently recommend vaccines and answer questions. Discussing vaccines with hesitant patients, while not always easy, provides an opportunity to honor the principles of patient-centered care by demonstrating an interest in patients' opinions, engaging in dialogue, and ideally increasing patients' confidence in vaccine recommendations.

FACTORS IN EFFECTIVE VACCINE RECOMMENDATIONS

Vaccine recommendations ideally should be made within an established, trusting patient–provider relationship in which patients are comfortable asking questions and voicing concerns, even if their views on vaccines contradict the HCP's recommendations. Recommending vaccines requires both provision of information and effective communication. There is no single "best practice" for how providers should approach recommending vaccines to vaccine-hesitant individuals. In general, all vaccine recommendations should be (1) strong, making it clear that the provider supports and recommends vaccination; (2) tailored, acknowledging the vaccine attitudes and potential concerns of individual patients; (3) transparent and accurate, highlighting the benefits of vaccines while also communicating the risks; (4) supported by trustworthy information resources that patients can access and review after the clinical encounter; and (5) revisited, with repetition and reinforcement during follow-up health care encounters.

Strength of the Recommendation HCPs should make it explicit (in the absence of medical contraindications) that vaccination based on the recommended schedule is the best option. While HCPs should take time to elicit patients' questions and address concerns, the recommendation for vaccination should be made in clear and unambiguous terms.

Tailored Communication Vaccine hesitancy occurs on a continuum (Fig. 3-1). Therefore, it is helpful for HCPs to have some understanding of their patients' attitudes toward vaccination at the start of the health care appointment. Unfortunately, vaccine-hesitancy surveys for use as part of vaccine consultation visits have not been validated on a large scale. However, the following are some examples of questions that can be asked, depending on the setting. (1) Did you have a chance to review the vaccine leaflet we provided? Did you have any questions about it? (2) Have you ever been reluctant or hesitant about getting a vaccination for yourself or your child? If so, what were the reasons? (3) Are there other pressures in your life that prevent you from getting yourself or your child immunized on time? (4) Whom/what resources do you trust the most for information about vaccines? Whom/what resources do you trust the least?

Communication style and content for patients in the active-demand category for vaccination will be different from those for individuals who are hesitant, late and selective, or strongly inclined to refuse vaccines. Two communication styles have been proposed for vaccine recommendations. Evidence shows that a *presumptive/directive* approach ("Your child is due for MMR vaccination.") results in higher rates of vaccine uptake than a *participatory/guiding* approach ("What are your thoughts about the MMR vaccine?"). However, adopting a strictly presumptive/directive approach may alienate some patients, especially those who are higher up on the hesitancy pyramid and who may feel that they are being pressured into vaccination before their concerns have been heard and addressed. Adopting a participatory/guiding approach and clarifying receptivity to vaccines may be more suitable for hesitant individuals with many doubts and concerns, persons with a late or selective attitude, and those who are strongly inclined to refuse vaccines. In addition, a participatory/guiding approach provides an opportunity for ongoing clinical rapport and dialogue between unvaccinated or under-vaccinated patients and their HCPs, even when it does not result in immediate vaccine uptake. Regardless of which approach is used, a strong vaccine recommendation should be made at each encounter.

Transparency and Accuracy Vaccine recommendations should be transparent, should include accurate information about both the benefits and the risks of the vaccine, and should emphasize why the benefits outweigh the risks. For example, when evidence supports an association between a vaccine and an adverse event, the occurrence of the adverse event is often very rare and the event quickly resolves **(Chap. 123).** U.S. Federal law (under the National Childhood Vaccine Injury Act) requires HCPs to provide a copy of the current Vaccine Information Statement from the Centers for Disease Control and Prevention (CDC), which describes both benefits and risks of vaccines to an adult patient or to a child's parent/legal representative before vaccination.

CDC Vaccine Information Statements should not replace a discussion with the HCP. Depending on the provider and the patient, a description of benefits and risks may include words and numbers, graphics, and personal anecdotes (e.g., why the provider vaccinates his or her own children). Personal anecdotes are powerful, and many hesitant patients seek and are influenced by them.

A discussion of benefits and risks provides an opportunity to address specific misconceptions about a particular vaccine or about vaccines overall. For example, patients may be concerned about adverse events following vaccination that are not supported by evidence, such as autism following MMR vaccination or myocardial infarction following influenza vaccination in the elderly.

Most adults—even those whose children are fully immunized—still have questions, misconceptions, or concerns about vaccines that should be addressed. A risk/benefit discussion allows HCPs to describe the vaccine safety monitoring systems in place. Providers should emphasize that vaccines are developed and approved through a highly regulated process that includes prelicensure clinical trials, review and approval by designated regulatory authorities (e.g., the U.S. Food and Drug Administration, Health Canada), strict manufacturing regulations, and ongoing postmarketing safety surveillance.

Support from Accessible Information Sources All vaccine recommendations should be supported by additional information sources patients can assess after the health care encounter. HCPs play an important role as information intermediaries for their patients. They can navigate information (and misinformation) about vaccines and direct patients toward reliable, appropriate resources. HCPs should consider what resources will be suitable for a patient or patient population. Vaccine information resources are available in different media formats and use a combination of images and text to communicate the information to various audiences. See "Further Reading," below, for suggestions or refer to resources provided by local health authorities.

Revisiting and Reinforcement of Vaccine Recommendations All health care encounters offer an opportunity to revisit and reinforce vaccine recommendations. Vaccine-hesitant individuals who do not accept vaccines but are willing to review information should be offered a follow-up appointment to reinforce previously made recommendations and address further questions. Vaccine-hesitant

patients who accept vaccines should be seen at a follow-up appointment to confirm and document vaccine receipt (if vaccine is not given at the point of care), ascertain whether the vaccine was well tolerated, and reinforce the message about vaccine safety and effectiveness. Patients who actively demand vaccines usually do not require much follow-up other than to confirm and document the receipt of vaccine (if it is not given at the point of care) and to address additional questions or concerns arising subsequent to vaccination. Often this follow-up can be covered without an office visit.

WHAT TO SAY TO VACCINE-HESITANT PATIENTS

Engaging vaccine-hesitant individuals requires confidence, knowledge, skills, time, and creativity to tailor the approach to each individual patient. Examples for each part of the vaccine recommendation are listed in **Table 3-2.**

OTHER CONSIDERATIONS DURING CLINICAL ENCOUNTERS

Missed Opportunities The World Health Organization defines a missed opportunity for vaccination as "any contact with health services by an individual (child or person of any age) who is eligible for vaccination (e.g., unvaccinated or partially vaccinated and free of contraindications to vaccination), which does not result in the person receiving one or more of the vaccine doses for which he or she is eligible." HCPs who do not offer point-of-care vaccination frequently miss the opportunity to recommend vaccines to their patients. Missed opportunities for recommending and providing vaccines during routine health care encounters contribute to under-vaccination. Studies show that up to 45% of under-vaccinated children could be up to date with all age-appropriate vaccines and up to 90% of female adolescents could be up to date with human papillomavirus (HPV) vaccination if all opportunities to vaccinate were taken.

Vaccine counseling and vaccination should be incorporated into clinical care for individuals of all ages, not just young children. Because many adolescents and adults do not have regular health care follow-up, providers need to take advantage of every health care encounter to recommend and provide vaccines. For example, a visit to an emergency department, a routine follow-up visit at a diabetes clinic, or a visit planning for elective orthopedic surgery offer opportunities to inquire about the patient's vaccination status and to recommend vaccines.

HCPs should make preemptive vaccine recommendations (e.g., initiating discussions about infant vaccines during pregnancy, informing parents about HPV vaccine before their child becomes eligible). Such advance discussions may be especially helpful in identifying

TABLE 3-2 Sample Vaccine Conversations

STRONG VACCINE RECOMMENDATION
"We are headed into the flu season. Getting flu vaccine not only protects you, but it helps protect other people around you who can get very sick from flu. I strongly recommend you get your flu shot. Do you know where to get it?"
"You will be turning 50 next year. This means you will be eligible for a vaccine that prevents shingles, and I strongly recommend you receive it. Have you heard about this vaccine before? Can I answer your questions about it?"
"I know you are not comfortable getting vaccinated today. I do want to make it clear that I recommend vaccines because I am convinced they are the best way to protect you from some serious diseases. Is there something that would lead you to think about getting vaccinated in the future?"
TAILORED COMMUNICATION
"I recommend that children and adults stay up to date on recommended vaccines. I see from your vaccine record that you've had your childhood vaccines, but you haven't gotten any adult vaccines. I wanted to clarify whether this is because you decided not to get vaccines or something else prevented you from getting vaccinated."
"I understand that you are here for your pneumococcal vaccine. This is the best way to protect yourself and those around you from pneumonia. Do you have any questions before I give you the vaccine?"
"I understand you have some concerns about vaccines. What are you most concerned about? Would you like me to explain why I recommend giving your child these vaccines?"
TRANSPARENCY AND ACCURACY
"Serious side effects can develop after MMR vaccination but are very rare. On average, 3 out of 10,000 children who get MMR vaccine will have a febrile seizure/convulsion in the days after vaccination. Febrile seizures can be frightening, but nearly all children who have a febrile seizure recover very quickly and without any long-term consequences. On the other hand, 1 out of 1000 children who get measles will develop encephalitis (brain inflammation) that not only causes seizures but can also lead to permanent damage."
"About 10 out of every 10,000 Americans who do not get vaccinated against flu die because of influenza every year, and many more are hospitalized. While flu vaccine does not prevent all cases of influenza, it is the most effective vaccine we have. By getting the vaccine, you also help protect people around you from getting sick."
"You are correct, aluminum is used in some vaccines to help the body's immune system respond. However, aluminum is also present in food and drinking water. In fact, the amount of aluminum present in vaccines is similar to or less than what is present in breast milk or infant formulas."
SUPPORT FROM ACCESSIBLE INFORMATION SOURCES
"Your child and other boys and girls his age will be eligible for the human papillomavirus vaccine this coming school year. Have you heard about this vaccine before? What questions do you have about it? Here's a list of websites for parents and teenagers that explain what it is about."
"There's a lot of information about vaccines on the internet, and a lot of that information is not based on facts. Here is a list of websites that have been reviewed by health care professionals and accurately describe benefits and risks of each vaccine. The information is written in lay language and includes helpful illustrations."
REVISITING AND REINFORCEMENT OF THE RECOMMENDATION
"During our last visit, we talked about MMR vaccine for your son and some of the concerns you had about potential side effects. Have you had a chance to look at the take-home information I gave you? Was there anything else you would like to ask about? I recommend that we vaccinate your child today."
"During our last visit, we talked about receiving a pertussis booster during pregnancy and where you can get vaccinated. Have you had a chance to get your pertussis vaccine?"
"I see that you got your vaccines at the public health clinic last week. How did it go? Did you have any questions?"
"It's possible that the symptoms you experienced after receiving the vaccine were an adverse reaction to the vaccine. I will report this to the health authority. Let's discuss what we can do next time to prevent symptoms from occurring again."

Note: Specific vaccine recommendations, vaccine eligibility guidelines, and statistics used to communicate benefits and risks will vary with the health jurisdiction and the country. Several sample statements here are adapted from the Australian National Centre for Immunisation Research and Surveillance website (*www.talkingaboutimmunisation.org.au*). For patient vaccine information resources, see also the Immunization Action Coalition website for the public developed in partnership with the CDC (*vaccineinformation.org*).

vaccine-hesitant patients and ensuring that they have enough time to ask questions and make decisions before vaccines are due.

HCPs should ensure that a vaccine recommendation is followed by vaccination. Providers who recommend vaccines but do not vaccinate at the point of care should inform patients where they can be vaccinated. This discussion may include information about public health clinics, travel clinics, and pharmacies or a referral to another provider. HCPs should follow up with their patients at subsequent appointments to confirm that they were vaccinated.

Adverse Events Following Vaccination Although rare, adverse events **(Chap. 123)** may influence vaccine acceptance and willingness to be vaccinated in the future. It is important for providers to identify and follow up with all patients who experience an adverse event, regardless of the patients' vaccine attitudes prior to the event. Adverse events following vaccination should be reported to the relevant vaccine monitoring system: the U.S. Vaccine Adverse Event Reporting System or the Canadian Adverse Event Following Immunization Surveillance System.

Addressing Inequities In Vaccine Access Discrepancies in access to health care services create inequitable access to vaccines for children and adults and contribute to under-vaccination. A U.S. study found that socially disadvantaged individuals were more likely than other persons to be under-vaccinated, in part because of a lack of access to health care services. HCPs must recognize that socially disadvantaged individuals and populations are often at greater risk of vaccine-preventable diseases (e.g., as a result of crowded living conditions, limited access to sanitation, poor nutrition, or substance abuse) and also at greater risk of being under-vaccinated because they have limited access to health care services. In addition, specific vaccines may be recommended for some socially disadvantaged populations or communities. For example, in the wake of several outbreaks of hepatitis A among the U.S. homeless population, the CDC now recommends that everyone >1 year of age experiencing homelessness receive hepatitis A vaccine.

Depending on the setting and the patient, some recommended vaccines may not be covered through public funding or private insurance coverage. HCPs should be aware of alternative funding models, such as the Vaccines for Children Program, which provides free vaccines for U.S. children (<19 years of age) with financial barriers to vaccine access. When vaccines are not publicly funded or covered by private insurance and patients perceive that they cannot afford a vaccine, HCPs should not withhold a vaccine recommendation. The risks and benefits of vaccination still need to be communicated, with a strong recommendation, and the patient should be provided the opportunity to decide whether they can afford the vaccine.

Further Communication With Patients Who Refuse Vaccines Fortunately, the proportion of people who completely refuse all vaccines and are not willing to talk to their HCP is small. Nevertheless, in some cases, attempts to initiate discussion and address vaccine refusal may be futile. When possible, HCPs should focus on the common goals of care and preserve the therapeutic relationship. Vaccine refusal should be well documented in the patient's chart. The HCP should continue with tailored communication and be open to future discussions. Vaccine demand and vaccine refusal are rarely static over time. **(See "Focus: COVID-19 Vaccine Hesitancy," below.)**

CONCLUSION

In summary, vaccine hesitancy is complex and context specific. It varies with time, place, patient, and vaccine. HCPs are well positioned to address vaccine hesitancy and should develop the skills, knowledge, and confidence to make strong vaccine recommendations to their patients.

FOCUS: COVID-19 VACCINE HESITANCY

As COVID-19 vaccines are used to control SARS-CoV-2, some individuals will have concerns about these vaccines and a proportion of the population will reject them. While worrisome, hesitancy about COVID-19 vaccines is not unexpected; it mirrors public concerns expressed about past pandemic influenza vaccines and other newly introduced vaccines. It has been established that the newness of any vaccine, be it a pandemic influenza vaccine or a COVID-19 vaccine, raises concern in a large percentage of the population. Politicization of COVID-19 vaccines raises additional issues for some patients.

Past Experience with New Vaccines Past experience with new vaccines, including the H1N1 pandemic influenza vaccine in 2009 and the human papillomavirus vaccine in the early 2000s, provides a guide to topics that need to be addressed with regard to COVID-19 vaccines. While resistance is often framed as uncertainty about a vaccine's "newness," further discussion translates this uncertainty into concern about the new vaccine's safety. This concern encompasses both short- and long-term side effects. Frequent, acute adverse effects can be captured in clinical trial data, whereas worries about rare and long-term side effects can be addressed only by direct evidence after the initiation of a new vaccination program. In addition to queries about the overall safety of the vaccine, HCPs can expect specific questions regarding the safety of individual ingredients included in the vaccine, whether or not these ingredients are new and whether or not relevant safety data are available. Information on the incidence of common or expected health events in an unvaccinated population (i.e., background rates) over a 4-week period is helpful in distinguishing what is normal and expected from a point of concern. Studies that have examined this issue with regard to other vaccines can be used as a basis for presenting background rates of expected events in the context of COVID-19 vaccines for some groups; however, it is important to ensure that more specific background-rate information is available to HCPs with regard to the individual groups being vaccinated. HCPs, public health programs, and vaccine manufacturers can anticipate these questions and should develop answers and information to respond to them.

Specific Concerns about COVID-19 Vaccines While some concerns can be anticipated on the basis of past experience with new vaccines, several characteristics of COVID-19 vaccines require new approaches to adequately address individual concerns, and HCPs need to educate themselves in several specific areas. First, an overwhelming amount of attention has been paid to the speed of development of COVID-19 vaccines, with some jurisdictions even skipping the usual clinical-trial steps in an effort to provide vaccine more rapidly to their populations. This situation directly increases concerns about the "newness" of the vaccine and its safety and, unfortunately, raises questions about the entire vaccine development process. Education is required to explain how a process that normally requires 5–10 years was condensed to this degree. (See Lurie et al [2020] for an excellent explanation of the COVID-19 vaccine development process.) In addition, transparency with regard to clinical trial data is required to enable scientists, HCPs, and consumers to read and understand the development and evaluation processes. The usually shrouded, proprietary development process is unsuitable if the final vaccine product is to garner public trust. Education on existing vaccine-safety monitoring systems also needs to be provided. HCPs must familiarize themselves with the vaccine development process and safety monitoring systems if they are to present this information to their patients.

Second, several newer vaccine platforms that are being used for COVID-19 vaccines (e.g., nucleic acid–based vaccines, viral vector) have not been used in the past. This novelty exacerbates public concern about the unfamiliarity of new vaccines and further heightens misgivings about vaccine safety and the potential for long-term adverse effects. Again, HCPs need to familiarize themselves with the new technology and develop effective messaging for their patients. Public health officials have developed resources to address this issue (see *www.cdc.gov/vaccines/covid-19/vaccinate-with-confidence.html*), but, even in the absence of such resources, HCPs can anticipate questions about the new technology involved and become comfortable explaining it.

Third, clinical trial safety and efficacy data were lacking for all groups initially prioritized to receive the vaccine. For example, long-term-care residents were prioritized for vaccine receipt, but clinical trial data were not available for the range of chronic health conditions that exist in older adults. While observational studies have filled some of these gaps, HCPs need to extrapolate on the basis of available evidence in considering individual patients and must make a recommendation without knowing all the answers.

Fourth, some minority and marginalized communities who have been disproportionately affected by COVID-19 express hesitancy or reject COVID-19 vaccines. For some Black, Indigenous, Latinx, and other communities, COVID-19 hesitancy stems directly from systematic discrimination, racism, and mistreatment in the health care system. Black and Indigenous communities also share a horrific legacy of unethical medical experimentation,[1] which, when combined with current discrimination and overt racism, creates a powerful climate of mistrust in HCPs, the medical system, and science.

Social and Cultural Trends The social and cultural trends already discussed in this chapter—in particular, traditional media, the Internet, and social media—are exerting influence and pressure that did not affect the introduction of older vaccines, even the H1N1 pandemic vaccines. The media attention given to the development of transverse myelitis in one clinical-trial participant following receipt of COVID-19 vaccine is but one example of the intense media scrutiny of the vaccine development process. Unfortunately, in the United States, efforts to control COVID-19, including vaccine development, have become highly politicized. This degree of politicization has not occurred with past vaccines, so HCPs are in uncharted territory in terms of how to address it or even to understand its potential influence on vaccine acceptance. Again, individual HCPs need to navigate complex conversations with their patients and possibly their communities. Below are some suggestions that may prove helpful in formulating these conversations.

Tips for Discussion of COVID-19 Vaccines • **ADDRESS CONCERNS ABOUT "NEWNESS"** HCPs need to understand and be able to explain the newer vaccine platforms (mRNA, DNA, and viral vector vaccines) and to provide examples of other, older vaccines that have been developed by similar techniques. This information makes COVID-19 vaccines more familiar.

ADDRESS CONCERNS ABOUT VACCINE SAFETY HCPs need to understand and explain how vaccines are evaluated before being approved for use and how vaccine safety is monitored after vaccines are used in the population. It is important to be honest and state that potential rare and long-term effects are not yet known, but then to speak to what is from the animal and clinical trial data and to comment on background rates for rare events. Placing potential vaccine risks in the context of known COVID-19 disease risks is helpful for some patients.

Depending on the context, explain why specific high-risk groups may have been prioritized to receive the vaccine. Patients who have been prioritized may still need a strong recommendation from an HCP to accept the vaccine. An HCP recommendation is as important here as it is for acceptance of routine vaccines. As with other vaccines, many patients' decision to accept a COVID-19 vaccine rests upon whether their HCP recommends it.

Address implicit or overt racism and systemic discrimination in the medical system and create culturally safe health care spaces. HCPs need to be aware of the legacy of discrimination, racism, and medical experimentation and the distrust it fosters in some communities. While SARS-CoV-2 has critically highlighted fractures in our health care system for minority and marginalized communities, addressing these underlying issues goes beyond addressing vaccine hesitancy and is clearly needed for all types of medical care in these communities.

EMPHASIZE THE IMPORTANCE OF KEEPING UP TO DATE WITH OTHER ROUTINE VACCINES DURING THE COVID-19 PANDEMIC These vaccines include but are not limited to seasonal influenza vaccine and the childhood primary vaccination series.

[1]The Tuskegee Syphilis Study is the most infamous example of medical experimentation in Black communities in the United States. (See Brandt [1978] for details.) Numerous examples of medical experimentation on Indigenous peoples are available. For example, a 12-year trial of an experimental bacille Calmette-Guérin vaccine for tuberculosis was conducted on Cree and Nakoda Oyadebi infants in Saskatchewan during the 1930s. (See Lux [2016] for details.)

4 Decision-Making in Clinical Medicine

Daniel B. Mark, John B. Wong

Practicing medicine at its core requires making decisions. What makes medical practice so difficult is not only the specialized technical knowledge required but also the intrinsic uncertainty that surrounds each decision. Mastering the technical aspects of medicine alone, unfortunately, does not ensure a mastery of the practice of medicine. Sir William Osler's familiar quote "Medicine is a science of uncertainty and an art of probability" captures well this complex duality. Although the science of medicine is often taught as if the mechanisms of the human body operate with Newtonian predictability, every aspect of medical practice is infused with an element of irreducible uncertainty that the clinician ignores at her peril. Although deeply rooted in science, more than 100 years after the practice of medicine took its modern form, it remains at its core a craft, to which individual doctors bring varying levels of skill and understanding. With the exponential growth in medical literature and other technical information and an ever-increasing number of testing and treatment options, twenty-first century physicians who seek excellence in their craft must master a more diverse and complex set of skills than any of the generations that preceded them. This chapter provides an introduction to three of the pillars upon which the craft of modern medicine rests: (1) expertise in clinical reasoning (what it is and how it can be developed); (2) rational diagnostic test use and interpretation; and (3) integration of the best available research evidence with clinical judgment in the care of individual patients (evidence-based medicine [EBM]).

BRIEF INTRODUCTION TO CLINICAL REASONING

Clinical Expertise Defining "clinical expertise" remains surprisingly difficult. Chess has an objective ranking system based on skill and performance criteria. Athletics, similarly, have ranking systems to distinguish novices from Olympians. But in medicine, after physicians complete training and pass the boards (or get recertified), no tests or benchmarks are used to identify those who have attained the highest levels of clinical performance. At each institution, there are often a few "elite" clinicians who are known for their "special problem-solving prowess" when particularly difficult or obscure cases have baffled everyone else. Yet despite their skill, even such master clinicians typically cannot explain their exact processes and methods, thereby limiting the acquisition and dissemination of the expertise used to achieve their impressive results. Furthermore, clinical virtuosity appears not to be generalizable, e.g., an expert on hypertrophic cardiomyopathy may be no better (and possibly worse) than a first-year medical resident at diagnosing and managing a patient with neutropenia, fever, and hypotension.

Broadly construed, clinical expertise encompasses not only cognitive dimensions involving the integration of disease knowledge with verbal and visual cues and test interpretation but also potentially the complex fine-motor skills necessary for invasive procedures and tests. In addition, "the complete package" of expertise in medicine requires effective communication and care coordination with patients and members of the medical team. Research on medical expertise remains sparse overall and mostly centered on diagnostic reasoning, so in this chapter, we focus primarily on the cognitive elements of clinical reasoning.

Because clinical reasoning occurs in the heads of clinicians, objective study of the process is difficult. One research method used for this area asks clinicians to "think out loud" as they receive increments of clinical information in a manner meant to simulate a clinical encounter. Another research approach focuses on how doctors should reason diagnostically, to identify remediable "errors," rather than on how they actually do reason. Much of what is known about clinical reasoning comes from empirical studies of nonmedical problem-solving behavior. Because of the diverse perspectives contributing to this area, with important contributions from cognitive psychology, medical education, behavioral economics, sociology, informatics, and decision sciences, no single integrated model of clinical reasoning exists, and not infrequently, different terms and reasoning models describe similar phenomena.

Intuitive Versus Analytic Reasoning A useful contemporary model of reasoning, the dual-process theory distinguishes two general conceptual modes of thinking as fast or slow. *Intuition* (System 1) provides rapid effortless judgments from memorized associations using pattern recognition and other simplifying "rules of thumb" (i.e., heuristics). For example, a very simple pattern that could be useful in certain situations is "black woman plus hilar adenopathy equals sarcoid." Because no effort is involved in recalling the pattern, the clinician is often unable to say how those judgments were formulated. In contrast, *Analysis* (System 2), the other form of reasoning in the dual-process model, is slow, methodical, deliberative, and effortful. A student might read about causes of hilar adenopathy and from that list (e.g., **Chap. 66**), identify diseases more common in black women or examine the patient for skin or eye findings that occur with sarcoid. These dual processes, of course, represent two exemplars taken from the cognitive continuum. They provide helpful descriptive insights but very little guidance in how to develop expertise in clinical reasoning. How these idealized systems interact in different decision problems, how experts use them differently from novices, and when their use can lead to errors in judgment remain the subject of study and considerable debate.

Pattern recognition, an important part of System 1 reasoning, is a complex cognitive process that appears largely effortless. One can recognize people's faces, the breed of a dog, an automobile model, or a piece of music from just a few notes within milliseconds without necessarily being able to articulate the specific features that prompted the recognition. Analogously, experienced clinicians often recognize familiar diagnostic patterns very quickly. The key here is having a large library of stored patterns that can be rapidly accessed. In the absence of an extensive stored repertoire of diagnostic patterns, students (as well as experienced clinicians operating outside their area of expertise and familiarity) often must use the more laborious System 2 analytic approach along with more intensive and comprehensive data collection to reach the diagnosis.

The following brief patient scenarios illustrate three distinct patterns associated with hemoptysis that experienced clinicians recognize without effort:

- A 46-year-old man presents to his internist with a chief complaint of hemoptysis. An otherwise healthy, nonsmoker, he is recovering from an apparent viral bronchitis. This presentation pattern suggests that the small amount of blood-streaked sputum is due to acute bronchitis, so that a chest x-ray provides sufficient reassurance that a more serious disorder is absent.
- In the second scenario, a 46-year-old patient who has the same chief complaint but with a 100-pack-year smoking history, a productive morning cough with blood-streaked sputum, and weight loss fits the pattern of carcinoma of the lung. Consequently, along with the chest x-ray, the clinician obtains a sputum cytology examination and refers this patient for a chest CT scan.
- In the third scenario, the clinician hears a soft diastolic rumbling murmur at the apex on cardiac auscultation in a 46-year-old patient with hemoptysis who immigrated from a developing country and orders an echocardiogram as well, because of possible pulmonary hypertension from suspected rheumatic mitral stenosis.

Pattern recognition by itself is not, however, sufficient for secure diagnosis. Without deliberative systematic reflection, undisciplined pattern recognition can result in premature closure: mistakenly jumping to the conclusion that one has the correct diagnosis before all the relevant data are in. A critical second step, therefore, even when the diagnosis seems obvious, is *diagnostic verification*: considering whether

the diagnosis adequately accounts for the presenting symptoms and signs and can explain all the ancillary findings. The following case based on a real clinical encounter provides an example of premature closure. A 45-year-old man presents with a 3-week history of a "flulike" upper respiratory infection (URI) including dyspnea and a productive cough. The emergency department (ED) clinician pulled out a "URI assessment form," which defines and standardizes the information gathered. After quickly acquiring the requisite structured examination components and noting in particular the absence of fever and a clear chest examination, the physician prescribed a cough suppressant for acute bronchitis and reassured the patient that his illness was not serious. Following a sleepless night at home with significant dyspnea, the patient developed nausea and vomiting and collapsed. He was brought back to the ED in cardiac arrest and was unable to be resuscitated. His autopsy showed a posterior wall myocardial infarction (MI) and a fresh thrombus in an atherosclerotic right coronary artery. What went wrong? Presumably, the ED clinician felt that the patient was basically healthy (one can be misled by the way the patient appears on examination—a patient that does not appear "sick" may be incorrectly assumed to have an innocuous illness). So, in this case, the physician, upon hearing the overview of the patient from the triage nurse, elected to use the URI assessment protocol even before starting the history, closing consideration of the broader range of possibilities and associated tests required to confirm or refute these possibilities. In particular, by concentrating on the abbreviated and focused URI protocol, the clinician failed to elicit the full dyspnea history, which was precipitated by exertion and accompanied by chest heaviness and relieved by rest, suggesting a far more serious disorder.

Heuristics or rules of thumb are a part of the intuitive system. These cognitive shortcuts provide a quick and easy path to reaching conclusions and making choices, but when used improperly, they can lead to errors. Two major research programs have studied heuristics in a mostly nonmedical context and have reached very different conclusions about the value of these cognitive tools. The "heuristics and biases" program focuses on how these mental shortcuts can lead to incorrect judgments. So far, however, little evidence exists that educating physicians and other decision makers to watch for the >100 cognitive biases identified to date has had any effect on the rate of diagnostic errors. In contrast, the "fast and frugal heuristics" research program explores how and when relying on simple heuristics can produce good decisions. Although many heuristics have relevance to clinical reasoning, only four will be mentioned here.

When diagnosing patients, clinicians usually develop diagnostic hypotheses based on the similarity of that patient's symptoms, signs, and other data to their mental representations (memorized patterns) of the disease possibilities. In other words, clinicians pattern match to identify the diagnoses that share the most similar findings to the patient at hand. This cognitive shortcut is called the representativeness heuristic. Consider a patient with hypertension who has headache, palpitations, and diaphoresis. Based on the representativeness heuristic, clinicians might judge pheochromocytoma to be quite likely given this classic presenting symptom triad suggesting pheochromocytoma. Doing so, however, would be incorrect given that other causes of hypertension are much more common than pheochromocytoma and this triad of symptoms can occur in patients who do not have it. Thus, clinicians using the representativeness heuristic may overestimate the likelihood of a particular disease based on the presence of representative symptoms and signs, failing to account for its low underlying prevalence (i.e., the prior, or pretest, probabilities). Conversely, atypical presentations of common diseases may lead to underestimating the likelihood of a particular disease. Thus, inexperience with a specific disease and with the breadth of its presentations may also lead to diagnostic delays or errors, e.g., diseases that affect multiple organ systems, such as sarcoid or tuberculosis, may be particularly challenging to diagnose because of the many different patterns they may manifest.

A second commonly used cognitive shortcut, the availability heuristic, involves judgments based on how easily prior similar cases or outcomes can be brought to mind. For example, a clinician may recall a case from a morbidity and mortality conference in which an elderly patient presented with painless dyspnea of acute onset and was evaluated for a pulmonary cause but was eventually found to have acute MI, with the diagnostic delay likely contributing to the development of ischemic cardiomyopathy. If the case was associated with a malpractice accusation, such examples may be even more memorable. Errors with the availability heuristic arise from several sources of recall bias. Rare catastrophic outcomes become memorable cases with a clarity and force disproportionate to their likelihood for future diagnosis—for example, a patient with a sore throat eventually found to have leukemia or a young athlete with leg pain subsequently found to have an osteosarcoma—and those publicized in the media or recently experienced are, of course, easier to recall and therefore more influential on clinical judgments.

The third commonly used cognitive shortcut, the anchoring heuristic (also called conservatism or stickiness), involves insufficiently adjusting the initial probability of disease up (or down) following a positive (or negative test) when compared with Bayes' theorem, i.e., sticking to the initial diagnosis. For example, a clinician may still judge the probability of coronary artery disease (CAD) to be high despite a negative exercise perfusion test and go on to cardiac catheterization (see "Measures of Disease Probability and Bayes' Rule," below).

The fourth heuristic states that clinicians should use the simplest explanation possible that will adequately account for the patient's symptoms and findings (Occam's razor or, alternatively, the simplicity heuristic). Although this is an attractive and often used principle, it is important to remember that no biologic basis for it exists. Errors from the simplicity heuristic include premature closure leading to the neglect of unexplained significant symptoms or findings.

For complex or unfamiliar diagnostic problems, clinicians typically resort to analytic reasoning processes (System 2) and proceed methodically using the *hypothetico-deductive model of reasoning*. Based on the patient's stated reasons for seeking medical attention, clinicians develop an initial list of diagnostic possibilities in *hypothesis generation*. During the history of the present illness, the initial hypotheses evolve in *diagnostic refinement* as emerging information is tested against the mental models of the diseases being considered with diagnoses increasing and decreasing in likelihood or even being dropped from consideration as the working hypotheses of the moment. These mental models often generate additional questions that distinguish the diagnostic possibilities from one another. The focused physical examination contributes to further distinguishing the working hypotheses. Is the spleen enlarged? How big is the liver? Is it tender? Are there any palpable masses or nodules? *Diagnostic verification* involves testing the adequacy (whether the diagnosis accounts for all symptoms and signs) and coherency (whether the signs and symptoms are consistent with the underlying pathophysiologic causal mechanism) of the working diagnosis. For example, if the enlarged and quite tender liver felt on physical examination is due to acute hepatitis (the hypothesis), then certain specific liver function tests will be markedly elevated (the prediction). Should the tests come back normal, the hypothesis may have to be discarded and others reconsidered.

Although often neglected, negative findings are as important as positive ones because they reduce the likelihood of the diagnostic hypotheses under consideration. Chest discomfort that is not provoked or worsened by exertion and not relieved by rest in an active patient lowers the likelihood that chronic ischemic heart disease is the underlying cause. The absence of a resting tachycardia and thyroid gland enlargement reduces the likelihood of hyperthyroidism in a patient with paroxysmal atrial fibrillation.

The acuity of a patient's illness may override considerations of prevalence and the other issues described above. "Diagnostic imperatives" recognize the significance of relatively rare but potentially catastrophic conditions if undiagnosed and untreated. For example, clinicians should consider aortic dissection routinely as a possible cause of acute severe chest discomfort. Although the typical presenting symptoms of dissection differ from those of MI, dissection may mimic MI, and because it is far less prevalent and potentially fatal if mistreated, diagnosing dissection remains a challenging diagnostic imperative **(Chap. 280)**.

Clinicians taking care of acute, severe chest pain patients should explicitly and routinely inquire about symptoms suggestive of dissection, measure blood pressures in both arms for discrepancies, and examine for pulse deficits. When these are all negative, clinicians may feel sufficiently reassured to discard the aortic dissection hypothesis. If, however, the chest x-ray shows a possible widened mediastinum, the hypothesis should be reinstated and an appropriate imaging test ordered (e.g., thoracic computed tomography [CT] scan or transesophageal echocardiogram). In nonacute situations, the prevalence of potential alternative diagnoses should play a much more prominent role in diagnostic hypothesis generation.

Cognitive scientists studying the thought processes of expert clinicians have observed that clinicians group data into packets, or "chunks," that are stored in short-term or "working memory" and manipulated to generate diagnostic hypotheses. Because short-term memory is limited (classically humans can accurately repeat a list of 7 ± 2 numbers read to them), the number of diagnoses that can be actively considered in hypothesis-generating activities is similarly limited. For this reason, the cognitive shortcuts discussed above play a key role in the generation of diagnostic hypotheses, many of which are discarded as rapidly as they are formed, thereby demonstrating that the distinction between analytic and intuitive reasoning is an arbitrary and simplistic, but nonetheless useful, representation of cognition.

Research into the hypothetico-deductive model of reasoning has had difficulty identifying the elements of the reasoning process that distinguish experts from novices. This has led to a shift from examining the problem-solving process of experts to analyzing the organization of their knowledge for pattern matching as exemplars, prototypes, and illness scripts. For example, diagnosis may be based on the resemblance of a new case to patients seen previously (exemplars). As abstract mental models of disease, prototypes incorporate the likelihood of various disease features. Illness scripts include risk factors, pathophysiology, and symptoms and signs. Experts have a much larger store of exemplar and prototype cases, an example of which is the visual long-term memory of experienced radiologists. However, clinicians do not simply rely on literal recall of specific cases but have constructed elaborate conceptual networks of memorized information or models of disease to aid in arriving at their conclusions (illness scripts). That is, expertise involves an enhanced ability to connect symptoms, signs, and risk factors to one another in meaningful ways; relate those findings to possible diagnoses; and identify the additional information necessary to confirm the diagnosis.

No single theory accounts for all the key features of expertise in medical diagnosis. Experts have more knowledge about presenting symptoms of diseases and a larger repertoire of cognitive tools to employ in problem solving than nonexperts. One definition of expertise highlights the ability to make powerful distinctions. In this sense, expertise involves a working knowledge of the diagnostic possibilities and those features that distinguish one disease from another. Memorization alone is insufficient, e.g., photographic memory of a medical textbook would not make one an expert. But having access to detailed case-specific relevant information is critically important. In the past, clinicians primarily acquired clinical knowledge through their patient experiences, but now clinicians have access to a plethora of information sources. Clinicians of the future will be able to leverage the experiences of large numbers of other clinicians using electronic tools, but, as with the memorized textbook, the data alone will be insufficient for becoming an expert. Nonetheless, availability of these data removes one barrier for acquiring experience with connecting symptoms, signs, and risk factors to the possible diagnoses and identifying the additional distinguishing information necessary to confirm the diagnosis, thereby potentially facilitating the development of the working knowledge necessary for becoming an expert.

Despite all of the research seeking to understand expertise in medicine and other disciplines, it remains uncertain whether any didactic program can actually accelerate the progression from novice to expert or from experienced clinician to master clinician. Deliberate effortful practice (over an extended period of time, sometimes said to be 10 years or 10,000 practice hours) and personal coaching are two strategies often used outside medicine (e.g., music, athletics, chess) to cultivate expertise. Their use in developing medical expertise and maintaining or enhancing it has not yet been adequately explored. Some studies in medicine suggest that the most beneficial approach to education exposes students to both the signs and symptoms of specific diseases (disease pattern recognition) and, in addition, the lists of diseases that can present with specific symptoms and signs (differential diagnosis). Active learning opportunities useful for those in training include developing a personal learning system, e.g., systematically reflecting on diagnostic processes used (metacognition) and following-up to identify diagnoses and treatments for patients in their care.

DIAGNOSTIC VERSUS THERAPEUTIC DECISION-MAKING

The modern ideal of medical therapeutic decision-making is to "personalize" treatment recommendations. In the abstract, personalizing treatment involves combining the best available evidence about what works with an individual patient's unique features (e.g., risk factors, genomics, and comorbidities) and his or her preferences and health goals to craft an optimal treatment recommendation with the patient. Operationally, two different and complementary levels of personalization are possible: individualizing the risk of harm and benefit for the options being considered based on the specific patient characteristics (precision medicine), and personalizing the therapeutic decision process by incorporating the patient's preferences and values for the possible health outcomes. This latter process is sometimes referred to as shared decision-making and typically involves clinicians sharing their knowledge about the options and the associated consequences and trade-offs and patients sharing their health goals (e.g., avoiding a short-term risk of dying from coronary artery bypass grafting to see their grandchild get married in a few months).

Individualizing the evidence about therapy **does not** mean relying on physician impressions of benefit and harm from their personal experience. Because of small sample sizes and rare events, the chance of drawing erroneous causal inferences from one's own clinical experience is very high. For most chronic diseases, therapeutic effectiveness is only demonstrable statistically in large patient populations. It would be incorrect to infer with any certainty, for example, that treating a hypertensive patient with angiotensin-converting enzyme (ACE) inhibitors necessarily prevented a stroke from occurring during treatment, or that an untreated patient would definitely have avoided their stroke had they been treated. For many chronic diseases, a majority of patients will remain event free regardless of treatment choices; some will have events regardless of which treatment is selected; and those who avoided having an event through treatment cannot be individually identified. Blood pressure lowering, a readily observable surrogate endpoint, does not have a tightly coupled relationship with strokes prevented. Consequently, in most situations, demonstrating therapeutic effectiveness cannot rely simply on observing the outcome of an individual patient but should instead be based on large groups of patients carefully studied and properly analyzed.

Therapeutic decision-making, therefore, should be based on the best available evidence from clinical trials and well-done outcome studies. Trustworthy clinical practice guidelines that synthesize such evidence offer normative guidance for many testing and treatment decisions. However, all guidelines recognize that "one size fits all" recommendations may not apply to individual patients. Increased research into the heterogeneity of treatment effects seeks to understand how best to adjust group-level clinical evidence of treatment harms and benefits to account for the absolute level of risks faced by subgroups and even by individual patients, using, for example, validated clinical risk scores.

NONCLINICAL INFLUENCES ON CLINICAL DECISION-MAKING

More than three decades of research on variations in clinician practice patterns has identified important nonclinical forces that shape clinical decisions. These factors can be grouped conceptually into three overlapping categories: (1) factors related to an individual physician's practice, (2) factors related to practice setting, and (3) factors related to payment systems.

Factors Related to Practice Style To ensure that necessary care is provided at a high level of quality, physicians fulfill a key role in medical care by serving as the patient's advocate. Factors that influence performance in this role include the physician's knowledge, training, and experience. Clearly, physicians cannot practice EBM if they are unfamiliar with the evidence. As would be expected, specialists generally know the evidence in their field better than do generalists. Beyond published evidence and practice guidelines, a major set of influences on physician practice can be subsumed under the general concept of "practice style." The practice style serves to define norms of clinical behavior. Differing practice styles may be based on training, personal experience, and medical evidence. Beliefs about effectiveness of different therapies and preferred patterns of diagnostic test use are examples of different facets of a practice style. For example, cardiologists evaluating patients with lower risk chest pain symptoms often conceptualize their primary diagnostic objective as maximizing the detection of ischemia. For this reason, they may strongly favor stress imaging. Internists caring for the same patients may be more comfortable with initial use of exercise ECG testing without imaging. This latter practice style focuses less on ischemia detection and more on following guideline recommendations that indicate no outcome advantage for stress imaging in this context. Cardiologist may also favor a more liberal use of coronary angiography and revascularization in patients with stable ischemic symptoms relative to general internists.

Beyond the patient's welfare, physician perceptions about the risk of a malpractice suit resulting from either an erroneous decision or a bad outcome may drive clinical decisions and create a practice referred to as defensive medicine. This practice involves ordering tests and therapies with very small marginal benefits, ostensibly to preclude future criticism should an adverse outcome occur. With conscious or unconscious awareness of a connection to the risk of litigation or to payment, however, over time, such patterns of care may become accepted as part of the practice norm, thereby perpetuating their overuse, e.g., annual cardiac exercise testing in asymptomatic patients.

Practice Setting Factors Factors in this category relate to work systems including tasks and workflow (interruptions, inefficiencies, workload), technology (poor design or implementation, errors in use, failure, misuse), organizational characteristics (e.g., culture, leadership, staffing, scheduling), and the physical environment (e.g., noise, lighting, layout). *Physician-induced demand* is a term that refers to the repeated observation that once medical facilities and technologies become available to physicians, they will find ways to use them. Other environmental factors that can influence decision-making include the local availability of specialists for consultations and procedures; "high-tech" advanced imaging or procedure facilities such as MRI machines and proton beam therapy centers; and fragmentation of care.

Payment Systems Economic incentives are closely related to the other two categories of practice-modifying factors. Financial issues can exert both stimulatory and inhibitory influences on clinical practice. Historically, physicians are paid on a fee-for-service, capitation, or salary basis. In fee-for-service, physicians who do more get paid more, thereby encouraging overuse, consciously or unconsciously. When fees are reduced (discounted reimbursement), clinicians tend to increase the number of services provided to maintain revenue. Capitation, in contrast, provides a fixed payment per patient per year to encourage physicians to consider a global population budget in managing individual patients and ideally reducing the use of interventions with small marginal benefit. To discourage volume-based excessive utilization, fixed salary compensation plans pay physicians the same regardless of the clinical effort expended but may provide an (unintended) incentive to see fewer patients. In recognition of the nonsustainability of continued growth in medical expenditures and the opportunity costs associated with that (funds that might be more beneficially applied to education, energy, social welfare, or defense), current efforts seek to transition to a value-based payment system to reduce overuse and to reflect benefit. Work to define how to actually tie payment to value has mostly focused so far on "pay for performance" models. High-quality clinical trial evidence for the effectiveness of these models is still mostly lacking.

INTERPRETATION OF DIAGNOSTIC TESTS

Despite impressive technological advances in medicine over the past century, uncertainty still abounds and challenges all aspects of medical decision-making. Compounding this challenge, massive information overload characterizes modern medicine. Clinicians on average subscribe to seven journals, presenting them with >2500 new articles each year, and need access to 2 million pieces of information to practice medicine. Of course, to be useful, this information must be sifted for quality and examined for applicability for integration into patient-specific care. Although computers appear to offer an obvious solution both for information management and for quantification of medical care uncertainties, many practical problems remain to be solved before computerized decision support can be routinely incorporated into the clinical reasoning process in a way that demonstrably improves the quality of care. For the present, understanding the nature of diagnostic test information can help clinicians become more efficient users of such data. The next section reviews select concepts related to diagnostic testing.

DIAGNOSTIC TESTING: MEASURES OF TEST ACCURACY

The purpose of performing a test on a patient is to reduce uncertainty about the patient's diagnosis or prognosis in order to facilitate appropriate management. Although diagnostic tests commonly refer to laboratory (e.g., blood count) or imaging tests or procedures (e.g., colonoscopy or bronchoscopy), any information that changes a provider's understanding of the patient's problem qualifies as a diagnostic test. Thus, even the history and physical examination can be considered as diagnostic tests. In clinical medicine, it is common to reduce the results of a test to a dichotomous outcome, such as positive or negative, normal or abnormal. Although this simplification often suppresses useful information (such as the degree of abnormality), it facilitates illustrating some important principles of test interpretation that are described below.

The accuracy of any diagnostic test is assessed relative to a "gold standard," where a positive gold standard test defines the patients who have disease and a negative test securely rules out disease (Table 4-1). Characterizing the diagnostic performance of a new test requires identifying an appropriate population (ideally, patients representative of those in whom the new test would be used) and applying both the new and the gold standard tests to all subjects. Biased estimates of test performance occur when diagnostic accuracy is defined using an inappropriate population or one in which gold standard determination of disease status is incomplete. The accuracy of the new test in distinguishing disease from health is determined relative to the gold standard results and summarized in four estimates. The sensitivity or true-positive rate reflects how well the new test identifies patients with disease. It is the proportion of patients with disease (defined by the gold standard) who have a positive test. The proportion of patients with disease who have a negative test is the false-negative rate, calculated as 1 – sensitivity. The specificity, or true-negative rate, reflects how well

TABLE 4-1 Measures of Diagnostic Test Accuracy

	DISEASE STATUS	
TEST RESULT	**PRESENT**	**ABSENT**
Positive	True positives (TP)	False positives (FP)
Negative	False negatives (FN)	True negatives (TN)
Test Characteristics in Patients with Disease		
True-positive rate (sensitivity) = TP/(TP + FN)		
False-negative rate = FN/(TP + FN) = 1 – true-positive rate		
Test Characteristics in Patients without Disease		
True-negative rate (specificity) = TN/(TN + FP)		
False-positive rate = FP/(TN + FP) = 1 – true-negative rate		

the new test correctly identifies patients without disease. It is the proportion of patients without disease (defined by the gold standard) who have a negative test. The proportion of patients without disease who have positive test is the false-positive rate, calculated as 1 – specificity. In theory, a perfect test would be one with a sensitivity of 100% and a specificity of 100% and would completely distinguish patients with disease from those without it. A useful mnemonic to help remember the somewhat paradoxical relationship between what the test is best at technically versus what it is most useful for clinically is: a test with a very high sensitivity (Sn) when *negative* (N) helps *rule out* (out) disease (SnNout), and a test with a very high specificity (Sp) when *positive* (P) helps *rule in* (in) disease (SpPin).

Calculating sensitivity and specificity requires selection of a threshold value or cut point above which the test is considered "positive." Making the cut point "stricter" (e.g., raising it) lowers sensitivity but improves specificity, while making it "laxer" (e.g., lowering it) raises sensitivity but lowers specificity. This dynamic trade-off between more accurate identification of subjects with disease versus those without disease is often displayed graphically as a receiver operating characteristic (ROC) curve **(Fig. 4-1)** by plotting sensitivity (*y* axis) versus 1 – specificity (*x* axis). Each point on the curve represents a potential cut point with an associated sensitivity and specificity value. The area under the ROC curve often is used as a quantitative measure of the information content of a test. Values range from 0.5 (no diagnostic information from testing at all; the test is equivalent to flipping a coin) to 1.0 (perfect test). The choice of cut point should in theory reflect the relative harms and benefits of treatment for those without versus those with disease. For example, if treatment was safe with substantial benefit, then choosing a high-sensitivity cut point (upper right of the ROC curve) for a low-risk test may be appropriate (e.g., phenylketonuria in newborns), but if treatment had substantial risk for harm, then choosing a high-specificity cut point (lower left of the ROC curve) may be appropriate (e.g., chemotherapy for cancer). The choice of cut point may also depend on the prevalence of disease, with low prevalence placing a greater emphasis on the harms of false-positive tests (e.g., HIV testing in marriage applicants) or the harms of false-negative tests (e.g., HIV testing in blood donors).

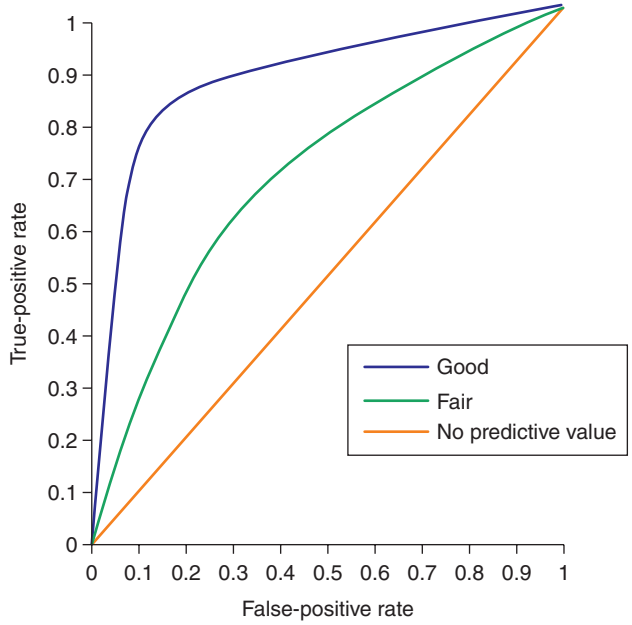

FIGURE 4-1 Each receiver operating characteristic (ROC curve) illustrates a trade-off that occurs between improved test sensitivity (accurate detection of patients with disease) and improved test specificity (accurate detection of patients without disease), as the test value defining when the test turns from "negative" to "positive" is varied. A 45° line would indicate a test with no predictive value (sensitivity = specificity at every test value). The area under each ROC curve is a measure of the information content of the test. Thus, a larger ROC area signifies increased diagnostic accuracy.

MEASURES OF DISEASE PROBABILITY AND BAYES' RULE

In the absence of perfect tests, the true disease state of the patient remains uncertain after every test. Bayes' rule provides a way to quantify the revised uncertainty using simple probability mathematics (and thereby avoid anchoring bias). It calculates the *posttest probability*, or likelihood of disease after a test result, from three parameters: the pretest probability of disease, the test sensitivity, and the test specificity. The *pretest probability* is a quantitative estimate of the likelihood of the diagnosis before the test is performed and is usually estimated from the prevalence of the disease in the underlying population (if known) or clinical context (e.g., age, sex, and type of chest pain). For some common conditions, such as CAD, existing nomograms and statistical models generate estimates of pretest probability that account for history, physical examination, and test findings. The posttest probability (also called the predictive value of the test, see below) is a recalibrated statement of the probability of the diagnosis, accounting for both pretest probability and test results. For the probability of disease following a positive test (i.e., positive predictive value), Bayes' rule is calculated as:

$$\text{Posttest probability} = \frac{\text{Pretest probability} \times \text{test sensitivity}}{\text{Pretest probability} \times \text{test sensitivity} + (1 - \text{Pretest probability}) \times (\text{false-positive test rate})}$$

For example, consider a 64-year-old woman with atypical chest pain who has a pretest probability of 0.50 and a "positive" diagnostic test result (assuming test sensitivity = 0.90 and specificity = 0.90).

$$\text{Posttest probability} = \frac{(0.50)(0.90)}{(0.50)(0.90)+(0.50)(0.10)} = 0.90$$

The term *predictive value* has often been used as a synonym for the posttest probability. Unfortunately, clinicians commonly misinterpret reported predictive values as intrinsic measures of test accuracy rather than calculated probabilities. Studies of diagnostic test performance compound the confusion by calculating predictive values from the same sample used to measure sensitivity and specificity. Such calculations are misleading unless the test is applied subsequently to populations with exactly the same disease prevalence. For these reasons, the term *predictive value* is best avoided in favor of the more descriptive posttest probability following a positive or a negative test result.

The nomogram version of Bayes' rule **(Fig. 4-2)** helps us to understand at a conceptual level how it estimates the posttest probability of disease. In this nomogram, the impact of the diagnostic test result is summarized by the likelihood ratio, which is defined as the ratio of the probability of a given test result (e.g., "positive" or "negative") in a patient with disease to the probability of that result in a patient without disease, thereby providing a measure of how well the test distinguishes those with from those without disease.

The *likelihood ratio for a positive test* is calculated as the ratio of the true-positive rate to the false-positive rate (or sensitivity/[1 – specificity]). For example, a test with a sensitivity of 0.90 and a specificity of 0.90 has a likelihood ratio of 0.90/(1 – 0.90), or 9. Thus, for this hypothetical test, a "positive" result is 9 times more likely in a patient with the disease than in a patient without it. Most tests in medicine have likelihood ratios for a positive result between 1.5 and 20. Higher values are associated with tests that more substantially increase the posttest likelihood of disease. A very high likelihood ratio positive (>10) usually implies high specificity, so a positive high specificity test helps "rule in" disease (the "SpPin" mnemonic introduced earlier). If sensitivity is excellent but specificity is less so, the likelihood ratio positive will be reduced substantially (e.g., with a 90% sensitivity but a 55% specificity, the likelihood ratio positive is 2.0).

The corresponding *likelihood ratio for a negative test* is the ratio of the false-negative rate to the true-negative rate (or [1 – sensitivity]/specificity).

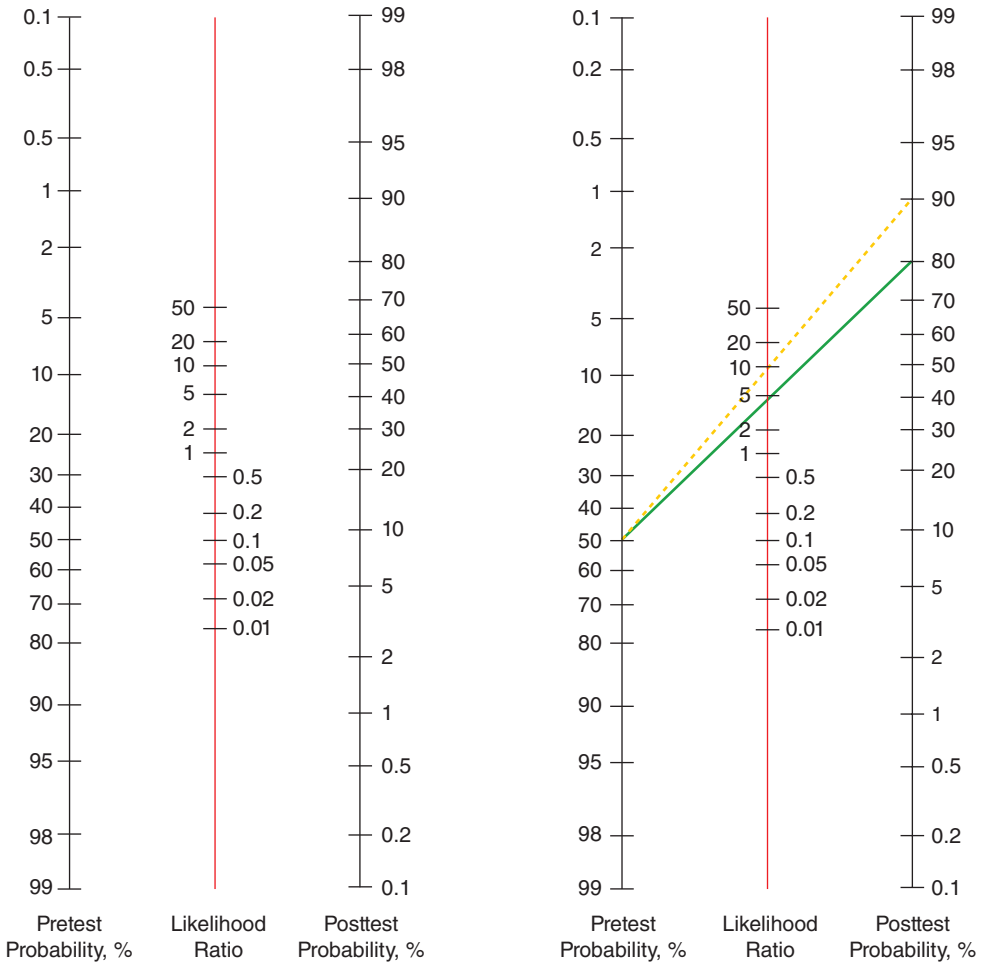

FIGURE 4-2 Nomogram version of Bayes' theorem used to predict the posttest probability of disease (right-hand scale) using the pretest probability of disease (left-hand scale) and the likelihood ratio for a positive or a negative test (middle scale). See text for information on calculation of likelihood ratios. To use, place a straightedge connecting the pretest probability and the likelihood ratio and read off the posttest probability. The right-hand part of the figure illustrates the value of a positive exercise treadmill test (likelihood ratio 4, *green line*) and a positive exercise thallium single-photon emission CT perfusion study (likelihood ratio 9, broken *yellow line*) in a patient with a pretest probability of coronary artery disease of 50%. *(Adapted from Centre for Evidence-Based Medicine: Likelihood ratios. Available at http://www.cebm.net/likelihood-ratios/.)*

Lower likelihood ratio negative values more substantially lower the posttest likelihood of disease. A very low likelihood ratio negative (falling below 0.10) usually implies high sensitivity, so a negative high sensitivity test helps "rule out" disease (the SnNout mnemonic). The hypothetical test considered above with a sensitivity of 0.9 and a specificity of 0.9 would have a likelihood ratio for a negative test result of (1 – 0.9)/0.9, or 0.11, meaning that a negative result is about one-tenth as likely in patients with disease than in those without disease (or about 10 times more likely in those without disease than in those with disease).

APPLICATIONS TO DIAGNOSTIC TESTING IN CAD

Consider two tests commonly used in the diagnosis of CAD: an exercise treadmill and an exercise single-photon emission CT (SPECT) myocardial perfusion imaging test **(Chap. 241)**. A positive treadmill ST-segment response has an average sensitivity of ~60% and an average specificity of ~75%, yielding a likelihood ratio positive of 2.4 (0.60/[1 – 0.75]) (consistent with modest discriminatory ability because it falls between 2 and 5). For a 41-year-old man with nonanginal pain and a 10% pretest probability of CAD, the posttest probability of disease after a positive result rises to only ~30%. For a 60-year-old woman with typical angina and a pretest probability of CAD of 80%, a positive test result raises the posttest probability of disease to ~95%.

In contrast, exercise SPECT myocardial perfusion test is more accurate for diagnosis of CAD. For simplicity, assume that the finding of a reversible exercise-induced perfusion defect has both a sensitivity and a specificity of 90% (a bit higher than reported), yielding a likelihood ratio for a positive test of 9.0 (0.90/[1 – 0.90]) (consistent with intermediate discriminatory ability because it falls between 5 and 10). For the same 10% pretest probability patient, a positive test raises the probability of CAD to 50% (Fig. 4-2). However, despite the differences in posttest probabilities between these two tests (30 vs 50%), the more accurate test may not improve diagnostic likelihood enough to change patient management (e.g., decision to refer to cardiac catheterization) because the more accurate test has only moved the physician from being fairly certain that the patient did not have CAD to a 50:50 chance of disease. In a patient with a pretest probability of 80%, exercise SPECT test raises the posttest probability to 97% (compared with 95% for the exercise treadmill). Again, the more accurate test does not provide enough improvement in posttest confidence to alter management, and neither test has improved much on what was known from clinical data alone.

In general, positive results with an accurate test (e.g., likelihood ratio for a positive test of 10) when the pretest probability is low (e.g., 20%) do not move the posttest probability to a range high enough to rule in disease (e.g., 80%). In screening situations, pretest probabilities are often particularly low because patients are asymptomatic. In such cases, specificity becomes especially important. For example, in screening first-time female blood donors without risk factors for HIV, a positive test raised the likelihood of HIV to only 67% despite a specificity of 99.995% because the prevalence was 0.01%. Conversely, with a high pretest probability, a negative test may not rule out disease adequately if it is not sufficiently sensitive. Thus, the largest change in diagnostic likelihood following a test result occurs when the clinician is most uncertain (i.e., pretest probability between 30 and 70%). For example, in patients with a pretest probability for CAD of 50%, a positive exercise treadmill test moves the posttest probability to 80% and a positive exercise SPECT perfusion test moves it to 90% (Fig. 4-2).

As presented above, Bayes' rule employs a number of important simplifications that should be considered. First, few tests provide only "positive" or "negative" results. Many tests have multidimensional outcomes (e.g., extent of ST-segment depression, exercise duration, and exercise-induced symptoms with exercise testing). Although Bayes' theorem can be adapted to this more detailed test result format, it is computationally more complex to do so. Similarly, when multiple sequential tests are performed, the posttest probability may be used as the pretest probability to interpret the second test. However, this simplification assumes conditional independence—that is, that the results of the first test do not affect the likelihood of the second test result—and this is often not true.

Finally, many texts assert that sensitivity and specificity are prevalence-independent parameters of test accuracy. This statistically useful assumption, however, is often incorrect. A treadmill exercise test, for example, has a sensitivity of ~30% in a population of patients with one-vessel CAD, whereas its sensitivity in patients with severe three-vessel CAD approaches 80%. Thus, the best estimate of sensitivity

to use in a particular decision may vary, depending on the severity of disease in the local population. A hospitalized, symptomatic, or referral population typically has a higher prevalence of disease and, in particular, a higher prevalence of more advanced disease than does an outpatient population. Consequently, test sensitivity will likely be higher in hospitalized patients and test specificity higher in outpatients.

STATISTICAL PREDICTION MODELS

Bayes' rule, when used as presented above, is useful in studying diagnostic testing concepts, but predictions based on multivariable statistical models can more accurately address these more complex problems by simultaneously accounting for additional relevant patient characteristics. In particular, these models explicitly account for multiple, even possibly overlapping, pieces of patient-specific information and assign a relative weight to each on the basis of its unique independent contribution to the prediction in question. For example, a logistic regression model to predict the probability of CAD ideally considers all the relevant independent factors from the clinical examination and diagnostic testing and their relative importance instead of the limited data that clinicians can manage in their heads or with Bayes' rule. However, despite this strength, prediction models are usually too complex computationally to use without a calculator or computer. Guideline-driven treatment recommendations based on statistical prediction models available online, e.g., the American College of Cardiology/American Heart Association risk calculator for primary prevention with statins and the CHA_2DS_2-VASC calculator for anticoagulation for atrial fibrillation, have generated more widespread usage. When electronic health records (EHRs) will provide sufficient platform support to allow for routine use of predictive models in clinical practice and increase their impact on clinical encounters and outcomes remains uncertain.

One reason for limited clinical use is that, to date, only a handful of prediction models have been validated sufficiently (for example, Wells criteria for pulmonary embolism; **Table 4-2**). The importance of independent validation in a population separate from the one used to develop the model cannot be overstated. An unvalidated prediction model should be viewed with the skepticism appropriate for any new drug or medical device that has not had rigorous clinical trial testing.

When statistical survival models in cancer and heart disease have been compared directly with clinicians' predictions, the survival models have been found to be more consistent, as would be expected, but not always more accurate. On the other hand, comparison of clinicians with websites and apps that generate lists of possible diagnoses to help patients with self-diagnosis found that physicians outperformed the currently available programs. For students and less-experienced clinicians, the biggest value of diagnostic decision support may be in extending diagnostic possibilities and triggering "rational override," but their impact on knowledge, information-seeking, and problem-solving needs additional research.

TABLE 4-2 Wells Clinical Prediction Rule for Pulmonary Embolism (PE)

CLINICAL FEATURE	POINTS
Clinical signs of deep-vein thrombosis	3
Alternative diagnosis is less likely than PE	3
Heart rate >100 beats/min	1.5
Immobilization ≥3 days or surgery in previous 4 weeks	1.5
History of deep-vein thrombosis or pulmonary embolism	1.5
Hemoptysis	1
Malignancy (with treatment within 6 months) or palliative	1
INTERPRETATION	
Score >6.0	High
Score 2.0–6.0	Intermediate
Score <2.0	Low

FORMAL DECISION SUPPORT TOOLS

DECISION SUPPORT SYSTEMS

Over the past 50 years, many attempts have been made to develop computer systems to aid clinical decision-making and patient management. Conceptually, computers offer several levels of potentially useful support for clinicians. At the most basic level, they provide ready access to vast reservoirs of information, which may, however, be quite difficult to sort through to find what is needed. At higher levels, computers can support care management decisions by making accurate predictions of outcome, or can simulate the whole decision process, and provide algorithmic guidance. Computer-based predictions using Bayesian or statistical regression models inform a clinical decision but do not actually reach a "conclusion" or "recommendation." Machine learning methods are being applied to pattern recognition tasks such as the examination of skin lesions and the interpretation of x-rays. Artificial intelligence (AI) systems attempt to simulate or replace human reasoning with a computer-based analogue. Natural language processing allows the system to access and process large amounts of data, both from the EHR and from the medical literature. To date, such approaches have achieved only limited success. The most prominent example, IBM's Watson program, introduced publicly in 2011, has yet to produce persuasive evidence of clinical decision support utility. Reminder or protocol-directed systems do not make predictions but use existing algorithms, such as guidelines or appropriate utilization criteria, to direct clinical practice. In general, however, decision support systems have so far had little impact on practice. Reminder systems built into EHRs have shown the most promise, particularly in correcting drug dosing and promoting adherence to guidelines. Checklists may also help avoid or reduce errors.

DECISION ANALYSIS

Compared with the decision support methods discussed earlier, decision analysis represents a normative prescriptive approach to decision-making in the face of uncertainty. Its principal application is in complex decisions. For example, public health policy decisions often involve *trade-offs* in length versus quality of life, benefits versus resource use, population versus individual health, and *uncertainty* regarding efficacy, effectiveness, and adverse events as well as *values* or preferences regarding mortality and morbidity outcomes.

One recent analysis using this approach involved the optimal screening strategy for breast cancer, which has remained controversial, in part because a randomized controlled trial to determine when to begin screening and how often to repeat screening mammography is impractical. In 2016, the National Cancer Institute–sponsored Cancer Intervention and Surveillance Network (CISNET) examined eight strategies differing by whether to initiate mammography screening at age 40, 45, or 50 years and whether to screen annually, biennially, or annually for women in their forties and biennially thereafter (hybrid). The six simulation models found biennial strategies to be the most efficient for average-risk women. Biennial screening for 1000 women from age 50–74 years versus no screening avoided seven breast cancer deaths. Screening annually from age 40–74 years avoided three additional deaths but required 20,000 additional mammograms and yielded 1988 more false-positive results. Factors that influenced the results included patients with a 2–4-fold higher risk for developing breast cancer in whom annual screening from age 40–74 years yielded similar benefits as biennial screening from age 50–74. For average-risk patients with moderate or severe comorbidities, screening could be stopped earlier, at age 66–68 years.

This analysis involved six models that reproduced epidemiologic trends and a screening trial result, accounted for digital technology and treatments advances, and considered quality of life, risk factors, breast density, and comorbidity. It provided novel insights into a public health problem in the absence of a randomized clinical trial and helped weigh the pros and cons of such a health policy recommendation. Although such models have been developed for selected clinical problems, their benefit and application to individual real-time clinical management has yet to be demonstrated.

DIAGNOSIS AS AN ELEMENT OF QUALITY OF CARE

High-quality medical care begins with accurate diagnosis. The incidence of diagnostic errors has been estimated by a variety of methods including postmortem examinations, medical record reviews, and medical malpractice claims, with each yielding complementary but different estimates of this quality of care patient-safety problem. In the past, diagnostic errors tended to be viewed as a failure of individual clinicians. The modern view is that they are mostly a system of care deficiencies. Current estimates suggest that nearly everyone will experience at least one diagnostic error in their lifetime, leading to mortality, morbidity, unnecessary tests and procedures, costs, and anxiety.

Solutions to the "diagnostic errors as a system of care" problem have focused on system-level approaches, such as decision support and other tools integrated into EHRs. The use of checklists has been proposed as a means of reducing some of the cognitive errors discussed earlier in the chapter, such as premature closure. While checklists have been shown to be useful in certain medical contexts, such as operating rooms and intensive care units, their value in preventing diagnostic errors that lead to patient adverse events remains to be shown.

EVIDENCE-BASED MEDICINE

Clinical medicine is defined traditionally as a practice combining medical knowledge (including scientific evidence), intuition, and judgment in the care of patients **(Chap. 1)**. Evidence-based medicine (EBM) updates this construct by placing much greater emphasis on the processes by which clinicians gain knowledge of the most up-to-date and relevant clinical research to determine for themselves whether medical interventions alter the disease course and improve the length or quality of life. The phrase "evidence-based medicine" is now used so often and in so many different contexts that many practitioners are unaware of its original meaning. The intention of the EBM program, as described in the early 1990s by its founding proponents at McMaster University, becomes clearer through an examination of its four key steps:

1. Formulating the management question to be answered
2. Searching the literature and online databases for applicable research data
3. Appraising the evidence gathered with regard to its validity and relevance
4. Integrating this appraisal with knowledge about the unique aspects of the patient (including the patient's preferences about the possible outcomes)

The process of searching the world's research literature and appraising the quality and relevance of studies can be time-consuming and requires skills and training that most clinicians do not possess. In a busy clinical practice, the work required is also logistically not feasible. This has led to a focus on finding recent systematic overviews of the problem in question as a useful shortcut in the EBM process. Systematic reviews are regarded by some as the highest level of evidence in the EBM hierarchy because they are intended to comprehensively summarize the available evidence on a particular topic. To avoid the potential biases found in narrative review articles, predefined reproducible explicit search strategies and inclusion and exclusion criteria seek to find all of the relevant scientific research and grade its quality. The prototype for this kind of resource is the Cochrane Database of Systematic Reviews. When appropriate, a meta-analysis is used to quantitatively summarize the systematic review findings (discussed further below).

Unfortunately, systematic reviews are not uniformly the acme of the EBM process they were initially envisioned to be. In select circumstances, they can provide a much clearer picture of the state of the evidence than is available from any individual clinical report, but their value is less clear when only a few trials are available, when trials and observational studies are mixed, or when the evidence base is only observational. They cannot compensate for deficiencies in the underlying research available, and many are created without the requisite clinical insights. The medical literature is now flooded with systematic reviews of varying quality and clinical utility. The peer review system has, unfortunately, not proved to be an effective arbiter of quality of these papers. Therefore, systematic reviews should be used with circumspection in conjunction with selective reading of some of the best empirical studies.

SOURCES OF EVIDENCE: CLINICAL TRIALS AND REGISTRIES

The notion of learning from observation of patients is as old as medicine itself. Over the past 50 years, physicians' understanding of how best to turn raw observation into useful evidence has evolved considerably. Medicine has received a hard refresher lesson in this process from COVID-19 pandemic. Starting in the spring of 2020, case reports, personal and institutional anecdotal experience, and small single-center case series started appearing in the peer-reviewed literature and within months turned into a flood of confusing and often contradictory evidence. Observational reports of treatments for COVID-19 fueled the confusion. Despite >40,000 publications appearing in the first 7 months of the pandemic, an enormous amount of uncertainty around prevention, diagnosis, treatment, and prognosis of the disease remained. Many of the early 2020 publications were either small observational series or reviews of published series, neither of which can resolve the key uncertainties clinicians need to address in caring for these patients. These small observational studies often have substantial limitations in validity and generalizability, and although they may generate important hypotheses or be the first reports of adverse events or therapeutic benefit, they have no role in formulating modern standards of practice. The major tools used to develop reliable evidence consist of randomized clinical trials supplemented strategically by large (high-quality) observational registries. A registry or database typically is focused on a disease or syndrome (e.g., different types of cancer, acute or chronic CAD, pacemaker capture, or chronic heart failure), a clinical procedure (e.g., bone marrow transplantation, coronary revascularization), or an administrative process (e.g., claims data used for billing and reimbursement).

By definition, in observational data, the investigator does not control patient care. Carefully collected prospective observational data, however, can at times achieve a level of evidence quality approaching that of major clinical trial data. At the other end of the spectrum, data collected retrospectively (e.g., chart review) are limited in form and content to what previous observers recorded and may not include the specific research data being sought (e.g., claims data). Advantages of observational data include the inclusion of a broader population as encountered in practice than is typically represented in clinical trials because of their restrictive inclusion and exclusion criteria. In addition, observational data provide primary evidence for research questions when a randomized trial cannot be performed. For example, it would be difficult to randomize patients to test diagnostic or therapeutic strategies that are unproven but widely accepted in practice, and it would be unethical to randomize based on sex, racial/ethnic group, socioeconomic status, or country of residence or to randomize patients to a potentially harmful intervention, such as smoking or deliberately overeating to develop obesity.

A well-done prospective observational study of a particular management strategy differs from a well-done randomized clinical trial most importantly by its lack of protection from treatment selection bias. The use of observational data to compare diagnostic or therapeutic strategies assumes that sufficient uncertainty and heterogeneity exists in clinical practice to ensure that similar patients will be managed differently by diverse physicians. In short, the analysis assumes that a sufficient element of randomness (in the sense of disorder rather than in the formal statistical sense) exists in clinical management. In such cases, statistical models attempt to adjust for important imbalances to "level the playing field" so that a fair comparison among treatment options can be made. When management is clearly not random (e.g., all eligible left main CAD patients are referred for coronary bypass surgery), the problem may be too confounded (biased) for statistical correction, and observational data may not provide reliable evidence.

In general, the use of concurrent controls is vastly preferable to that of historical controls. For example, comparison of current surgical management of left main CAD with medically treated patients with left main CAD during the 1970s (the last time these patients were routinely treated with medicine alone) would be extremely misleading because "medical therapy" has substantially improved in the interim.

Randomized controlled clinical trials include the careful prospective design features of the best observational data studies but also include the use of random allocation of treatment. This design provides the best protection against measured and unmeasured confounding due to treatment selection bias (a major aspect of internal validity). However, the randomized trial may not have good external validity (generalizability) if the process of recruitment into the trial resulted in the exclusion of many potentially eligible subjects or if the nominal eligibility for the trial describes a very heterogeneous population.

Consumers of medical evidence need to be aware that randomized trials vary widely in their quality and applicability to practice. The process of designing such a trial often involves many compromises. For example, trials designed to gain U.S. Food and Drug Administration (FDA) approval for an investigational drug or device must fulfill regulatory requirements (such as the use of a placebo control) that may result in a trial population and design that differ substantially from what practicing clinicians would find most useful.

META-ANALYSIS

The Greek prefix *meta* signifies something at a later or higher stage of development. Meta-analysis is research that combines and summarizes the available evidence quantitatively. Although it is used to examine nonrandomized studies, meta-analysis is most useful for summarizing all available randomized trials examining a particular therapy used in a specific clinical context. Ideally, unpublished trials should be identified and included to avoid publication bias (i.e., missing "negative" trials that may not be published). Furthermore, the best meta-analyses obtain and analyze individual patient-level data from all trials rather than using only the summary data from published reports. Nonetheless, not all published meta-analyses yield reliable evidence for a particular problem, so their methodology should be scrutinized carefully to ensure proper study design and analysis. The results of a well-done meta-analysis are likely to be most persuasive if they include at least several large-scale, properly performed randomized trials. Meta-analysis can especially help detect benefits when individual trials are inadequately powered (e.g., the benefits of streptokinase thrombolytic therapy in acute MI demonstrated by ISIS-2 in 1988 were evident by the early 1970s through meta-analysis). However, in cases in which the available trials are small or poorly done, meta-analysis should not be viewed as a remedy for deficiencies in primary trial data or trial design.

Meta-analyses typically focus on summary measures of relative treatment benefit, such as odds ratios or relative risks. Clinicians should also examine what absolute risk reduction (ARR) can be expected from the therapy. A metric of absolute treatment benefit that is frequently reported is the number needed to treat (NNT) to prevent one adverse outcome event (e.g., death, stroke). NNT should not be interpreted literally as a causal statement. NNT is simply 1/ARR. For example, if a hypothetical therapy reduced mortality rates over a 5-year follow-up by 33% (the relative treatment benefit) from 12% (control arm) to 8% (treatment arm), the ARR would be 12% – 8% = 4% and the NNT would be 1/.04, or 25. This does not mean literally that 1 patient benefits and 24 do not. However, it can be conceptualized as an informal measure of treatment efficiency. If the hypothetical treatment was applied to a lower-risk population, say, with a 6% 5-year mortality, the 33% relative treatment benefit would reduce absolute mortality by 2% (from 6% to 4%), and the NNT for the same therapy in this lower-risk group of patients would be 50. Although not always made explicit, comparisons of NNT estimates from different studies should account for the duration of follow-up used to create each estimate. In addition, the NNT concept assumes a homogeneity in response to treatment that may not be accurate. The NNT is simply another way of summarizing the absolute treatment difference and does not provide any unique information.

CLINICAL PRACTICE GUIDELINES

Per the 1990 Institute of Medicine definition, clinical practice guidelines are "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances." This definition emphasizes several crucial features of modern guideline development. First, guidelines are created by using the tools of EBM. In particular, the core of the development process is a systematic literature search followed by a review of the relevant peer-reviewed literature. Second, guidelines usually are focused on a clinical disorder (e.g., diabetes mellitus, stable angina pectoris) or a health care intervention (e.g., cancer screening). Third, the primary objective of guidelines is to improve the quality of medical care by identifying care practices that should be routinely implemented, based on high-quality evidence and high benefit-to-harm ratios for the interventions. Guidelines are intended to "assist" decision-making, not to define explicitly what decisions should be made in a particular situation, in part because guideline-level evidence alone is never sufficient for clinical decision-making (e.g., deciding whether to intubate and administer antibiotics for pneumonia in a terminally ill individual, in an individual with dementia, or in an otherwise healthy 30-year-old mother).

Guidelines are narrative documents constructed by expert panels whose composition often is determined by interested professional organizations. These panels vary in expertise and in the degree to which they represent all relevant stakeholders. The guideline documents consist of a series of specific management recommendations, a summary indication of the quantity and quality of evidence supporting each recommendation, an assessment of the benefit-to-harm ratio for the recommendation, and a narrative discussion of the recommendations. Many recommendations simply reflect the expert consensus of the guideline panel because literature-based evidence is insufficient or absent. A recent examination of this issue in cardiovascular guidelines showed that <15% of guideline recommendations were based on the highest level of clinical trial evidence, and this proportion had not improved in 10 years despite a substantial number of trials being conducted and published. The final step in guideline construction is peer review, followed by a final revision in response to the critiques provided.

Guidelines are closely tied to the process of quality improvement in medicine through their identification of evidence-based best practices. Such practices can be used as quality indicators. Examples include the proportion of acute MI patients who receive aspirin upon admission to a hospital and the proportion of heart failure patients with a depressed ejection fraction treated with an ACE inhibitor.

CONCLUSIONS

Thirty years after the introduction of the EBM movement, it is tempting to think that all the difficult decisions practitioners face have been or soon will be solved and digested into practice guidelines and computerized reminders. However, EBM provides practitioners with an ideal rather than a finished set of tools with which to manage patients. Moreover, even with such evidence, it is always worth remembering that the response to therapy of the "average" patient represented by the summary clinical trial outcomes may not be what can be expected for the specific patient sitting in front of a provider in the clinic or hospital. In addition, meta-analyses cannot generate evidence when there are no adequate randomized trials, and most of what clinicians confront in practice will never be thoroughly tested in a randomized trial. For the foreseeable future, excellent clinical reasoning skills and experience supplemented by well-designed quantitative tools and a keen appreciation for the role of individual patient preferences in their health care will continue to be of paramount importance in the practice of clinical medicine.

5 Precision Medicine and Clinical Care

The Editors

DISEASE NOSOLOGY AND PRECISION MEDICINE

Modern disease nosology arose in the late nineteenth century and represented a clear departure from the holistic, limited descriptions of disease dating to Galen. In this rubric, the definition of any disease is largely based on clinicopathologic observation. As the correlation between clinical signs and symptoms with pathoanatomy required autopsy material, diseases tended to be characterized by the end organ in which the primary syndrome was manifest and by late-stage presentations. Morgagni institutionalized this framework with the publication of *De Sedibus et Causis Morborum per Anatomen Indagatis* in 1761, in which he correlated the clinical features of patients with more than 600 autopsies at the University of Padua, demonstrating an anatomic basis for disease pathophysiology. Clinicopathologic observation served as the basis for inductive generalization coupled with the application of Occam's razor in which disease complexity was reduced to its simplest possible form. While this approach to defining human disease has held sway for over a century and facilitated the conquest of many diseases previously considered incurable, overly inclusive and simplified Oslerian diagnostics suffer from significant shortcomings. These include, but are not limited to, failure to distinguish the underlying etiology of different diseases with common pathophenotypes. For example, many different diseases can cause end-stage kidney disease or heart failure. Over time, the classification of neurodegenerative disorders or lymphomas, as well as many other diseases, is becoming more refined and precise as the underlying etiologies are identified. These distinctions are important for providing predictable prognostic information for individual patients with even highly prevalent diseases. Additionally, therapies may be ineffective owing to a lack of understanding of the often subtle molecular complexities of specific disease drivers.

Beginning in the mid-twentieth century, the era of molecular medicine offered the idealized possibility of identifying the underlying molecular basis of every disease. Using a conventional reductionist paradigm, physician-scientists explored disease mechanism at ever-increasing molecular depth, seeking the single (or limited number of) molecular cause(s) of many human diseases. Yet, as effective as this now conventional scientific approach was at uncovering many disease mechanisms, the clinical manifestations of very few diseases could be explained on the basis of a single molecular mechanism. Even knowledge of the globin β chain mutation that causes sickle cell disease does not predict the many different manifestations of the disease (stroke syndrome, painful crises, and hemolytic crisis, among others). Clearly, the profession had expected too much from oversimplified reductionism and failed to take into consideration the extraordinary biologic variety and its accompanying molecular and genetic complexity that underpin both normal and pathologic diversity. The promise of the Human Genome Project provided new tools and approaches and unleashed efforts to identify a monogenic, oligogenic, or polygenic cause for every disease (allowing for environmental modulation). Yet, once again, disappointment reigned as the pool of genomes expanded without the expected revelations (aside from rare variants). The arc of progressive reductionism (as illustrated for tuberculosis in **Fig. 5-1**) in refining and explaining disease reached a humbling plateau, revealing the need for new approaches to understand better the etiology, manifestations, and progression of most diseases. The stage was set for a return to holism. However, in contrast to the holism of ancient physicians, we adopted one that is integrative, taking genomic context into account in all dimensions. In the course of elaborating this complex pathobiologic landscape, disease definition must become more precise and progressively more individualized, setting the stage for what we term *precision medicine*.

Oversimplification of phenotype is a natural outgrowth of the observational scientific method. Categorizing individuals as falling into groups or clusters that are reasonably similar simplifies the task of the diagnostician and also facilitates the application of "specific" therapies more broadly. Biomedicine has been viewed as less quantitative and precise than other scientific disciplines, with biologic and pathobiologic diversity (biologic "noise") viewed as the norm. Thus, distilling such observational complexity to a fundamental group of symptoms or signs that are reasonably invariant across a group of sick individuals has served as the basis for the approach to disease and its treatment since the earliest days of medicine. This approach to diagnosis and therapy has remained in place into the twenty-first century, serving as the basis for the development of standard diagnostic tests and of broadly applied drug therapies. Targeting larger groups of patients is efficient when applied to large populations. As successful as this approach has been in advancing medical care, it is important to point out its limitations, which include significant predictive inaccuracies and sizeable segments of the disease population who do not respond to the most "effective" drugs (upward of 60% by some estimates). Clearly, a more nuanced approach to diagnosis and therapy is required to achieve better prognostic and therapeutic outcomes.

Turning first to phenotype, astute clinicians know full well the subtle and vivid differences in presentation that are often manifest among individuals with the same disease. In some cases, these differences in pathophenotype lead to new subclassifications of the disease, such as heart failure with preserved ejection fraction versus heart failure with reduced ejection fraction. Often, these relatively crude efforts at making diagnoses more precise are driven by new technologies or new ways of applying established technologies. In other cases, differences in pathophenotype are more subtle, not necessarily clinically apparent, and often driven by measures of endophenotype, such as distinctions among vasculitides facilitated by refinements in serologies or immunophenotyping. The impetus to create these subclasses of disease is largely determined by the need to improve prognosis and apply more precise and effective therapies. Based on these guiding principles, many experienced clinicians will argue—and rightly so—that they have been practicing personalized, precision medicine throughout their careers: they characterize each patient's illness in great detail, and choose therapies that respect and are guided by those individualized clinical and laboratory features, limited though they may be.

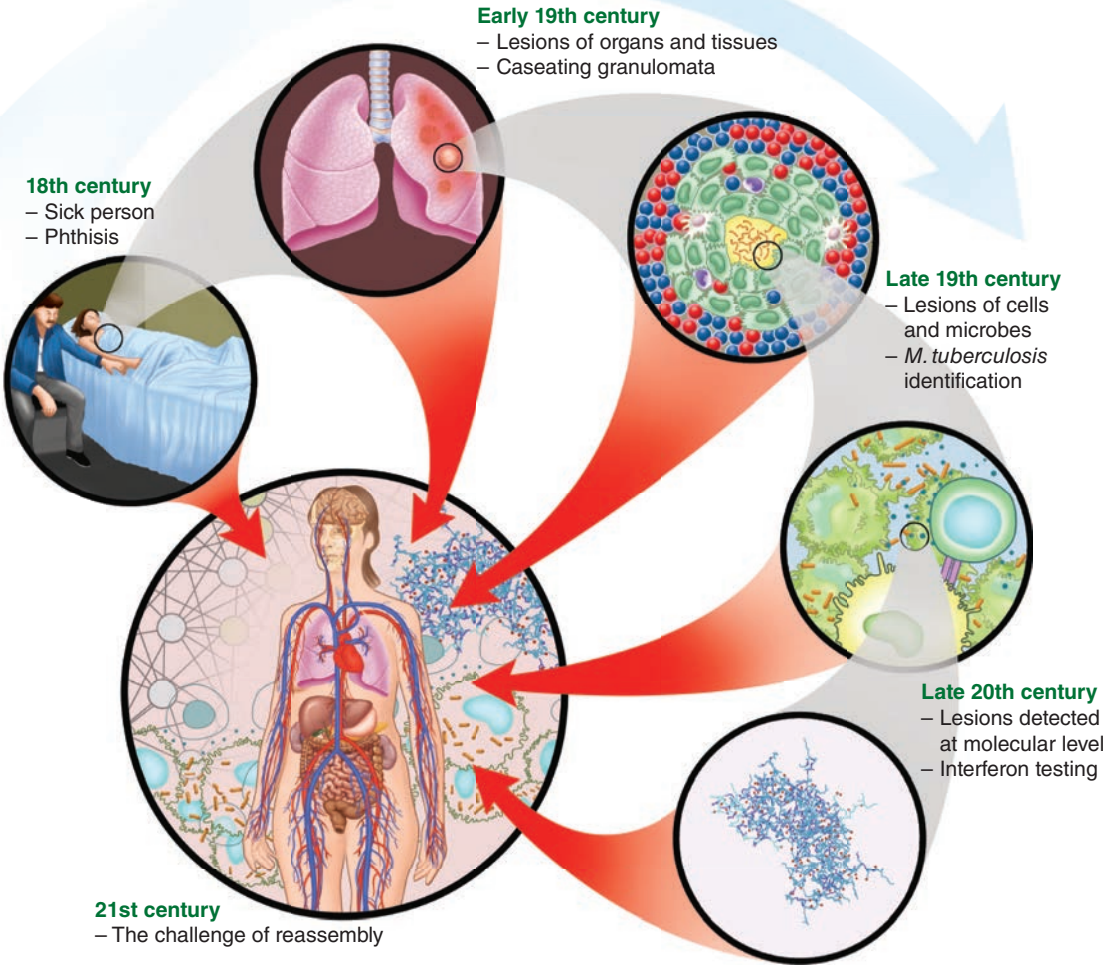

FIGURE 5-1 Arc of reductionism in medicine. *(From JA Greene, J Loscalzo. Putting the patient back together–social medicine, network medicine, and the limits of reductionism. N Engl J Med 377:2493, 2017. Copyright © 2017 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

For many diseases, genomic variation, whether inherited or acquired, provides opportunities to refine diagnostic precision with even greater fidelity and predictive accuracy. For this reason, the field of precision medicine has now entered a new era that couples the molecular reductionism of the last century with an integrative, systems-level understanding of the basis for pathophenotype. Equally important, modern genomics has established that genomic context, sometimes referred to as modifier genes, is distinctive for each individual person; hence, understanding that context provides the insight necessary to predict how a primary disease driver or drivers may manifest a clinical pathophenotype—e.g., why some individuals with sickle cell anemia will develop stroke, while others will develop acute chest syndrome. *This concept that primary genetic and/or environmental drivers of a disease differentially affect disease expression based on an individual's unique genomic context serves as the ultimate basis for much of what we denote as precision medicine.*

To develop a precision medicine strategy for any disease, the clinician needs to be aware of two important, confounding principles. First, patients with different diseases can manifest similar pathophenotypes, i.e., *convergent phenotypes*. Examples of this principle include the hypertrophied myocardium found in hypertrophic cardiomyopathy, infiltrative cardiomyopathies, critical aortic stenosis, and untreated, long-standing hypertension; and the thrombotic microangiopathy found in malignant hypertension, scleroderma renal crisis, thrombotic thrombocytopenic purpura, eclampsia, and antiphospholipid syndrome. Second, patients with the same basic disease can manifest very different pathophenotypes, i.e., *divergent phenotypes* **(Chap. 466)**. Examples of this principle include the different clinical manifestations of cystic fibrosis or sickle cell disease and the incomplete penetrance of many common genetic diseases. These common presentations of different diseases and different presentations of the same disease are both a consequence of genomic context coupled with unique exposures over an individual's lifetime **(Fig. 5-2)**. Understanding the interplay among these many complex molecular determinants of disease expression is essential for the success of precision medicine.

Given the complexity of the genomic and environmental context of an individual, one must ask the question: How precise do we need to be in order to practice effective precision medicine? Complete knowledge of a person's comprehensive genome (DNA, gene expression, mitochondrial function, proteome, metabolome, posttranslational modification of the proteome, and metagenome, among others) and quantitative assessments of environmental and social history are not possible to acquire; yet, this shortcoming does not render the general problem intractable. Owing to the fact that the molecular networks that govern phenotype are overdetermined (i.e., redundant) and that there are primary drivers of disease expression that are modified in a weighted way by other genomic features of an individual, the practice of precision medicine can be realized without complete knowledge of all dimensions of the genome. Examples of how best to realize this strategy are discussed later in this chapter.

REQUIREMENTS FOR PRECISION MEDICINE

The essential elements of any precision medicine effort include phenotyping, endophenotyping (defining the characteristics of a disorder that are not readily observable), and genomic profiling **(Fig. 5-3)**. While subtle distinctions among individuals with the same disease are well known to clinicians, formalizing these nuanced differences is critical for achieving more precise phenotypes. Deep phenotyping requires a

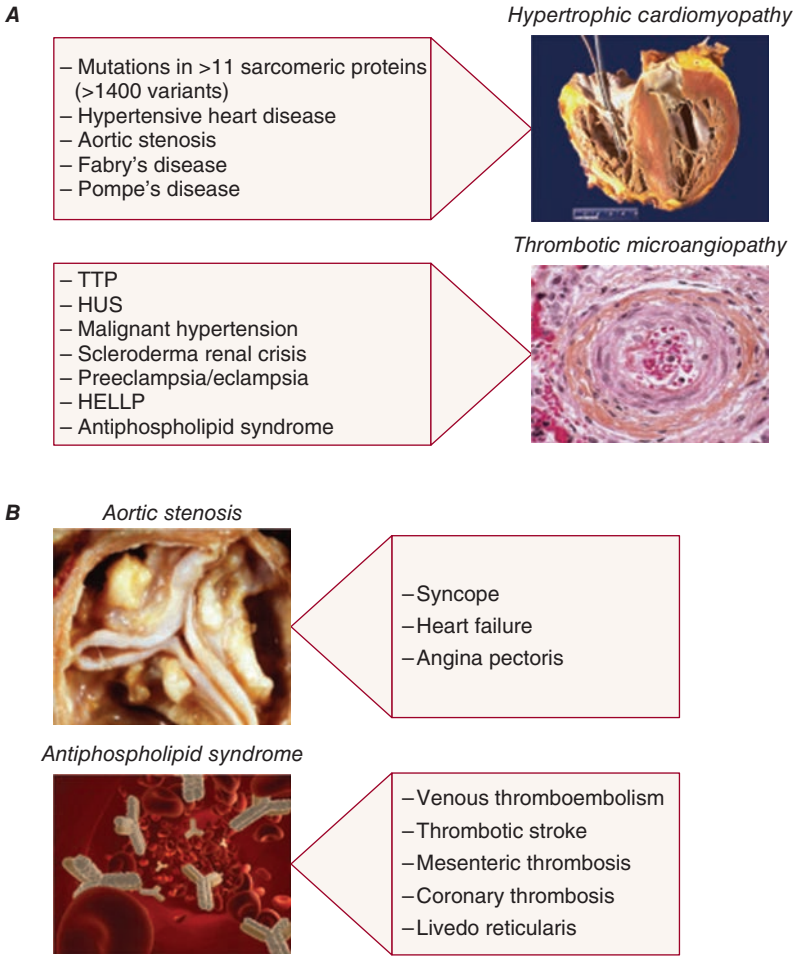

FIGURE 5-2 Convergent and divergent phenotypes. Examples of the former (***A***) include hypertrophic cardiomyopathy and thrombotic microangiopathy, and examples of the latter, and (***B***) include aortic stenosis and antiphospholipid syndrome, each of which can have several distinct clinical presentations. HELLP, hemolysis, elevated liver enzymes, and a low platelet count; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

detailed history, including family history and environmental exposures, as well as relevant (physiologic) functional studies and imaging, including molecular imaging where appropriate. Biochemical, immunologic, and molecular tests of body fluids provide additional detail to the overall phenotype. Importantly, these objective laboratory tests together with functional studies compose an assessment of the endophenotype (or endotype) of an individual, refining the overall discriminant power of the evaluation. One additional concept that has gained traction in recent years is the notion of orthogonal phenotyping, i.e., assessing clinical, molecular, imaging, or functional (endo)phenotypes seemingly unrelated to the clinical presentation. These features further enhance the ability to distinguish (sub) phenotypes and derive from the fact that diseases can be subtly (subclinically) manifest in organ systems different from that in which the primary symptoms or signs are expressed. While some diseases are well known to affect multiple organ systems (e.g., systemic lupus erythematosus) and in many cases involvement of those many systems is assessed at initial diagnosis, such is not the case for most other diseases. As we begin to understand the differences in the organ-specific expression of genomic variants that drive or modify disease, it is becoming increasingly apparent that orthogonal—or more appropriately, unbiased comprehensive—phenotyping should become the norm.

Genomic profiling must next be coupled to detailed phenotyping. The complex levels of genomic assessment continue to mature and include DNA sequencing (exomic, whole genome), gene expression (mRNA and protein expression), and metabolomics. In addition, the epigenome, the posttranslationally modified proteome, and the metagenome (the personal microbiome of an individual) are gaining traction as additional elements of comprehensive genomics (Chap. 483). Not all of these genomic features are yet available for clinical laboratory testing, and those that are available are largely confined to blood testing. While DNA sequencing using whole blood would generally apply to any organ-based disease,

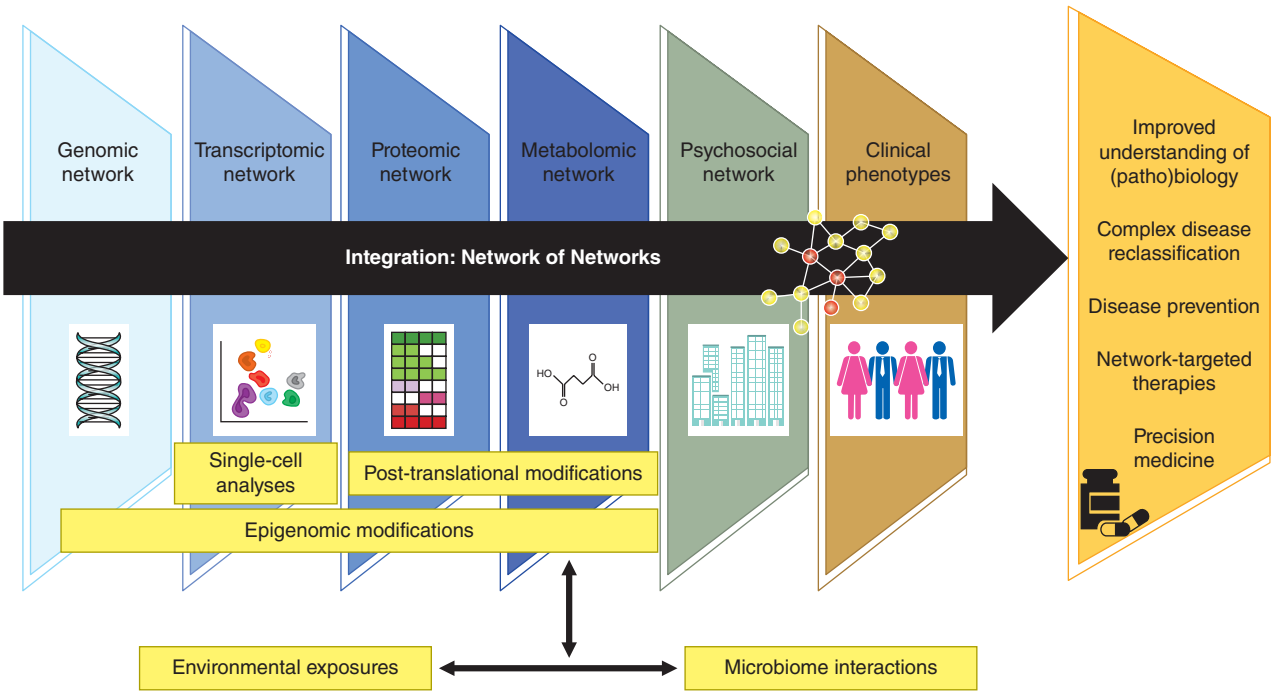

FIGURE 5-3 Universe of precision medicine. The totality of precision medicine incorporates multidimensional biologic networks, the integration of which leads to a network of networks whose components interact with each other and with environmental exposures to yield a distinctive phenotype or pathophenotype. *(Reproduced with permission from LY-H Lee, J Loscalzo: Network medicine in pathobiology. Am J Pathol 189:1311, 2019.)*

gene expression, metabolomics, and epigenetics are often tissue specific. As tissue specimens cannot always or easily be obtained from the organ of interest, attempts at correlating whole-blood mRNA, protein, or metabolite profiles with those of the involved organ are critical for precise prognostics and therapeutic choices. In many cases, systemic consequences to an organ-specific disease (e.g., systemic inflammatory responses in individuals with atherosclerosis) can be ascertained and may provide useful prognostic information or therapeutic strategies. These biomarker signatures are the subject of ongoing discovery and have provided useful guidance toward improved diagnostic precision in many diseases. However, in many diseases, the correlations between these plasma or blood markers and organ-based diseases are weak, indicating a need to analyze each condition and each resulting signature before applying it to clinical decision-making. It is important to note that one of the key determinants of the functional consequences of a genetic variant believed to drive a disease phenotype is not simply its expression in a tissue of interest but, more importantly, the coexpression of protein binding partners in that same tissue comprising specific (dys)functional pathways that govern phenotype **(Fig. 5-4)**. An alternative strategy currently under investigation is the conversion of induced pluripotent stem cells from a patient into a cell type of interest for gene expression or metabolomics study. As rational as this approach seems from first principles, it is important to note that gene expression patterns in these induced, differentiated cell types are not completely consonant with their native counterparts, offering often limited additional information at potentially great additional expense.

While phenotype features of many chronic diseases are assessed over time, genomic features tend to be limited to single time point sampling. Time trajectories are extremely informative in precision genotyping and phenotyping, with gene expression patterns and phenotypes changing over time in different ways among different patients with the same overarching phenotype. Cost, feasible sampling frequency, predictive power, and therapeutic choices will all drive the optimal strategy for the acquisition of timed samples in any given patient; however, with continued cost reduction in genomics technologies, this limitation may be progressively mitigated and clinical application may become a reality.

One important class of diseases that does not have most of these limitations in genomic profiling is cancer. Cancers can be (and are) sampled (biopsied) frequently to monitor temporal changes in the somatically mutating oncogenome and its consequences for the limited number of well-defined oncogenic driver pathways **(Chap. 68)**. A unique limitation of cancer in this regard, however, is that the frequency of somatic mutations over time (and, especially, with treatment) is great and the functional consequences of many of these mutations unknown. Equally important, assessment of single-cell mRNA sequencing patterns demonstrates great variability between apparently similar cells, challenging functional interpretation. Lastly, in solid tumors, stromal cells interact in a variety of ways (e.g., metabolically) with the associated malignant cells, and their gene expression signatures are also modified by the changing somatic mutational landscape of the primary malignancy. Thus, while much more information can be obtained over time in most cancer patients, the interpretation of these rich data sets continues to remain largely semi-empirical.

The possibility of identifying specific therapeutic targets remains a major goal of precision medicine. Doing so requires more than simple DNA sequencing and must include analysis of some level of gene expression, ideally in the involved organ(s). In addition to demonstrating the expression of a variant protein in the organ, one must ideally also demonstrate its functional consequences, which requires ascertaining the expression of binding partner proteins and the functional pathways they comprise. To achieve this goal, a variety of approaches have been tried, one of the most successful of which is the construction of the protein-protein interactome (the interactome), which is a comprehensive network map of the protein-protein interactions in a cell or organ of interest **(Chap. 486)**. This template provides information on the subnetworks that govern a disease phenotype (disease modules), which can be further individualized by incorporating individual variants and differentially expressed proteins that are patient specific. This type of analysis leads to the creation of an individual "reticulome" or reticulotype, which links the genotype to the phenotype of an individual **(Fig. 5-5)**. Using this approach, one can identify potential drug targets in a rational way or can even repurpose existing drugs by demonstrating the proximity of a known drug target to a disease module of interest **(Fig. 5-6)**. For example, in multicentric Castleman's disease, a disorder of unclear etiology, recognition that the PI3K/Akt/mTOR pathway is highly activated led to trials with an existing, approved drug, sirolimus. Precision medicine offers additional opportunities for optimizing the utilization of a drug by assessing the individualized pharmacogenomics of its disposition and metabolism, as demonstrated for the adverse consequences of variants in *TPMT* on azathioprine metabolism and in *CYP2C19* on clopidogrel metabolism **(Chap. 68)**.

EXAMPLES OF PRECISION MEDICINE APPLICATIONS

The field of precision medicine did not appear abruptly in medical history but, rather, evolved gradually as clinicians became more aware of differences among patients with the same disease. With the advent of modern genomics, in the ideal situation, these phenotype differences can now be mapped to genotype differences. Thus, we can consider precision medicine from the perspective of the pregenomic era and the postgenomic era. Pregenomic precision medicine was applied to many diseases as therapeutic classes expanded for those disorders. A prime example of this approach is in the field of heart failure, where diuretics, digoxin, beta blockers, afterload-reducing agents, venodilators, renin-angiotensin-aldosterone inhibitors, and brain natriuretic peptide (nesiritide) are commonly used in some combination for most patients. The choice of agents is governed by the evidence basis for their use, but tailored to the primary pathophysiologic phenotypes manifest in a patient, such as congestion, hypertension, and impaired contractility. These treatments were developed in the latter half of the last century based on empiric observation, reductionist experiments of specific pathways believed to be involved in the pathophysiology, and clinical response in prospective trials. As phenotyping became more refined (e.g., echocardiographic assessments of ventricular function and tissue Doppler characterization of ventricular relaxation), the syndrome was subclassified into heart failure with reduced ejection fraction and heart failure with preserved ejection fraction, the latter of which does not respond well to any of the classes of therapeutic agents currently available. In the postgenomic era, ever more refined and detailed methods are under investigation to characterize pathophenotypes as well as genotypes, which may then be matched to the idealized combination of therapeutic classes of agents.

Pulmonary arterial hypertension is another disease for which definitive therapies straddle the pre- and postgenomic eras of precision medicine. Prior to the 1990s, there were no effective therapies for this highly morbid and lethal condition. With the advent of molecular and biochemical characterization of vascular abnormalities in individuals with established disease, however, therapies with agents that restored normal vascular function improved morbidity and mortality. These included calcium channel blockers, prostacyclin congeners, and endothelin receptor antagonists. As genomic characterization of the disease has progressed over the past two decades, there is increasing recognition of distinct genotypes that yield unique phenotypes **(Chap. 283)**, such as the demonstration of a primarily fibrotic endophenotype governed by the (oxidized) scaffold protein NEDD-9 and its aldosterone-dependent, TGF-β-independent enhancement of collagen III expression. This approach will continue to evolve as therapies become more effective (e.g., for perivascular fibrosis) and therapeutic choices better targeted to individual patients.

Precision genomics has also led to a new classification of the dementias, conditions previously thought to have a single cause with varied clinical expression. These disorders can now be categorized based on the genes and pathways involved and the site where aggregated proteins first form and then spread in the nervous system. For example, the varied clinical presentations of frontotemporal dementia, including progressive aphasia, behavioral disturbances, and dementia with amyotrophic lateral sclerosis, can now be linked to specific genotypes and susceptible cells **(Chap. 432)**. In prion diseases, the clinical phenotype

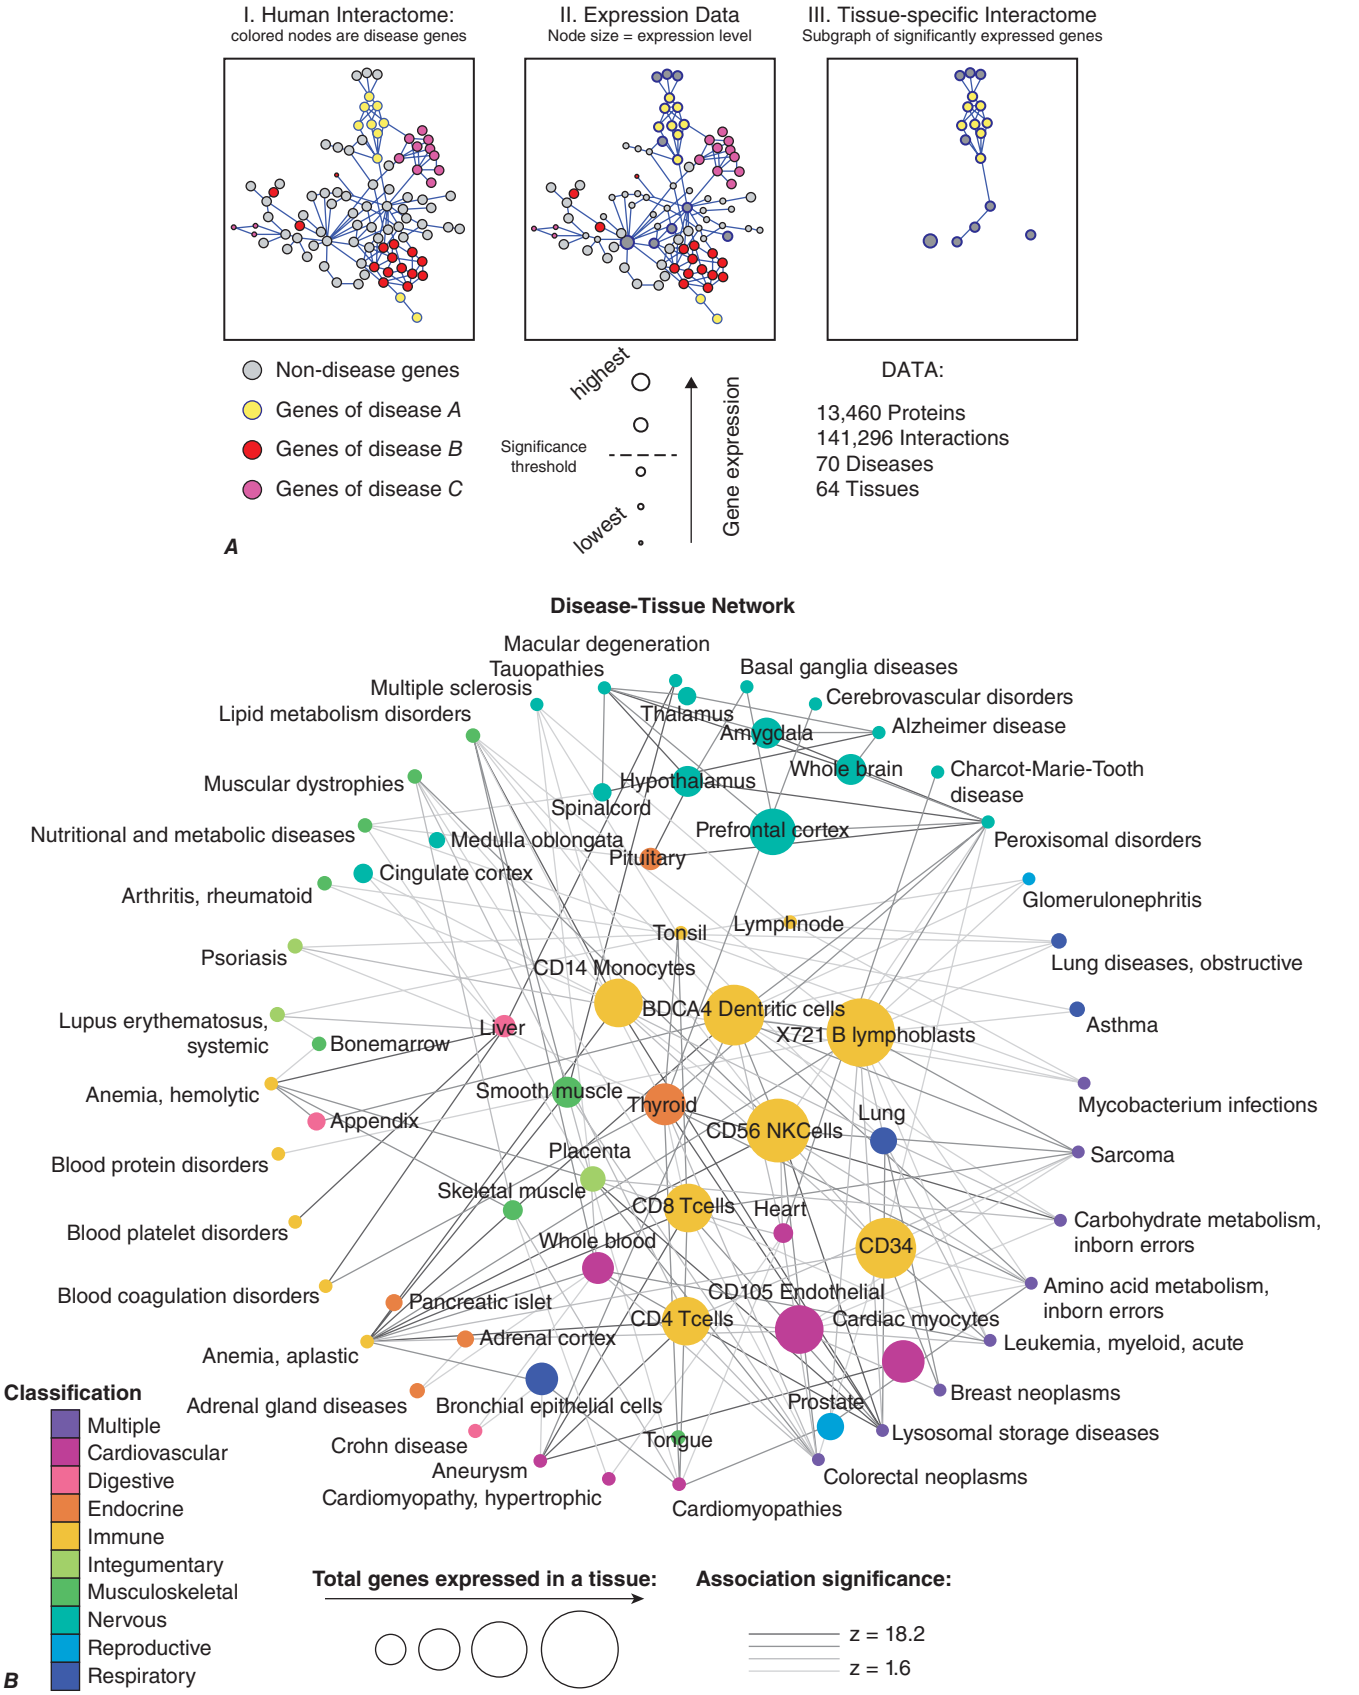

FIGURE 5-4 Gene expression and phenotype. ***A.*** The human protein-protein interactome is constructed, and a specific disease module is identified (I); gene expression within this module is ascertained (II); and the tissue specificity of gene expression is determined (III). This analysis leads to a reduction of the total number of disease module genes that govern phenotype in a specific organ, which is a reflection of the specific pathway (or pathways) that is (or are) expressed in their functional entirety in that tissue. ***B.*** A disease-tissue bipartite network is constructed wherein specific tissues are placed within the circle and linked to diseases shown on the circumference. Nodes are colored according to tissue classification, the sizes of nodes are proportional to the total number of genes expressed in them, and the widths (shades) of the lines or edges correspond to the significance of the associations with specific diseases. *(From M Kitsak et al: Tissue Specificity of Human Disease Module. Sci Rep 6: 35241, 2016, Figure 4.)*

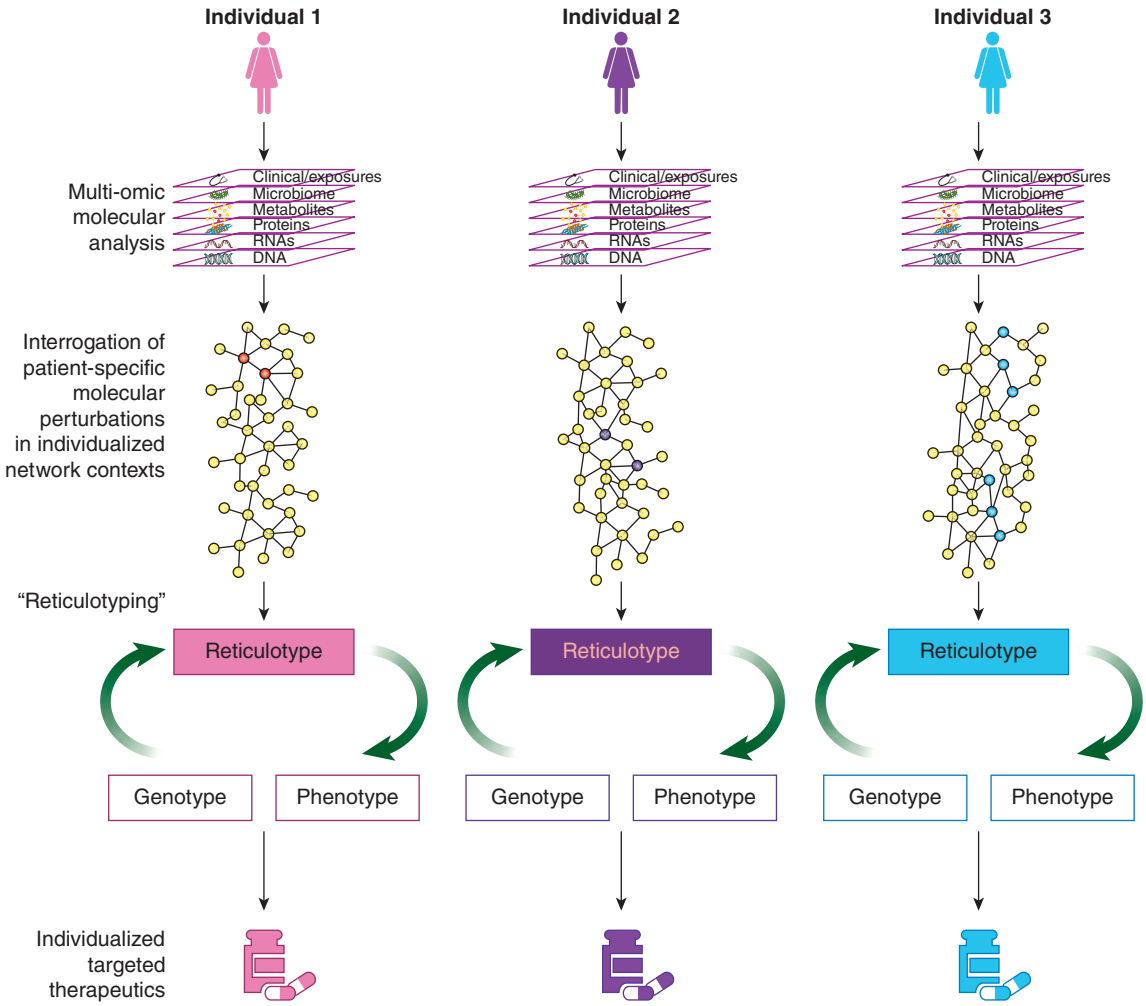

FIGURE 5-5 Reticulotype. Patient-specific genotype-phenotype relationships by multiomic network structures are depicted for three individuals. Each individual's unique molecular perturbations (genetic variants, differentially expressed genes) are examined within the context of the subject's unique integrative biologic network or reticulome derived from these multiomic analyses. These unique reticulotypes then serve as the basis for patient-specific, precision therapies. *(Reproduced with permission from LYH Lee, J Loscalzo: Network Medicine in Pathobiology. Am J Pathol 189:1311, 2019.)*

is determined by specific germline mutations present in the prion protein **(Chap. 438)**. Discovery of autoantibodies against aquaporin-4 (AQP-4) and myelin oligodendrocyte glycoprotein (MOG) has allowed neuromyelitis optica, previously considered a multiple sclerosis–like disorder, to be classified as a separate entity requiring different treatment **(Chap. 445)**. Similarly, in myasthenia gravis, the identification of novel autoantibodies now permits stratification and a more finely tuned precision approach to therapy **(Chap. 448)**.

Precision medicine approaches to cancers have, of course, become the prime example of the opportunity that this strategy offers. In the pregenomic era, chemotherapy was widely used with variable success despite continued efforts to characterize the molecular features of the specific tumors and their semi-empiric responses to specific chemotherapeutic agents. As cancer genome sequencing evolved, however, it became apparent that there are a limited number of oncogenic pathways (<20) that are represented in the great majority of malignancies, without regard for the organ in which the disease was primarily manifest. These genomic signatures served as a template for precisely targeted therapies that have led to dramatic changes in response to treatment, including, for example, imatinib (and congeners) for Bcr-Abl tyrosine kinase activity in chronic myelogenous leukemia, erlotinib for *EGFR*-mutant non-small cell lung cancers, and ibrutinib for Bruton tyrosine kinase in chronic lymphocytic leukemia, among many others.

As exciting as these approaches have been, there are at least three primary challenges associated with precision therapeutics that are unique to cancer: (1) the mutational landscape continues to evolve as the disease progresses, and therapy often (if not invariably) leads to selection for resistant clones; (2) the likelihood that any cancer can be definitively cured by any single agent, no matter its exquisite precision, is quite limited, necessitating

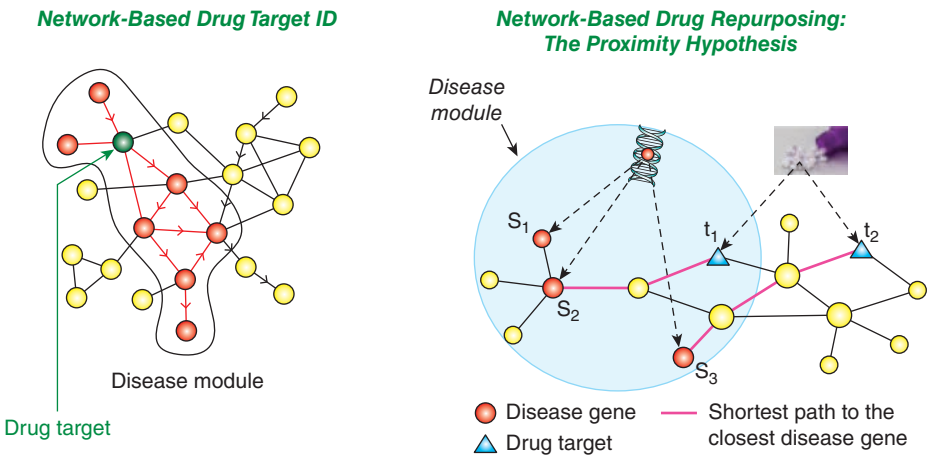

FIGURE 5-6 Network-based precision drug repurposing. *(Adapted from F Cheng et al: A genome-wide positioning systems network algorithm for in silico drug repurposing. Nat Commun 10:3476, 2019.)*

AFKEBOOKS
SINCE 2013

the development of rational polypharmaceutical approaches that take into account alternative pathways that achieve the same oncogenic goals as the primary targeted pathway, complicating drug development; and (3) there is marked genomic heterogeneity in many malignancies arguing that targeting a specific pathway—even with multiple drugs—may not ultimately succeed over the long term owing to the continued and heterogeneous evolution of the genomic landscape within a tumor within a patient. Despite these serious shortcomings, the application of progressively more refined and precisely targeted therapies used alone and in combination, such as with immune modulators, continues to offer great promise for the treatment of these diseases. In some ways, these approaches in cancer mirror earlier strategies in the treatment of infectious diseases in which the identification of the causative organism and its sensitivity to potential antimicrobials allows precision approaches to treatment. Combinatorial antimicrobial treatments represent an effective strategy to address acquired resistance. These diagnostic and therapeutic strategies can be applied without detailed knowledge of personalized responses to the infection or treatment (aside from serious adverse effects) with good outcomes in most cases. Yet, individuals do respond differently to specific infections and their treatments, possibly driven by different endophenotypes (e.g., different inflammatory responses), suggesting that more precise knowledge of these precise mechanistic differences may yield improved prognosis and therapeutic approaches. As with cancer, immune modulation, particularly for immune exhaustion in chronic infections, represents a new frontier, again amenable to the personalized, precise analyses described above.

THE FUTURE OF PRECISION MEDICINE

Precision medicine clearly holds great promise for the future of the practice of medicine. For precision medicine to continue to evolve successfully, however, several requirements will need to be met. First, both deeply refined personal phenotypic data and genomic data are essential as the information with which precision analysis is performed. These data sets are quite large and require sufficient storage for analysis, especially for individuals in whom time trajectories are acquired (as should be the case for every person). Equally important, the analytical methods required to extract useful information from these data sets are evolving and themselves quite complex. While great progress has been made in genomics and biochemical testing, our ability to capture meaningful immunologic endophenotypes and environmental exposures is limited by comparison. Machine learning and artificial (auxiliary) intelligence methods will be essential for extracting optimal information from these data sets, which include not only pathways that can be uniquely targeted therapeutically but also individualized genomic or phenotypic signatures that are highly predictive of outcome, with or without therapy. Gathering sufficient information on the "normal" segments of the population is also required to ensure appropriate comparison data sets for optimal prediction.

Second, phenotyping must continue to expand and become dimensionally richer. The phenotypic features included in this data gathering must incorporate not only data relevant to the clinical presentation but also orthogonal phenotypic data that may yield useful information on disease trajectory or preclinical disease markers. Personal device data, environmental exposure history, social network interactions, and health system data will all be incorporated increasingly in defining phenotype and will require great efforts on the part of the medical informatics community to harmonize data sets, standardize data collection, and optimize/standardize data analysis (Fig. 5-7).

Third, perhaps the greatest challenge to making precision medicine the standard approach to illness will be to determine the minimal data set required to predict outcome and response to therapy. Gathering data is comparatively simple; however, analyzing it to eliminate redundant information in these overdetermined biologic systems, weighting the determinants of an outcome, and using the data as phenomic/genomic signatures that are easier to collect than comprehensive, unbiased data sets are the ideal goals—a major challenge, but not insurmountable. Rapidly evolving machine learning and artificial intelligence strategies will also be essential for maximal success.

To return to the question of how precise precision medicine needs to be in order to be useful, please refer to Fig. 5-8 where the approaches

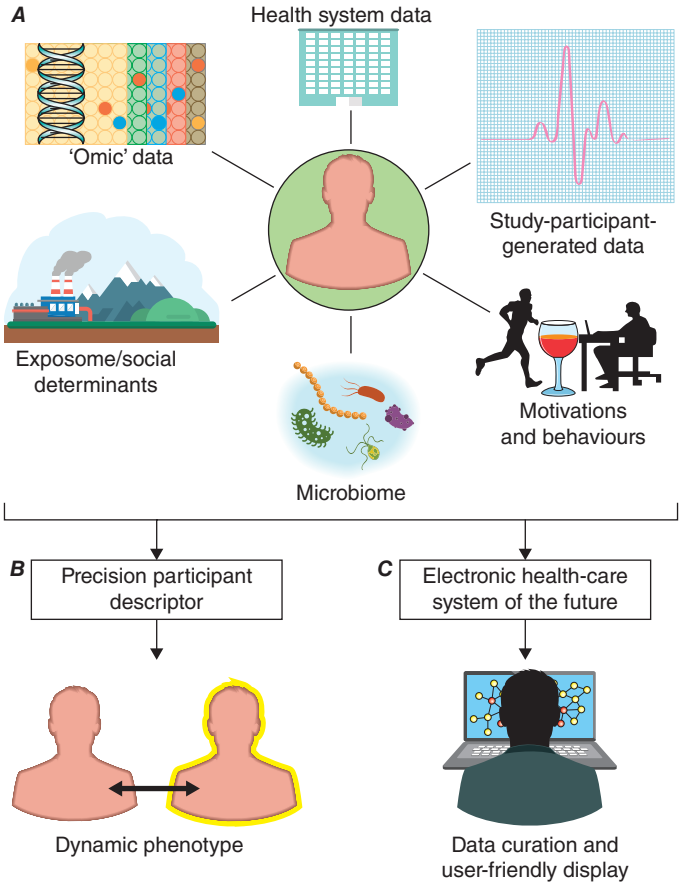

FIGURE 5-7 Big data in precision medicine. ***A.*** Six dimensions by which individuals may be characterized in the precision medicine era are described. ***B.*** The precision participant descriptor integrates the data from these six dimensions and varies over time. ***C.*** The electronic medical record increasingly must evolve to provide curated precision data in a user-friendly way. *(Reproduced with permission from EM Antman, J Loscalzo: Precision medicine in cardiology. Nat Rev Cardiol 13:591, 2016.)*

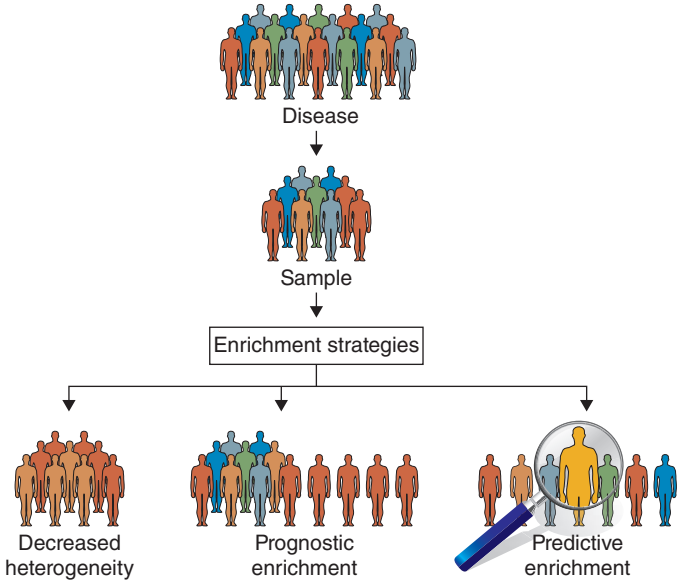

FIGURE 5-8 The basis for precision medicine. The notion of precision medicine evolved, in part, from clinical trial design. From the entire population of patients with the disease of interest, a sample cohort of individuals is enrolled in the trial that ideally is representative of the entire distribution. Enrichment strategies developed to decrease heterogeneity or increase the representation of individuals with a high risk of observed outcomes (prognostic enrichment) facilitate trial conduct but do not necessarily improve precision in defining treatment response. The predictive enrichment strategy utilizes both trial participant characteristics and data from experiments conducted before or during (adaptive design) the trial to improve the prediction of who is likely to have a more pronounced response to the treatment under study. *(Reproduced with permission from EM Antman, J Loscalzo: Precision medicine in cardiology. Nat Rev Cardiol 13:591, 2016.)*

to clinical trial design meant to improve therapeutic signal are illustrated. Decreasing heterogeneity and enriching the study population will enhance the effect size, but these strategies are based on analyses of prior data sets that define those individuals who are more likely than not to respond to a therapy. By contrast, the notion of predictive enrichment follows from the information provided by a detailed, big data–driven analysis of individuals that explores phenotypic and genomic features used to predict response. These features need not be precisely met by each patient; however, they can be collated or clustered to define a reasonably sized cohort predicted to respond in a particular way within certain confidence bounds. In this way, the boundaries to the practice of precision medicine are imprecise strictly speaking, but sufficiently predictive to be practical from the perspectives of clinical care and cost-effectiveness.

6 Screening and Prevention of Disease

Katrina A. Armstrong, Gary J. Martin

A primary goal of health care is to prevent disease or detect it early enough that intervention will be more effective. Tremendous progress has been made toward this goal over the past 50 years. Screening tests are available for many common diseases and encompass biochemical (e.g., cholesterol, glucose), physiologic (e.g., blood pressure, growth curves), radiologic (e.g., mammogram, bone densitometry), and cytologic (e.g., Pap smear) approaches. Effective preventive interventions have resulted in dramatic declines in mortality from many diseases, particularly infections. Preventive interventions include counseling about risk behaviors, vaccinations, medications, and, in some relatively uncommon settings, surgery. Preventive services (including screening tests, preventive interventions, and counseling) are different than other medical interventions because they are proactively administered to healthy individuals instead of in response to a symptom, sign, or diagnosis. Thus, the decision to recommend a screening test or preventive intervention requires a particularly high bar of evidence that testing and intervention are both practical and effective.

Because population-based screening and prevention strategies must be extremely low risk to have an acceptable benefit-to-harm ratio, the ability to target individuals who are more likely to develop disease could enable the application of a wider set of potential approaches and increase efficiency. Currently, there are many types of data that can predict disease incidence in an asymptomatic individual. Germline genomic data have received the most attention to date, at least in part because mutations in high-penetrance genes have clear implications for preventive care **(Chap. 467)**. Women with mutations in either *BRCA1* or *BRCA2*, the two major breast cancer susceptibility genes identified to date, have a markedly increased risk (five- to twentyfold) of breast and ovarian cancer. Screening and prevention recommendations include prophylactic oophorectomy and breast magnetic resonance imaging (MRI), both of which are considered to incur too much harm for women at average cancer risk. Some women with *BRCA* mutations opt for prophylactic mastectomy to dramatically reduce their breast cancer risk. Although the proportion of common disease explained by high-penetrance genes appears to be relatively small (5–10% of most diseases), mutations in rare, moderate-penetrance genes, and variants in low-penetrance genes, also contribute to the prediction of disease risk. Most recently, polygenic risk scores combining information about variants across hundreds of genes are being evaluated for identifying individuals at high risk of coronary heart disease and other conditions. The advent of affordable whole exome/whole genome sequencing is likely to speed the dissemination of these tests into clinical practice and may transform the delivery of preventive care.

Other forms of "omic" data also have the potential to provide important predictive information. Proteomics and metabolomics can provide insight into gene function, but it has proven challenging to develop reliable, predictive measures using these platforms. More recently, it has become possible to measure the presence of mutations in DNA circulating in the bloodstream and in stool, with early promising evidence that these assays can be used to detect cancer before existing screening tests.

In addition to "omic" data, imaging data are increasingly being integrated into risk-stratified prevention approaches as evidence grows about the predictive ability of these data. For example, coronary computed tomography (CT) scans are used in many preventive cardiology programs to inform decisions about beginning statin therapy when there is conflicting or uncertain information from other risk assessment approaches. Of course, these data may also be helpful in predicting the risk of harms from screening or prevention, such as the risk of a false-positive mammogram.

In addition to advances in risk prediction, there are several other reasons that screening and prevention are likely to gain importance in medical care in the near term. New imaging modalities are being developed that promise to detect changes at the cellular and subcellular levels, greatly increasing the probability that early detection improves outcomes. The rapidly growing understanding of the biologic pathways underlying initiation and progression of many common diseases has the potential to transform the development of preventive interventions, including chemoprevention. Furthermore, screening and prevention offer the promise of both improving health and sparing the costs of disease treatment, an issue that will continue to gain importance as long as health care costs in the United States remain a concern to patients, government agencies, and insurers.

This chapter will review the basic principles of screening and prevention in the primary care setting. Recommendations for specific disorders such as cardiovascular disease, diabetes, and cancer are provided in the chapters dedicated to those topics.

BASIC PRINCIPLES OF SCREENING

The basic principles of screening populations for disease were published by the World Health Organization in 1968 **(Table 6-1)**.

In general, screening is most effective when applied to relatively common disorders that carry a large disease burden **(Table 6-2)**. The five leading causes of mortality in the United States are heart diseases, malignant neoplasms, chronic obstructive pulmonary disease,

TABLE 6-1 Principles of Screening
The condition should be an important health problem.
There should be a treatment for the condition.
Facilities for diagnosis and treatment should be available.
There should be a latent stage of the disease.
There should be a test or examination for the condition.
The test should be acceptable to the population.
The natural history of the disease should be adequately understood.
There should be an agreed policy on whom to treat.
The cost of finding a case should be balanced in relation to overall medical expenditure.

accidents, and cerebrovascular diseases. Thus, many screening strategies are targeted at these conditions. From a global health perspective, these conditions are priorities, but malaria, malnutrition, AIDS, tuberculosis, and violence also carry a heavy disease burden **(Chap. 472)**.

Having an effective treatment for early disease has proven challenging for some common diseases. For example, although Alzheimer's disease is the sixth leading cause of death in the United States, there are no curative treatments and no evidence that early treatment improves outcomes. Lack of facilities for diagnosis and treatment is a particular challenge for developing countries and may change screening strategies, including the development of "see and treat" approaches such as those currently used for cervical cancer screening in some countries. A long latent or preclinical phase where early treatment increases the chance of cure is a hallmark of many cancers; for example, polypectomy prevents progression to colon cancer. Similarly, early identification of hypertension or hyperlipidemia allows therapeutic interventions that reduce the long-term risk of cardiovascular or cerebrovascular events. In contrast, lung cancer screening has historically proven more challenging because most tumors are not curable by the time they can be detected on a chest x-ray. However, the length of the preclinical phase also depends on the level of resolution of the screening test, and this situation changed with the development of chest CT. Low-dose chest CT scanning can detect tumors earlier and has been demonstrated to reduce lung cancer mortality by 20% in individuals who had at least a 30-pack-year history of smoking. The short interval between the ability to detect disease on a screening test and the development of incurable disease also contributes to the limited effectiveness of mammography screening in reducing deaths from some forms of breast cancer. At the other end of the spectrum, the early detection of prostate cancer may not lead to a difference in the mortality rate because the disease is often indolent and competing morbidities, such as coronary artery disease, may ultimately cause mortality **(Chap. 70)**. This uncertainty about the natural history is also reflected in the controversy about treatment of prostate cancer, further contributing to the challenge of screening in this disease. Finally, screening programs can incur significant economic costs that must be considered in the context of the available resources and alternative strategies for improving health outcomes.

METHODS OF MEASURING HEALTH BENEFITS

Because screening and preventive interventions are recommended to asymptomatic individuals, they are held to a high standard for demonstrating a favorable risk-benefit ratio before implementation. In general, the principles of evidence-based medicine apply to demonstrating the efficacy of screening tests and preventive interventions, where randomized controlled trials (RCTs) with mortality outcomes are the gold standard. However, because RCTs are often not feasible, observational studies, such as case-control designs, have been used to assess the effectiveness of some interventions such as colonoscopy for colorectal cancer screening. For some strategies, such as Pap smear screening for cervical cancer, the only data available are ecologic data demonstrating dramatic declines in mortality.

Irrespective of the study design used to assess the effectiveness of screening, it is critical that disease incidence or mortality is the primary endpoint rather than length of disease survival. This is important because lead time bias and length time bias can create the appearance of an improvement in disease survival from a screening test when there is no actual effect. Lead time bias occurs because screening identifies a case before it would have presented clinically, thereby creating the perception that a patient lived longer after diagnosis simply by moving the date of diagnosis earlier rather than the date of death later. Length time bias occurs because screening is more likely to identify slowly progressive disease than rapidly progressive disease. Thus, within a fixed period of time, a screened population will have a greater proportion of these slowly progressive cases and will appear to have better disease survival than an unscreened population.

A variety of endpoints are used to assess the potential gain from screening and preventive interventions.

1. *The absolute and relative impact of screening on disease incidence or mortality*. The absolute difference in disease incidence or mortality between a screened and nonscreened group allows the comparison of size of the benefit across preventive services. A meta-analysis of Swedish mammography trials (ages 40–70) found that ~1.2 fewer women per 1000 would die from breast cancer if they were screened over a 12-year period. By comparison, at least ~3 lives per 1000 would be saved from colon cancer in a population (aged 50–75) screened with annual fecal occult blood testing (FOBT) over a 13-year period, and an estimated 20–24 lives per 1000 would be saved over the entire 25-year period. Based on this analysis, colon cancer screening may actually save more women's lives than does mammography. However, the relative impact of FOBT (30% reduction in colon cancer death) is similar to the relative impact of mammography (14–32% reduction in breast cancer death), emphasizing the importance of both relative and absolute comparisons.
2. *The number of subjects screened to prevent disease or death in one individual*. The inverse of the absolute difference in mortality is the number of subjects who would need to be screened or receive a preventive intervention to prevent one death. For example, 731 women aged 65–69 would need to be screened by dual-energy x-ray absorptiometry (DEXA) (and treated appropriately) to prevent one hip fracture from osteoporosis.
3. *Increase in average life expectancy for a population*. Predicted increases in life expectancy for various screening and preventive interventions are listed in **Table 6-3**. It should be noted, however, that the increase in life expectancy is an average that applies to a population, not to an individual. In reality, the vast majority of the population does not derive any benefit from a screening test. A small subset of patients, however, will benefit greatly. For example, Pap smears do not benefit the 98% of women who never develop cancer of the cervix. However, for the 2% who would have developed cervical cancer, Pap smears may add as much as 25 years to their lives. Some studies suggest that a 1-month gain of life expectancy is a reasonable goal for a population-based screening or prevention strategy.

TABLE 6-2 Lifetime Cumulative Risk	
Breast cancer for women	10%
Colon cancer	6%
Cervical cancer for women[a]	2%
Domestic violence for women	Up to 15%
Hip fracture for white women	16%

[a]Assuming an unscreened population.

TABLE 6-3 Estimated Average Increase in Life Expectancy for a Population	
SCREENING OR PREVENTIVE INTERVENTION	AVERAGE INCREASE
Mammography:	
Women, 40–50 years	0–5 days
Women, 50–70 years	1 month
Pap smears, age 18–65	2–3 months
Getting a 35-year-old smoker to quit	3–5 years
Beginning regular exercise for a 40-year-old man (30 min, 3 times a week)	9 months–2 years

ASSESSING THE HARMS OF SCREENING AND PREVENTION

Just as with most aspects of medical care, screening and preventive interventions also incur the possibility of adverse outcomes. These adverse outcomes include side effects from preventive medications and vaccinations, false-positive screening tests, overdiagnosis of disease from screening tests, anxiety, radiation exposure from some screening tests, and discomfort from some interventions and screening tests. The risk of side effects from preventive medications is analogous to the use of medications in therapeutic settings and is considered in the U.S. Food and Drug Administration (FDA) approval process. Side effects from currently recommended vaccinations are primarily limited to discomfort and minor immune reactions. However, the concern about associations between vaccinations and serious adverse outcomes continues to limit the acceptance of many vaccinations despite the lack of data supporting the causal nature of these associations.

The possibility of a false-positive test occurs with nearly all screening tests, although the definition of what constitutes a false-positive result often varies across settings. For some tests such as screening mammography and screening chest CT, a false-positive result occurs when an abnormality is identified that is not malignant, requiring either a biopsy diagnosis or short-term follow-up. For other tests such as Pap smears, a false-positive result occurs because the test identifies a wide range of potentially premalignant states, only a small percentage of which would ever progress to an invasive cancer. This risk is closely tied to the risk of overdiagnosis in which the screening test identifies disease that would not have presented clinically in the patient's lifetime. Assessing the degree of overdiagnosis from a screening test is very difficult given the need for long-term follow-up of an unscreened population to determine the true incidence of disease over time. Recent estimates suggest that as much as 15–40% of breast cancers identified by mammography screening and 15–37% of prostate cancers identified by prostate-specific antigen testing may never have presented clinically. Screening tests also have the potential to create unwarranted anxiety, particularly in conjunction with false-positive findings. Although multiple studies have documented increased anxiety through the screening process, there are few data suggesting this anxiety has long-term adverse consequences, including subsequent screening behavior. Screening tests that involve radiation (e.g., mammography, chest CT) add to the cumulative radiation exposure for the screened individual. The absolute amount of radiation is very small from any of these tests, but the overall impact of repeated exposure from multiple sources is still being determined. Some preventive interventions (e.g., vaccinations) and screening tests (e.g., mammography) may lead to discomfort at the time of administration, but again, there is little evidence of long-term adverse consequences.

WEIGHING THE BENEFITS AND HARMS

The decision to implement a population-based screening and prevention strategy requires weighing the benefits and harms, including the economic impact of the strategy. The costs include not only the expense of the intervention but also time away from work, downstream costs from false-positive results, "incidentalomas" or adverse events, and other potential harms. Cost-effectiveness is typically assessed by calculating the cost per year of life saved, with adjustment for the quality of life impact of different interventions and disease states (i.e., quality-adjusted life-year). Typically, strategies that cost $50,000–100,000 per quality-adjusted year of life saved are considered "cost-effective" **(Chap. 4)**.

The U.S. Preventive Services Task Force (USPSTF) is an independent panel of experts in preventive care that provides evidence-based recommendations for screening and preventive strategies based on an assessment of the benefit-to-harm ratio **(Tables 6-4 and 6-5)**. Because

TABLE 6-4 Screening Tests Recommended by the U.S. Preventive Services Task Force for Average-Risk Adults

DISEASE	TEST	POPULATION	FREQUENCY	CHAPTER
Abdominal aortic aneurysm	Ultrasound	Men 65–75 who have ever smoked	Once	
Alcohol misuse	Alcohol Use Disorders Identification Test	All adults	Unknown	453
Breast cancer	Mammography with or without clinical breast examination	Women 50–75	Every 2 years	
Cervical cancer	Pap smear	Women 21–65	Every 3 years	70
	Pap smear and/or HPV testing	Women 30–65	Every 5 years if HPV negative	
Chlamydia/gonorrhea	Nucleic acid amplification test on urine or cervical swab	Sexually active women <25	Unknown	189
Colorectal cancer	Fecal occult blood testing	45–75	Every year	70, 81
	Fecal immunochemical-DNA	45–75	Every 1–3 years	
	Sigmoidoscopy	45–75	Every 5 years	
	Colonoscopy (or occult blood testing combined with sigmoidoscopy)	45–75	Every 10 years	
Depression	Screening questions	All adults	Periodically	
Diabetes	Fasting blood glucose or HgbA1c	Adults overweight, obese, or with hypertension	Every 3 years	403
Hepatitis C	Anti-HCV antibody followed by confirmatory PCR	18–79	Once	
HIV	Reactive immunoassay or rapid HIV followed by confirmatory test	15–65	At least once	
Hyperlipidemia	Cholesterol	40–75	Unknown	407
Hypertension	Blood pressure	All adults	Periodically	277
Intimate partner violence	Screening questions	Women of childbearing age	Unknown	
Lung cancer	Low-dose computed tomography	Adults 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the past 15 years	Yearly	
Obesity	Body mass index	All adults	Unknown	
Osteoporosis	DEXA	Women >65 or >60 with risk factors	Unknown	411

Abbreviations: DEXA, dual-energy x-ray absorptiometry; HCV, hepatitis C virus; HPV, human papillomavirus; PCR, polymerase chain reaction.

TABLE 6-5 Preventive Interventions Recommended for Average-Risk Adults

INTERVENTION	DISEASE	POPULATION	FREQUENCY	CHAPTER
Adult immunization				123, 124
Tetanus-diphtheria		>18	Every 10 years	
Varicella		Susceptibles only, >18	Two doses	
Measles-mumps-rubella		Women, childbearing age	One dose	
Pneumococcal		>64	13 followed by 23 valent	
Influenza		>18	Yearly	
Human papillomavirus		Up to age 27	If not done prior	
Zoster		>60	Once	
Chemoprevention				
Aspirin	Cardiovascular disease	Aged 50–59 years with a ≥10% 10-year cardiovascular disease risk (bleeding risk may = benefit for some groups)		
Folic acid	Neural tube defects in baby	Women planning or capable of pregnancy		
Tamoxifen/raloxifene	Breast cancer	Women at high risk for breast cancer		
Vitamin D	Fracture/falls	>64 at increased risk for falls		

there are multiple advisory organizations providing recommendations for preventive services, the agreement among the organizations varies across the different services. For example, all advisory groups support screening for hyperlipidemia and colorectal cancer, whereas consensus is lower for breast cancer screening among women in their forties and for prostate cancer screening. Because the guidelines are only updated periodically, differences across advisory organizations may also reflect the data that were available when the guideline was issued.

For many screening tests and preventive interventions, the balance of benefits and harms may be uncertain for the average-risk population but more favorable for individuals at higher risk for disease. Although age is the most commonly used risk factor for determining screening and prevention recommendations, the USPSTF also recommends some screening tests in populations based upon the presence of other risk factors for the disease. In addition, being at increased risk for the disease often supports initiating screening at an earlier age than that recommended for the average-risk population. For example, when there is a significant family history of colon cancer, it is prudent to initiate screening 10 years before the age at which the youngest family member was diagnosed with cancer.

Although informed consent is important for all aspects of medical care, shared decision-making may be a particularly important approach to decisions about preventive services when the benefit-to-harm ratio is uncertain for a specific population. For example, many expert groups, including the American Cancer Society, recommend an individualized discussion about prostate cancer screening, because the decision-making process is complex and relies heavily on personal issues. Some men may decline screening, whereas others may be more willing to accept the risks of an early detection strategy. Recent analysis suggests that many men may be better off not screening for prostate cancer because watchful waiting was the preferred strategy when quality-adjusted life-years were considered. Another example of shared decision-making involves the choice of techniques for colon cancer screening **(Chap. 70)**. In controlled studies, the use of annual FOBT reduces colon cancer deaths by 15–30%. Flexible sigmoidoscopy reduces colon cancer deaths by ~40–60%. Colonoscopy appears to offer a greater benefit than flexible sigmoidoscopy with a reduction in risk of ~70%, but its use incurs additional costs and risks. These screening procedures have not been compared directly in the same population, but models suggest that appropriate frequencies of each technique may be associated with similar numbers of lives saved and cost to society per life saved ($10,000–25,000). Thus, although one patient may prefer the ease of preparation, less time disruption, and the lower risk of flexible sigmoidoscopy, others may prefer the sedation, thoroughness, and time interval of colonoscopy.

COUNSELING ON HEALTHY BEHAVIORS

In considering the impact of preventive services, it is important to recognize that tobacco and alcohol use, diet, and exercise constitute the vast majority of factors that influence preventable deaths in developed countries. Perhaps the single greatest preventive health care measure is to help patients quit smoking **(Chap. 454)**. However, efforts in these areas frequently require behavior changes (e.g., weight loss, exercise) or the management of addictive conditions (e.g., tobacco and alcohol use) that are often recalcitrant to intervention. Although these are challenging problems, evidence strongly supports the role of counseling by health care providers **(Table 6-6)** in effecting health behavior change. Educational campaigns, public policy changes, and community-based interventions have also proven to be important parts of a strategy for addressing these factors in some settings. Although the USPSTF found that the evidence was conclusive to recommend a relatively small set of counseling activities, counseling in areas such as physical activity and injury prevention (including seat belts and bicycle and motorcycle helmets) has become a routine part of primary care practice.

IMPLEMENTING DISEASE PREVENTION AND SCREENING

The implementation of disease prevention and screening strategies in practice is challenging. A number of techniques can assist physicians with the delivery of these services. An appropriately configured electronic health record can provide reminder systems that make it easier for physicians to track and meet guidelines. Some systems give patients secure access to their medical records, providing an additional means to enhance adherence to routine screening. Systems that provide nurses and other staff with standing orders are effective for immunizations. The USPSTF has developed flow sheets and electronic tools to assist clinicians (*https://www.uspreventiveservicestaskforce.org/uspstf/information-health-professionals*). Many of these tools use age categories to help guide implementation. Age-specific recommendations for screening and counseling are summarized in **Table 6-7**.

Many patients see a physician for ongoing care of chronic illnesses, and this visit provides an opportunity to include a "measure of prevention" for other health problems. For example, a patient seen for management of hypertension or diabetes can have breast cancer

TABLE 6-6 Preventive Counseling Recommended by the U.S. Preventive Services Task Force (USPSTF)

TOPIC	CHAPTER REFERENCE
Alcohol and drug use	453, 456, 457
Genetic counseling for *BRCA1/2* testing among women at increased risk for deleterious mutations	79, 467
Nutrition and diet	332, 333
Sexually transmitted infections	136, 202
Sun exposure	61
Tobacco use	454

TABLE 6-7 Age-Specific Causes of Mortality and Corresponding Preventive Options

AGE GROUP	LEADING CAUSES OF AGE-SPECIFIC MORTALITY	SCREENING PREVENTION INTERVENTIONS TO CONSIDER FOR EACH SPECIFIC POPULATION
15–24	1. Accident 2. Homicide 3. Suicide 4. Malignancy 5. Heart disease	• Counseling on routine seat belt use, bicycle/motorcycle/ATV helmets (1) • Counseling on diet and exercise (5) • Discuss dangers of alcohol use while driving, swimming, boating (1) • Assess and update vaccination status (tetanus, diphtheria, hepatitis B, MMR, rubella, varicella, meningitis, HPV) • Ask about gun use and/or gun possession (2,3) • Assess for substance abuse history including alcohol (2,3) • Screen for domestic violence (2,3) • Screen for depression and/or suicidal/homicidal ideation (2,3) • Pap smear for cervical cancer screening after age 21 (4) • Discuss skin, breast awareness, and testicular self-examinations (4) • Recommend UV light avoidance and regular sunscreen use (4) • Measurement of blood pressure, height, weight, and body mass index (5) • Discuss health risks of tobacco use, consider emphasis on cosmetic and economic issues to improve quit rates for younger smokers (4,5) • Chlamydia and gonorrhea screening and contraceptive counseling for sexually active females, discuss STD prevention • Hepatitis B, and syphilis testing if there is high-risk sexual behavior(s) or any prior history of sexually transmitted disease • Hepatitis C screening starting at age 18 to 79 • HIV testing • Continue annual influenza vaccination
25–44	1. Accident 2. Malignancy 3. Heart disease 4. Suicide 5. Homicide 6. HIV	*As above plus consider the following:* • Readdress smoking status, encourage cessation at every visit (2,3) • Obtain detailed family history of malignancies and begin early screening/prevention program if patient is at significant increased risk (2) • Assess all cardiac risk factors (including screening for diabetes and hyperlipidemia) and consider primary prevention with aspirin for patients at >3% 5-year risk of a vascular event (3) and statin therapy for higher risk patients • Assess for chronic alcohol abuse, risk factors for viral hepatitis, or other risks for development of chronic liver disease • Consider individualized breast cancer screening with mammography at age 40 (2)
45–64	1. Malignancy 2. Heart disease 3. Accident 4. Diabetes mellitus 5. Cerebrovascular disease 6. Chronic lower respiratory disease 7. Chronic liver disease and cirrhosis 8. Suicide	• Consider prostate cancer screen with annual PSA and digital rectal examination at age 50 (or possibly earlier in African Americans or patients with family history) (1) • Begin colorectal cancer screening at age 45 or 50 with fecal occult blood testing, flexible sigmoidoscopy, or colonoscopy (1) • Reassess and update vaccination status at age 50 and vaccinate all smokers against *Streptococcus pneumoniae* at age 50 (6) • Consider screening for coronary disease in higher-risk patients (2,5) • Zoster vaccination at age 60 • Begin mammography screening by age 50 • Lung cancer screening at age 50 to 80 years if a 20 pack-year smoking history and currently smoke or have quit within the past 15 years, yearly.
≥65	1. Heart disease 2. Malignancy 3. Cerebrovascular disease 4. Chronic lower respiratory disease 5. Alzheimer's disease 6. Influenza and pneumonia 7. Diabetes mellitus 8. Kidney disease 9. Accidents 10. Septicemia	*As above plus consider the following:* • Readdress smoking status, encourage cessation at every visit (1,2,3,4) • One-time ultrasound for AAA in men 65–75 who have ever smoked • Consider pulmonary function testing for all long-term smokers to assess for development of chronic obstructive pulmonary disease (4,6) • Screen all postmenopausal women (and all men with risk factors) for osteoporosis • Continue annual influenza vaccination and vaccinate against *S. pneumoniae* at age 65 (4,6) • Screen for visual and hearing problems, home safety issues, and elder abuse (9) • Consider fall prevention exercise intervention if at higher risk (9)

Note: The numbers in parentheses refer to areas of risk in the mortality column affected by the specified intervention.

Abbreviations: AAA, abdominal aortic aneurysm; ATV, all-terrain vehicle; HPV, human papillomavirus; MMR, measles-mumps-rubella; PSA, prostate-specific antigen; STD, sexually transmitted disease; UV, ultraviolet.

screening incorporated into one visit and a discussion about colon cancer screening at the next visit. Other patients may respond more favorably to a clearly defined visit that addresses all relevant screening and prevention interventions. Because of age or comorbidities, it may be appropriate with some patients to abandon certain screening and prevention activities, although there are fewer data about when to "sunset" these services. For many screening tests, the benefit of screening does not accrue until 5–10 years of follow-up, and there are generally few data to support continuing screening for most diseases past age 75. In addition, for patients with advanced diseases and limited life

expectancy, there is considerable benefit from shifting the focus from screening procedures to the conditions and interventions more likely to affect quality and length of life.

7 Global Diversity of Health System Financing and Delivery

Richard B. Saltman

Health care systems are highly complex organizations, with many interdependent components. In developed countries, health systems have traditionally been classified by their type of financing—i.e., either predominantly tax-funded (such as the National Health Service in England and publicly operated regional care systems in the four European Nordic countries) or predominantly statutory social health insurance (SHI)-funded (such as in Germany, the Netherlands, and France). Over the past several decades, however, there has been structural convergence in the technical characteristics of both funding arrangements and in the associated delivery systems, making analytic observations about differences across national systems more difficult.

A second confounding factor has been that former Soviet Bloc countries in Central and Eastern Europe, including the Russian Federation, have, since 1991, replaced their former Soviet-style Semashko models (a top-down, national government–controlled funding and delivery structure with a parallel Communist Party administrative apparatus) with various hybrid arrangements built on national government–run SHI financing. Distinctions across developed country health systems, especially in Europe, have been further compressed by inadequate resources in many publicly funded systems in an era of rapid clinical and technological change, triggering increased private sector funding and provision.

In middle-income developing countries, institutional structures in the health sector typically reflect the country's preindependence administrative framework. Mexico, for example, has a Spanish-derived configuration with health insurance as part of social insurance for formally employed workers (via Instituto Mexicano del Seguro Social), supplemented by tax-funded health services (Seguro Popular) provided for those with informal employment and all other citizens, as well as a separate program (Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado) for public employees. Countries such as India and Egypt, reflecting British influence, have predominantly tax-funded and publicly operated health systems. China is an exception, with an internally generated system that is publicly funded and operated, although recent Communist Party policy has been to introduce SHI-based insurance with individual medical savings accounts (patterned after Singapore), promote private insurance, and expand private hospitals.

In lower-income developing countries, health services are typically provided by tax-funded public institutions, often with considerable inadequacies and sometimes with substantial copayments. It is important to note that governmentally organized systems in nearly all developing countries, as well as in former Soviet bloc countries and, to a lesser degree, in tax-funded developed countries, are supplemented to varying extents by a mix of private and/or employer-paid insurers and providers.

This chapter focuses on the individual patient care system: on the financing and delivery of individual clinical and preventive services. The individual patient care system is composed of the financing and delivery of necessary services to prevent death or serious harm ("rule of rescue"); to maintain quality of life; and to manage, reduce, and/or prevent the burden of illness on individual patients. While the technical dimensions of most clinical services are similar across countries, their organizational, social, and economic characteristics range widely. Health systems in both developed and developing countries exhibit substantial differences, for example, in access to care; in the design and reliance on quality assurance and provider payment mechanisms; in the relationship of primary care to hospital services; in the coordination of health care with home care and nursing home services; in the design and use of provider management strategies; in the way physicians work and are paid; in the decision-making roles of politically elected officials and of national, regional, and municipal governments; and in participation of both citizens and patients. These wide-ranging institutional and organizational characteristics reflect differing country contexts (geographical, social, economic, and political), differences in national culture (consisting of prioritized norms and values), and substantial variation in how health sector institutions are structured.

FINANCING INDIVIDUAL PATIENT CARE SERVICES IN DEVELOPED COUNTRIES

Funding for individual care services in developed countries comes from the particular national mix among four possible sources of revenue: national, regional, and/or municipal taxes; mandatory SHI; private health insurance (including employer-paid insurances); and out-of-pocket payments. Most countries have one preponderant payer, which then defines its funding arrangements and serves to frame the structure of its delivery system as well.

Total Health Expenditures The Organization for Economic Co-operation and Development (OECD) data from 2017 (adjusted for purchasing power parities) show that total health care expenditures in developed countries vary across a considerable range, tied to health system structure as well as national history and culture **(Table 7-1)**.

Per capita health expenditure figures provide a different, specific measurement of available funds in a country's health sector **(Table 7-2)**.

Tax-Funded Systems In the United Kingdom, 79% of all health care funding was furnished through general tax revenues allocated by the national government in its annual budget process (all figures from OECD for 2017). In Sweden, all public taxes combined raised 83.7% of total health care spending. Sweden's 21 regional-level elected governments provide approximately 70% of that 83.7%, with the remaining 13.7% of total health spending raised by national and municipal taxes. In Canada, 71% of total health spending was raised by tax revenues, with 66% of that 71% coming from provincial or territorial taxes, while 5% came from national and local government taxes.

In most tax-funded countries, a segment of the population also has individual-, company-, or union-purchased private complementary and/or supplemental insurance coverage. In Sweden, 2019 estimates are that about 600,000 individuals have private complementary policies in a total population of 9 million. In Denmark, 50% of the population purchase supplemental insurance, while 30% have complementary insurance (often purchased by employers) that pays for private sector services enabling them to bypass public sector queues. In Finland, many middle-class families purchase separate private health insurance for their children to enable them to bypass long waiting times

for primary and secondary pediatric health care services. More than 400,000 Finnish children (in a total population of 5 million) have privately purchased policies. In England in 2015, individual-, employer-, and union-purchased private complementary insurance covered an estimated 10.5% of the population, or about 6 million people. In Canada, individuals are not allowed by law to purchase private complementary insurance (except for Supreme Court–ordered insurance for three backlogged surgical procedures in Quebec Province—2005 Chaoulli decision); however, approximately 65% of the population have employer-, union-, or private group–purchased supplemental insurance for non–publicly covered services such as outpatient pharmaceutical prescriptions and home care.

Social Insurance–Funded Systems In Western Europe, SHI funds have traditionally been organized on a private not-for-profit basis, but with statutory responsibilities under national law. When former Soviet Bloc countries in Eastern Europe regained their independence in 1991, they returned to pre–World War II SHI models, but because there was no remaining organizational infrastructure, these post-1991 arrangements typically became a single SHI fund, run as an arm of the national government. In the United States, the Medicare social insurance system for citizens over age 65, enacted in 1965, is organized as a single fund tied to the national Social Security (public pension) Administration, an independent agency within the national government, with reimbursement arrangements supervised by the Centers for Medicare and Medicaid Services (CMS) inside the Department of Health and Human Services. Medicare covers inpatient hospital care plus limited post-hospital nursing home services (Medicare Part A). Supplemental private insurance policies are bought by covered individuals to help pay for outpatient physician visits (Medicare Part B) and for outpatient pharmaceuticals (Medicare Part D).

In Germany, 85% of the population is enrolled in one of 120 not-for-profit, monthly premium–based private SHI funds. This figure includes all individuals with annual incomes below 54,500 euros, who are required by law to join an SHI fund, as well as those with higher incomes who choose to enroll or remain. Eleven percent of the population—all having annual incomes above the mandatory SHI enrollment ceiling of 54,500 euros—have opted out of the SHI system to voluntarily enroll in claims-based private health insurance, whereas 4% of the citizenry is enrolled in sector-specific public programs such as the military. Since 2009, all SHI members pay a flat tax on gross monthly income as a contribution (8.2% in 2018, up to an upper income limit of 49,500 euros), which is transferred by their SHI fund to a national pool, and then redistributed back to their chosen fund on an individual risk-adjusted basis. Employers send 7.3% of each employee's salary to the same national pool. Special arrangements exist for payments from self-employed, retired, and unemployed workers. Since 1995, there has been a separate mandatory social insurance fund for long-term care (LTC), with an annual premium of 1.95% of each adult's gross monthly income, split 50%–50% with their employer. Pensioners since 2004 are required to pay the full 1.95% from their pensions. Childless SHI enrollees pay a surcharge of 0.25% of monthly gross income. Overall, 78% of all health care expenditures in Germany were paid from public and/or mandatory private SHI sources.

In the Netherlands since 2006, all adult citizens pay a fixed premium (about 1453 euros in 2019) to their choice among 35 private health insurers (not-for-profit and for-profit), with four large insurance groups having over 1 million members each. In addition, employers pay 6.95% of salary below 51,400 euros for each employee into a national health insurance fund. Self-employed individuals pay 4.85% into the national fund for taxable income up to the same limit. Retired and unemployed individuals also make payments. In addition to the individual premiums paid to their choice of private insurance fund, payments from the national health insurance fund, adjusted by individual age, sex, and health characteristics, also are made to the individual's chosen insurer. The Netherlands has a separate mandatory social insurance fund for LTC (the ABWZ, since 2015 the WLZ, and now only for residential nursing home care) to which each employee pays 9.5% of taxable income beneath 33,600 euros every year. Self-employed, unemployed, and retired individuals also are required to pay premiums to the WLZ. Overall, including SHI revenues, public spending provided 87% of total health expenditures in 2014.

In Estonia, a former Soviet Republic that re-established an SHI system in 1991 upon regaining its independence, there is one national SHI fund that is an arm of the national government. This fund collects mandatory payments of 13% from salaried workers and 20% from self-employed individuals, covering both health care and retirement pensions. Overall, including SHI revenues, public spending accounted for 74.5% of total health expenditures in 2017.

Singapore, Japan, South Korea, and Taiwan have predominantly SHI systems of funding for individual care services. In these Asian countries (except Japan), there is one SHI fund that typically is operated as an arm of the national government.

In Singapore, starting in 1983, all employees up to age 50 have been required to place 20% of their income (employers add 16% more) into a personal health savings account to pay for direct health care costs,

managed in their name by the Singapore government, called a Medisave account. Medisave accounts have a maximum amount, are tax-exempt, and receive interest payments (currently set at 4%). Consistent with a Confucian emphasis on family, the funds that accumulate in the Medisave account can be spent on health care for family members as well. If the accumulated funds are not spent on health care during the insured's life, they become part of the individual's personal estate and are distributed as a tax-free inheritance to his or her designated heirs. In addition, Singaporean citizens are also automatically enrolled into a second government-run health insurance plan called MediShield that pays for supplemental catastrophic, chronic, and long-term care. While citizens can opt out, 90% of citizens remain in the program. The Singapore government also operates a third, wholly tax-funded payer called Medifund that, with approval of a local neighborhood committee, will pay hospital costs for 3–4% of the population who are recognized as indigent. In part reflecting the high level of mandatory individual saving, public funding provided only 54.5% of total health expenditures in 2016.

In South Korea, a state-run SHI system was established in 1977, which in 1990 covered 30.9% of total health care costs. This percentage paid by the SHI system rose to 40.5% of total costs in 2017, with national tax revenue covering 16.9%, leaving out-of-pocket expenses at a relatively high 34.4% of total costs. Although there are legal ceilings on total out-of-pocket copayments for each 6-month period, over 70% of Korean adults purchase an additional private Voluntary Health Insurance policy to cover these additional direct expenditures. In 2000, three types of public SHI funds were merged into a single national state-run fund. As of 2018, 6% of an employee's salary must be paid as a social insurance contribution into this fund, with employees and employers each paying 50% of that amount. In 2008, an additional SHI fund was introduced to pay for LTC, operated by the main state-run SHI fund to reduce administrative costs. Contributions to the LTC fund are set at 6.55% of the individual's regular SHI contribution, coupled with 20% copayments for institutional care and 15% copayments for home care services.

The United States There is no single preponderant source of health care spending in the United States. The federal government's CMS reported that, for 2017, private health insurance covered 34% of total health expenditures, Medicare (mandatory SHI program for all citizens over 65) covered 20%, Medicaid (a joint federal-state welfare program for low-income citizens) covered 17%, and out-of-pocket paid 10%. Sources of funds for these programs were 28% from the federal government, 17% from state and local governments, 28% from private households, and 20% from private business (e.g., employers). The World Bank set public funding in the United States at 50.2% of total health expenditures in 2017.

In 2010, the passage of the Affordable Care Act (ACA) extended privately provided but heavily regulated and federally subsidized health insurance to many low- and middle-income uninsured individuals and families. Since the same act reduced the availability of existing individually purchased private health insurance, the total increase in the number of newly covered individuals was less than expected. Insurance premium increases for 2017 rose from 20% to over 100%, depending on the particular state, with additional increases in up-front deductible requirements, raising questions about the long-term sustainability of the ACA initiative. The recent Republican administration sought to repeal major financial and tax elements of the ACA and to replace existing subsidy arrangements with a system of refundable tax credits toward the establishment of individual health savings accounts and/or purchase of private health insurance on open cross-state markets (currently, private health insurance in the United States remains controlled at the separate 50-state level of government).

DELIVERING INDIVIDUAL PATIENT CARE SERVICES IN DEVELOPED COUNTRIES

Hospital Services In Europe, hospitals in both tax-funded and SHI-funded health systems are mostly publicly owned and operated by regional or municipal governments. In tax-funded health systems, most hospital-based physicians are civil servants, employed on a negotiated salary basis (often by a physician labor union), and subject to most of the usual advantages and disadvantages of being a public sector employee. There are somewhat more private hospitals in SHI-funded health systems. However, most larger hospitals are public institutions operated by local governments, and most hospital physicians (with the notable exception of the Netherlands, where they are private contractors organized in private group practices) are, like those in tax-funded systems, public sector employees. In most tax-funded European countries (but not continental SHI-funded countries), few specialist physicians have office-based practices, and in both tax- and SHI-funded systems, office-based specialists do not have admitting privileges to publicly operated hospitals.

Most public hospitals in both tax-funded and SHI-funded health systems are single free-standing institutions that can be classified into three broad categories by complexity of patients admitted and number of specialties available: (1) district hospitals (four specialties: internal medicine, general surgery, obstetrics, and psychiatry); (2) regional hospitals (20 specialties); and (3) university hospitals (>40 specialties). In addition, many countries have a number of small, 15- to 20-bed, freestanding, private (typically for-profit) clinics. Recently, some tax-funded countries have begun to merge district and regional hospitals in an effort to improve the quality of care and create financial efficiencies (for example, Norway; planned for Denmark, also for Ireland; however, failed Parliamentary passage and brought down the coalition government, in Finland in 2019). Institutional mergers can be difficult to negotiate among publicly operated hospitals, due to the role that these large institutions play as important care providers and as large employers in smaller cities and towns, especially given political and union concerns about maintaining current employment levels. In the United States, financial and reimbursement pressures triggered by the implementation of the 2010 ACA have generated a number of private sector hospital mergers into larger hospital groups.

In tax-funded health systems, publicly funded patients who are admitted for an elective procedure cannot choose their specialist physician (except private-pay patients in "pay beds" in National Health Service [NHS] hospitals in England). Specialists are assigned by the clinic to a patient based on availability, with both junior and senior doctors placed in rotation.

Capital costs (buildings, large medical equipment) are publicly funded in all tax-funded systems and in most traditional SHI systems. For example, in Germany, capital costs for public hospitals are paid for by the regional governments. As a result, new capital investment is often allocated politically, according to location and political priorities. In Finland, local politicians in the 1980s would say that it "takes 10 years to build a hospital," meaning that it took that long to become a political priority for the regional government that controlled capital expenditures. Local politicians would therefore regularly overbuild when they got their one opportunity to obtain new capital.

Recently, efforts have been made to make public hospitals more responsible for their use of capital. In the Netherlands, public hospitals were shifted into private not-for-profit entities that are expected either to fund new capital from operating surplus or to borrow the funds from a bank based on a viable business plan. In England, more than 100 hospitals have been built using the Public Finance Initiative (PFI) program, in which private developers build turn-key facilities (thus taking capital costs off the public borrowing limit), and then rent these facilities back to the NHS and/or the relevant NHS Foundation Trust. In Sweden and Finland, while capital equipment is now a cost on hospital operating budgets, large new capital equipment and major building renovations remain politically driven processes often with extensive delays. In Stockholm County, the New Karolinska University Hospital opened in 2018 was built and is managed by a separate nonprofit public-private company.

In Singapore and South Korea, both of which are SHI funded, larger hospitals are publicly operated. However, there are a substantial number of smaller private clinics typically owned by specialist physicians. In the United States, the passage of the 2010 ACA has triggered the selling of many private specialist group practices to hospital groups,

transforming previously independent practicing physicians into hospital employees.

Primary Care Services Most primary health care in SHI-funded health systems, and also in an increasing number of tax-funded health systems (except in low-income areas of some large cities), is delivered by independent private general practitioners (GPs), working either individually or in small privately owned group practices. Recent changes in tax-funded health systems include Norway, where most primary care moved from municipally employed physicians to private-practice GPs in 2003, and Sweden, where, following a 2010 change in national reimbursement requirements, new privately owned not-for-profit and for-profit GP practices were established and now deliver 50% of all primary care visits.

In England, most primary care physicians are private GPs who are contractors to the NHS, working either independently or in small group practices. These private GPs own their own practices, which they can sell when they retire. However, as part of the original agreement to convince physicians to support the establishment of the NHS in 1948 (which most physicians strongly opposed), private GPs also receive a national government pension upon retirement. In the inner cities in England, there are some larger primary health clinics.

In 2001, England's private primary care doctors were organized into geographically based Primary Care Trusts (PCTs). These PCTs were allocated 80% of the total NHS budget to contract for elective hospital services required by their patients with both NHS hospital trusts as well as private hospitals. In 2013, PCTs were restructured into Clinical Commissioning Groups with similar contracting responsibilities.

In 2004, the Quality Outcomes Framework (QOF) was introduced as a quality of care–tied approach to providing additional income for NHS GPs. This regulatory mechanism in 2010 set 134 different standards for best practice primary care in four main domains: 86 clinical, 36 organizational, 4 preventive service, and 3 patient experience. GP income grew on average by 25% through the introduction of the QOF, with general practices averaging 96% of possible QOF points. Total spending on QOF in 2014 in England consumed 15% of all primary care expenditures.

In April 2019, a slightly revised QOF contract was implemented, which retired 28 low-value indicators, introduced 15 new more clinically appropriate indicators, added two Quality Improvement modules, and added a new personalized care adjustment option. Funding was only changed marginally.

Access for individuals to primary care services is considered good in SHI-funded systems such as those in Germany and the Netherlands. One often-cited reason is that private office-based physicians (both GPs and specialists) in these countries are paid on a modified fee-for-service basis. In Germany, office-based physicians are paid on a quarterly basis by the Sickness funds, acting jointly at the Länder (regional) level through a point-based system. A national agreement between the physician association and the association of sick funds establishes points for each clinical act. Similarly, the association of sick funds (led in each of Germany's 16 Länder by the fund with the most subscribers in that region) establishes a fixed budget for all office-based physician services for all sick fund patients each 3-month period. Retrospectively at the end of each period, the total number of points is divided into the sick funds' fixed allocation for office-based physicians for that Länder for that quarter, establishing the value of a point for that quarter. Subsequently, each office-based physician's point total is multiplied by that quarterly point value, resulting in that physician's total payment from the statutory sick funds.

In contrast to SHI systems, seeing a primary care doctor in a number of tax-funded health systems has become increasingly difficult over the past decade. In Sweden, in 2005, a "care guarantee" was introduced that required its predominantly publicly operated health centers to see a patient within 7 days after calling for an appointment. In Finland, where public primary health care centers used to provide most primary care visits, delays in getting public health center appointments have pushed up to 40% of all visits into a parallel occupational health system, as well as to publicly employed primary care physicians working privately in the afternoons.

In England in 2019, access to GP services has been labeled a "crisis," aggravated by a 6% fall in the number of practicing GPs, leading to delays of up to 30 days for an appointment in urban areas like London. A 2019 report by the King's Fund found that only 1 in 20 trainee GPs planned to work full time. Also in 2019, the Nuffield Trust published a report suggesting that future planning for primary care services in England should assume a permanent shortage of GPs, requiring large numbers of new nurse practitioners and other auxiliary personnel. In Central European countries that were formerly within the Soviet Bloc, primary care provision had to be newly established after independence was regained in 1991, since first-line care in the former Semashko model was provided in specialist polyclinics. Primary care doctors rapidly emerged as almost entirely private for-profit GPs, working on contract from the national SHI fund (Estonia, Hungary, North Macedonia), from state-regulated private insurance companies (Czech Republic), or from regional/municipal public payers (Poland). Private GPs in most Central European countries now are paid on a per-visit-tied basis. This arrangement was heavily influenced by the structure of primary care in Germany, where private office-based GPs are paid according to a point-system-tied framework.

In Asian countries such as Singapore, South Korea, and Japan, most primary care is provided by private for-profit GPs working independently or in small group practices. Private GPs are reimbursed at a set per-service fee by the national SHI fund(s). Access to primary care physicians is considered good.

Developed countries have varying policies regarding access to individual preventive services. Health systems in most countries provide vaccinations and mammography as part of funded health care services. In the United States, most insured individuals—and in Canada, most covered residents—automatically receive an annual physical exam including full blood profiles. In Norway and Denmark, adult physical exams are provided only upon special request by the individual, and in Sweden, adult physical exams are provided only to pregnant women. In Sweden, adults who wish to know their cholesterol or prostate-specific antigen (PSA) levels have begun to purchase blood tests out-of-pocket from private laboratories. In England in 2019, the NHS announced it would stop providing PSA screening tests for prostate cancer, even to men who requested one, similarly forcing concerned patients to purchase private laboratory testing.

Patients must make copayments to see a primary care doctor in some tax-funded health systems and in most SHI countries. In tax-funded systems, for example, Swedish patients are required to make a county-council-set copayment for each primary care visit up to a national-government-set annual ceiling, after which ambulatory visits (both primary and outpatient specialist) are not charged. Finland has a fixed copay for public health center visits, while Denmark's private GP visits do not have a copayment. In England, there is no copayment for GP visits.

In SHI health care systems in Europe and in Asia, patients usually are responsible for a copayment for both primary and office-based specialist care. To defray these charges (and to pay for other nonfunded services), a high percentage of citizens typically purchase additional supplemental health insurance. In France, where 95% of patients in 2015 purchased private supplemental insurance, patients paid directly the full fee for 65% of outpatient primary and specialist services, reimbursed subsequently by both their SHI fund and their supplemental insurance carrier for all payments (after deductibles), while for 35% of services (for low-income individuals and certain high-cost procedures), full agreed prices were paid directly to providers by SHI.

Access to Elective Specialist Care Approximately half of all European health care systems have a gatekeeping system that requires referrals from primary care physicians in order to book hospital specialist visits (for publicly paid visits). In most tax-funded health systems (although not in most SHI systems), there are substantial waiting times, typically several months or more, for elective specialist appointments as well as for high-tech diagnostic and treatment procedures. Waiting times can be particularly long for cancer and other elective surgical or high-demand services. In Sweden, government figures from the

summer of 2017 showed that, nationally, only 5–10% of prostate cancer operations were performed within 60 days after diagnosis.

In the English NHS, waiting lists for elective surgery in 2019 were often 6 months or longer. In August 2017, there were over 4,000,000 patients on NHS waiting lists. In January 2018, what administrators termed "a severe flu season," during which hospital emergency rooms were overwhelmed with elderly patients requiring admission, led to a national-level NHS decision to cancel all elective operating room procedures in all hospitals in England (>50,000 procedures in 1200 hospitals) for the entire month of January, further lengthening waiting lists. Regarding quality of care, again in England, a March 2018 report from the national Office of Health Economics found that, in 2016 and 2017, up to three-quarters of patients who could have undergone key-hole procedures were forced to undergo open surgery, resulting in an estimated 1 million procedures each year that were more invasive than clinically necessary.

Delays in some tax-funded systems also are procedural. In England, for example, a patient who requires a further consultation with a second specialist typically has to return to their primary care physician for a second referral and then has to wait in the regular patient queue for that second appointment.

There is also substantial waiting time for radiologic imaging services in most tax-funded systems. In Malta, the tax-funded health system's recent efforts to prioritize elective MRI investigations have succeeded in reducing waiting times from 18 months to 4 months. In both the Alberta and British Columbia Provinces in Canada, waiting times for a publicly funded nonemergency MRI can extend up to several months, whereas privately paid MRIs were available in both provinces within 1 week.

This issue of waiting times for specialist services in tax-funded health systems reflects a combination of growing demand (increasing/aging populations and changing clinical indications), financial constraints, and insufficient capacity, including inadequate physician working hours. For example, in the 1980s, when several surgical procedures for the elderly became more routine practice (e.g., hip replacement, coronary artery bypass graft, corneal lens implantation), the waiting list problem worsened. It had been mitigated somewhat through increased service capacity by the early 2000s, only to return as a growing policy challenge once public sector financial resources became constrained again after the 2008 global financial crisis. Timely cancer diagnosis and care continue to be a particularly sensitive issue, with tax-funded systems often taking several months for a patient to see an oncologist and then months more to begin treatment. In 2013 in Sweden, a newspaper journalist set off a political storm when he described women patients in one large county council (Malmo) who had to wait more than 40 days to receive the results from their breast cancer biopsy. In September 2019 in England, only 76.9% of patients with suspected cancer began treatment within 2 months of an urgent referral from a GP.

In response to pressure from national patient associations, a number of tax-funded health care systems introduced maximum waiting times for elective hospital procedures in the early 2000s. (Most Western European SHI systems do not have long waiting times or treatment guarantees for hospital care.) These maximum waiting times typically include initial primary care visits as well as specialist evaluations and treatment. In Denmark, a patient has the right to go to a different Danish public hospital for care after waiting 30 days without treatment. In Sweden, under the 2005 "waiting time guarantee," an untreated patient's local county council is required to pay for care in another county's hospital after 180 days. In a parallel process at the European Union (EU) level, beginning in 1997, the EU Court of Justice steadily expanded the right of all EU citizens to travel to another EU country in order to receive "timely" care, with their home country health system required to pay for that care.

In private not-for-profit SHI-funded health systems such as in Germany and Switzerland, waiting times for specialist visits and hospital procedures are typically a few weeks to 1 month. In the SHI system in France, which is more centrally organized and funded (part of the Napoleonic tradition of public administration), ongoing disputes about insufficient central government funding for public hospitals and staff salaries led in March 2019 to 9 months of hospital staff strikes, particularly in accident and emergency departments. In November 2019, the national government announced that it would take over 10 billion euros in public hospital debt as part of an effort to reverse staff cutbacks, bed and operating theater closures, and personnel flight to the private sector.

Long-Term Care Services LTC (consisting of residential and home-based services) consumes a relatively small but increasing proportion of gross domestic product (GDP) in developed countries. In 2016, Norway (2.95% GDP), Sweden (2.87% GDP), and the Netherlands (2.64% GDP) all spent more than one-fourth of their total health expenditures on LTC (Eurostat and OECD figures). More than one-fifth of all health care expenditures went to LTC in Belgium (2.16% GDP), Ireland (1.55% GDP), and Denmark (2.5% GDP). Lower-spending countries included the United Kingdom (18% of health expenditures; 1.75% GDP), Germany (12% of expenditures; 1.33% GDP), and Spain (9% of expenditures; 0.81% GDP). In the United States, official figures put total LTC expenditures in 2016 at 4.9% of total health expenditures, or 0.9% of total GDP. (Note that these figures do not include emergency, inpatient, or outpatient hospital costs generated by elderly patients.)

Since nursing home care is more expensive than home care (nursing home care requires the provision of housing, food, and around-the-clock care providers), government policymakers seek to keep the elderly and the chronically ill out of nursing homes for as long as feasible. Moreover, in developed countries like Sweden, Norway, and the United States, some 70% of all home care services come from informal caregivers: spouses, children (typically daughters), neighbors, and nonprofit community groups. While some SHI systems (e.g., Germany) have separate public LTC insurance (funded by mandatory premiums paid by all adults) that make available cash payments for LTC that can be used to compensate informal caregivers, most policymakers work hard to not monetize what is a large amount of essentially free care. Indeed, policymakers actively seek to encourage those providing these services to continue to do so as long as possible, trying to postpone caregiver burnout by providing support services such as free respite care, special call-in lines for caregiving advice, pension points toward retirement for the informal caregiver (Nordic countries), and free day-care center services.

In most tax-funded and SHI-funded European countries, home care services are organized at the municipal government level. In tax-funded systems, these services are also delivered mostly by municipal employees, working according to union-negotiated protocols. In some European SHI systems, and recently in tax-funded Sweden and Finland, private companies also provide home care services on contract to municipal governments. In combination with national legislation, these municipal systems also provide important support for informal caregivers, since the financial costs of caring for adults in their own home are substantially less than providing housing, food, and caregiver support in publicly funded homes for the aged or in nursing homes.

A high proportion of nursing homes in European tax-funded and SHI-funded health systems are publicly owned facilities operated by municipal governments; in some instances, in SHI-funded systems (Israel, the Netherlands), they are operated by private not-for-profit organizations. Recently, in some tax-funded systems (e.g., Sweden), private for-profit chains have begun to open nursing homes that are funded on a contract basis with local municipal governments. Costs for nursing home care can be expensive: in Norway, the cost per patient is often over $100,000 per year in a publicly funded home, with the patient responsible for paying up to 80% depending on the family's economic status. In Sweden, patients living in publicly funded nursing homes in Stockholm County pay a relatively small official fee, but they also pay room rent and up to 2706 Swedish krona (SEK) per month (about $270 U.S. dollars [USD]) for food out of their monthly public pension payments.

In 2012, in an effort to reduce demand for expensive hospital and nursing home services, Norway and Denmark began elderly care reforms that shifted service delivery as well as funding responsibilities

to municipal governments. Among innovations in Norway, municipalities are required to establish a municipal acute bed unit (MAU) to treat stable elderly patients and provide observation beds for evaluation. Partial funding for these units is provided by the four public regional health care administrations. Some municipalities have also embedded primary care units inside their regional hospital to arrange discharge and to coordinate care for the chronically ill elderly. Norwegian municipalities are also responsible through their contracted (mostly private) primary care physicians to implement the National Pathways Program, which established treatment protocols for cross-sector conditions such as diabetes and cardiovascular conditions.

A differently configured structural innovation to better integrate LTC for the chronically ill elderly with clinical individual health services has been to consolidate both social and health care services within the same public administrative organization. In 2019, as part of health reforms in Ireland and Denmark and a proposed (unenacted) reform in Finland, as well as a pilot decentralization program in England for 2.8 million people in Greater Manchester, social and health care programs are to be administered by a single responsible agency.

In the SHI-funded system in the Netherlands, almost 7% of the population live in a residential home. National government legislation revised the structure of nursing home funding and care in 2015. Three acts restructured the separate public LTC SHI fund, which requires mandatory payments by 100% of Dutch adults, and introduced delivery-related reforms that reduced the number and overall cost of nursing home patients paid for by the fund. Determination of eligibility for public payment for nursing home care is now made by an independent national assessment body (the Centre for Needs Assessment). Moreover, municipal governments now play a stronger role in funding and delivering home care services. The reforms created social care teams that hold "kitchen table talks" to steer the elderly first toward seeking care from family, neighbors, churches, and other local community organizations before they qualify for publicly paid in-home care. In 2012, some 1.5 million people (12% of total population) provided informal care to ill or disabled persons, averaging 22 hours per week of care per person.

Home care recipients in the Netherlands can choose to set up a "personal budget," using their public funding allocation to select their preferred individual care personnel (either publicly employed or publicly approved private providers). This arrangement also enables these home care recipients to determine the particular mix of services they want, as well as to augment the allocated public funds with personal funds. A number of innovative not-for-profit nursing homes have been created to provide additional services to elderly living in their neighborhood (primary care home visits), as well as terminal hospice care (e.g., the Saffier De Residentie Groep residences in The Haag).

In the United States, nursing home and home care are funded and delivered in a variety of different ways. For individuals who have minimal financial assets, nursing home costs are paid by a joint federal-regional (state) welfare program called Medicaid. Most state government Medicaid programs pay out more than 40% of their total budget for nursing home care. In the past, Medicaid did not pay for home care services. However, some states have programs with private for-profit and not-for-profit providers that provide home care as a way to forestall the need for the more expensive nursing home care.

Many private individuals take out private LTC insurance, typically from commercial insurance companies. These policies require individuals to make premium payments for years in advance (often 20 or more) before the individual learns whether they will, in fact, require home or nursing home care. Some private insurers have also raised premiums after individuals have paid in for many years and canceled policies if the new higher rate is not affordable. The 2010 ACA contained a new public LTC insurance program. However, the program was designed to be voluntary, and U.S. Department of Health and Human Services administrators decided in 2013 not to implement that portion of the law.

In addition to the tax-funded Medicaid program and privately purchased LTC insurance, many middle-class families pay for care from savings, by selling the elderly person's home, or by direct contribution from children and other family members. Expenses can reach between $60,000 and $100,000 per year depending on the location of a facility and who operates it.

Nursing home care in the United States is provided by a wide mix of private not-for-profit and for-profit providers, ranging from church-owned single-site homes to large stock market–listed companies. Many of these homes are purpose-built as assisted-living or memory-care facilities. Home care services are delivered by a mix of private not-for-profit and for-profit providers.

In Japan, a national LTC insurance fund was introduced in 2000. Although the new fund applies uniformly across the country, the program is administered by municipal governments and the premium level differs across municipalities, with an average monthly premium of 3000 yen (about $30 USD). In South Korea, an SHI fund for LTC is funded by mandatory contributions of 4.78% of a person's regular national health insurance contribution, with an additional 20% of total LTC expenditures provided by national government funds. The client copayment for home care is set at 15% of expenses and at 20% for residential care.

PHARMACEUTICALS

Pharmaceutical expenditures in developed countries (inpatient and outpatient combined) vary widely across different health system types, as well as between different countries within each institutional type. OECD figures for 2018 show drug expenditures in tax-funded countries in Western Europe ranging from 6.3% of total health expenditures (THE) in Denmark to 11.9% of THE in the United Kingdom and 18.6% of THE in Spain. In SHI-funded Western European systems, pharmaceuticals absorbed 7.5% of THE in the Netherlands, while in Germany, that figure was 14.1%. In the hybrid tax-funded SHI systems of Central Europe, the pharmaceutical percentage of THE is higher: 18.2% of THE in Estonia to 27.9% of THE in Hungary. Similarly, in Asian SHI systems, pharmaceuticals consumed 20.7% of THE in South Korea and 18.6% of THE in Japan. The OECD's 2018 figures for pharmaceutical spending in North America are 12.0% of THE in the United States and 16.7% in Canada.

Contributing factors to this wide-ranging variation are (1) differences in national practice and prescription patterns reflecting differing cultural expectations; (2) the ratio problem (relatively fixed level of pharmaceutical costs due to international prices—the numerator—divided by a greatly varying per capita health expenditure cost in different developed country health systems); (3) the range and type of pharmaceutical price controls in each country; and (4) the degree of limitation placed on pharmaceutical supply, tied to formularies and/or explicit forms of drug rationing.

Most European health systems have tight national controls on the cost and, in some tax-based countries, on the availability of pharmaceuticals. Most European countries also use a number of different regulatory measures to limit prices and/or availability of both inpatient and outpatient drugs, including mandatory generic prescribing, reference pricing, patient copays (sometimes with an annual ceiling, after which copayments are no longer required), and (particularly in tax-funded systems) national formularies tied to clinical effectiveness. Norway, for example, allows only about 2300 different preparations—including dosage, delivery method, and box size—to be stocked by pharmacies. Prices for drugs can vary considerably across different European countries, tied to economic development and domestic pricing patterns. One consequence of these differential national pricing controls has been the development of a parallel import market, in which drug wholesalers and pharmacists in the more expensive countries purchase supplies from a cheaper market elsewhere in Europe.

Access to expensive drugs has also been intentionally limited in some tax-funded health systems in Europe. One basis for rationing has been rationing tied to quality-adjusted life-years (QALYs). Rationing also reflects a clash between strained public drug budgets and public pressure. For example, in the case of cancer drugs in England, the recommendation of the National Institute for Health and Care Excellence (NICE) against funding the breast cancer drug trastuzumab (Herceptin) was subsequently overturned by the Minister of Health.

Expensive cancer drugs continue to be rationed in England where the NHS Cancer Drug Fund, established in 2011 to provide access to non-NHS-provided drugs on a case-by-case basis, ran out of funds in 2015, forcing it to drop 25 of 83 covered drugs and close down for 3 months to restructure its operations.

As part of earlier medical patterns in Asian countries, office-based physicians traditionally filled prescriptions as well as prescribing drugs to patients. These sales also served to supplement their income in a setting of relatively low per-visit payments from state-run SHI funds. Concerned about cost and overuse, both Taiwan (in 1997, except for emergency cases or rural regions) and South Korea (for the whole country in 2003) implemented "separation reforms," which ended these physician sales. In Japan, a series of fee and reimbursement reforms have trimmed the percentage of all prescriptions dispensed in 2016 by physicians to 26% of prescriptions filled.

GOVERNANCE AND REGULATION

Health care services in developed countries are steered, constrained, monitored, and (to varying degrees) assessed by governments and governmentally established and/or empowered bodies. Although these measures apply particularly to the financial efficiency of government-funded services, they also seek to promote patient and community safety, equity of access, and high-quality clinical outcomes. This oversight is often strongly focused on privately operated and contracted providers and insurers, although in principle, it applies to publicly operated organizations as well.

Governance consists of macro national-level policy, meso institutional-level management, and micro clinic-level care decisions. This complex mix of governance decisions is often shared among different national, regional, and local governments, depending on the degree of centralization, decentralization, or, recently, recentralization (e.g., Norway and Denmark). While most systems officially prioritize "good governance," governance activities frequently comingle with political objectives as core policy concepts are developed and transformed into concrete organizational targets.

In Sweden, health system governance is shared among national, regional (county), and local municipal governments. The national government has responsibility to pass "frame" legislation, which establishes the basic structure of the system. To cite one example, until recently, the national government had limited an adult patient's total copayments for outpatient physician care (specialist and primary care) and pharmaceuticals to 2800 SEK (about $280 USD) for a 12-month period. The 20 regional governments, in turn, made policy decisions within that legislation, deciding how to apportion the specific copayments for each primary care and specialist outpatient visit. Since Swedes can self-refer to specialists, some counties double the copayment to hospital-based doctors to discourage unnecessary appointments. Similarly, fiscal policy normally is shared between the regional government, which raises about 70% of total health expenditures through its own county-set flat income tax, and the national government, which provides additional purpose-tied funds for national objectives such as consolidating open-heart surgery across county lines as well as supplementing lower tax receipts in rural counties with smaller working populations. However, this normal funding relationship across governments can change. In the early 1990s, the national government placed a "stop" on raising county taxes prior to Sweden's admission in 1995 to the EU. In 2016, each of the 20 counties could set their own ceilings, which were almost all at 3300 SEK (about $330 USD).

In Spain's tax-funded health system (71.1% publicly funded in 2015), 17 regional "autonomous communities" were given full managerial responsibility for the provision of health services in a 1990s decentralization process, along with ownership of all publicly operated hospitals. The national government generates a substantial proportion of health care resources, which are included in the broad block grants it allocates to the regional governments, which then add regional tax revenue to make up the full public sector budget. In a mechanism to steer regional government operating policies in this decentralized environment, the national Spanish government established a joint federal-regional council to review quality and performance data (through the 2003 Health System Cohesion and Quality Act). Italy's tax-funded health system (75.8% publicly funded in 2014) similarly shares governance responsibilities between national and regional governments. Health services are provided by local health authorities (Azienda Sanitaria Locale) supervised by 20 regional governments within a nationally established governance framework, financed through a complicated mix of national and nationally stipulated but regionally collected taxes. Again, like Spain, the national government established a federal-regional government council, seeking to better coordinate care standards and information among the regions and with national government agencies. In 2006, the national government imposed strict financial plans on 10 regions that were systematically in deficit.

In Germany, where funding for its SHI-based health system is predominantly the responsibility of 120 private not-for-profit sickness funds, governance decisions are shared among these private sector sickness funds and public sector national, regional, and municipal governments. The sickness funds receive a risk-adjusted premium payment for each enrolled individual, according to a national government–determined formula, and from a national government–run health insurance pool. Most hospitals are owned and operated by municipal governments, while investment capital for structural renovations and new building comes from the 16 regional Länder taken from their tax revenues. Payment frameworks and amounts for public hospitals are negotiated between associations of these municipally owned hospitals and associations of the private sickness funds, without formal government participation.

Regulation is an essential element of an effective health care system and a key component of overall health system governance. Regulation incorporates both broad standard requirements that affect all organizations that operate in a country (e.g., hiring, firing, and wage decisions) as well as specific health sector–related regulations (e.g., proper handling, use, and disposal of low-grade nuclear waste from radiation treatments). Recent examples of health sector regulation in England, for example, include the following:

1. Requiring all cancer drugs adopted for use in the NHS to cost no more than $41,268/QALY;
2. Requiring in their employment contract that junior doctors in hospitals work a specific number of Sundays; and
3. Requiring that all emergency department patients receive care within 4 h of their arrival.

A powerful tool that has the force of law, regulation can have substantial negative as well as positive effects. A well-known political science corollary of regulatory power is that "the right to regulate is also the right to destroy." For example, in the United States, the federal Environmental Protection Agency, as part of its pursuit of cleaner air, issued wide-ranging regulatory orders setting performance standards that resulted in the closing of many West Virginia coal mines, with the loss of tens of millions of dollars of productive capacity and thousands of high-paying jobs, and likely contributing to social conditions that helped spawn that state's high rates of opioid abuse among unemployed males. Similarly, in some tax-funded European systems, such as those in Sweden and England, there is growing pressure from public health advocates for national regulations to prohibit the making of a profit from publicly paid funds. In Sweden, the national government's Reepalu report in 2016 honored a pledge made by the Social Democratic government to its Left (socialist) Party ally by calling for a legislated ban on profit-making in the provision of publicly funded health care services. The report's publication triggered substantial divestment of existing investor-owned primary care, nursing home, and home care companies.

FUTURE CHALLENGES

Health systems in developed countries face continued challenges in the coming years. These include financial, organizational, and policy dilemmas for which institutionally viable, financially sustainable, and politically supportable solutions will be complicated to develop and difficult to implement. On the delivery side, a key question is whether

privately structured GP-based primary care is more efficient and effective than various clinic-based forms of primary care services. Recent movement in Northern and Central Europe toward more private GPs, along with continued private office–based primary care in much of Canada, the United States, and economically developed countries in Asia, raises complex policy issues for international organizations like the World Health Organization (WHO), as well as national policymakers. In the hospital sector, existing levels of clinical quality and patient responsiveness in publicly operated command-and-control institutions will increasingly have to compete with those of semi-autonomous public hospitals, as well as various types of private, sometimes very innovative providers. In the financing arena, continued pressure on publicly raised health system revenues is likely to erode longtime commitments in some tax-funded health systems to minimal patient copayments and low out-of-pocket funding.

An additional set of challenges will arise from recent commitments by international organizations like WHO to restructure health systems in developed countries to better address the social determinants of health. This new, incomplete strategy calls for a dramatic expansion of health sector responsibility to include a wide range of existing institutional arrangements in housing, education, work-life, and social and political decision-making. The influential 2010 Strategic Review of Health Inequalities in England entitled "Fair Society, Healthy Lives," led by Sir Michael Marmot, a British epidemiologist, called for the elimination of all "inequities in power, money, and resources." Separate from the political dimensions of this proposed new paradigm, how such fundamental societal change will be funded and implemented has yet to be addressed.

Looking forward, among the most essential challenges to national decision-makers in the coming period will be four specific health system imperatives:

1. **Finding a more sustainable balance between ethics and funding.** Policymakers in publicly funded health systems face a growing gap between patient expectations of high-quality clinical care, staff expectations of better compensation, and the economic imperative of no new taxes. Recent research has suggested that SHI-funded health systems, faced with increasing aging and thus proportionally fewer employed, face a similar gap. While the present solidaristic foundation for raising collective revenues is insufficient, available nonsolidaristic tools (copayments, supplemental insurance, private pay) inevitably contribute to overall inequality. But what then are the realistic policy alternatives? The minimalist new policy goal necessarily will have to become one of raising new revenues while doing the least economic and social harm.
2. **Developing better strategies to steer provider diversity.** Health systems in developed countries are becoming more diverse with more and different types of public owners: hospital trusts, state enterprises, and mixed public-private hospital owners/managers. There also are more and different types of private providers: not-for-profit community groups, foundations, and cooperatives, as well as for-profit small local entrepreneurs, large international companies, and risk capital funds (venture capital). Furthermore, new innovative delivery models are reorganizing traditional service boundaries: not-for-profit private nursing homes in the Netherlands also provide outpatient primary care to neighborhood elderly patients, as well as hospice care; Israeli technology companies combine high-tech home-based patient monitoring with standard medical and custodial home care services. Public pressure from citizens for more choice and better outcomes will pressure policymakers toward new, more accommodative health system arrangements. A 2019 national government report in Sweden on the hospital sector recommended a new emphasis on better access to out-of-office hours and out-of-hospital acute care by private as well as public providers.
3. **Ensuring better coordination between social and health services.** Tax-funded and SHI-funded systems alike are under intense policy pressure to develop better strategies to integrate services for the chronically ill elderly, as a way to improve the quality of services that these patients receive and to keep them at home healthier and longer, reducing expensive acute visits to hospitals and emergency departments. The clear delivery system goal will increasingly be to keep the elderly out of nursing homes and acute care facilities for as long as possible.
4. **Building labor unions into provider innovation.** In many developed countries, health sector staff, including hospital physicians, are members of labor unions. Effective policymaking will require finding mechanisms to build these personnel unions into accelerated health system restructuring processes. This process will necessarily involve integrating unions into more innovative, flexible, fiscally sustainable organizational arrangements with contracts that reward active participation in organizational change, contracts that pay incentives to more productive employees, quicker reassignment and redundancy procedures (firing health sector workers can take a year or longer in some European health systems), and establishing profit-sharing payments to teams/unions, also in public sector organizations.

While the structure and complexity of resolving these specific organizational challenges will vary depending on a country's cultural and institutional context, the commonality of these problems suggests that health systems in the developed world require a new, broader range of targeted policy strategies and solutions.

FINANCING AND PROVIDING HEALTH SERVICES IN DEVELOPING COUNTRIES (See also Chap. 474)

Health systems in developing countries reflect a complex combination of the same core elements found in developed country systems (hospitals, primary care facilities, medical staff, pharmaceuticals) adapted to different, widely varying organizational, social, political, and economic contexts and conditions. System structure and provider institutions typically vary by differing national characteristics including historical relationships (Anglophone/Francophone/Hispanic/Soviet Semashko/American institutional and educational links); GDP and per capita annual national income (low- or middle-income developing countries); political norms and values; and ethnic and/or cultural mix. Predominantly public sector funding, particularly in lower-income countries, typically generates substantially lower levels of resources per capita than in developed countries and tends to be less reliable, particularly in countries where the economy is dependent on commodity exports.

Service delivery arrangements in developing countries, in turn, typically have higher provider-to-population ratios as well as, in public sector institutions, more mixed quality of care. In a number of middle-income developing countries, migration of trained medical staff to practice in higher-paying developed country health systems (often going to countries with historical relationships and/or where they received advanced training) further depletes available medical resources. In nearly all developing countries, private sector providers play an important supplemental role, with some middle-income developing countries like China currently encouraging their further development.

Most middle- and lower-income developing countries struggle to fund high-quality individual health services. Recent emphasis on universal health coverage has intensified that struggle. In middle-income developing countries (Table 7-3), World Bank data from 2016 show

TABLE 7-3 Middle-Income Developing Countries: Total Health Expenditure (% of gross domestic product)

Middle-Income Developing Countries	
Kazakhstan	3.53%
Thailand	3.71%
Malaysia	3.80%
Turkey	4.31%
China	4.98%
Botswana	5.46%
Mexico	5.47%
Colombia	5.91%

TABLE 7-4 Low-Income Developing Countries: Total Health Expenditure (% of gross domestic product)	
Low-Income Developing Countries	
Nigeria	3.65%
India	3.66%
Ethiopia	3.97%
Nepal	6.29%
Honduras	8.40%

TABLE 7-6 Low-Income Developing Countries: Per Capital Health Expenditures	
Low-Income Developing Countries	
Ethiopia	$27
Nepal	$45
India	$62
Nigeria	$79
Honduras	$199

a range of health expenditure rates as a percentage of GDP, including Kazakhstan at 3.53% of GDP, Thailand at 3.71%, Malaysia at 3.80%, Turkey at 4.31%, China at 4.98%, Botswana at 5.46%, Mexico at 5.47%, and Colombia at 5.91%. Total health spending in low-income developing countries **(Table 7-4)** ranges from 3.65% of GDP for Nigeria, 3.66% for India, 3.97% for Ethiopia, 6.29% for Nepal, to 8.40% for Honduras.

Given lower aggregate GDP levels, per capita annual expenditures are considerably less than those found in developed countries. In middle-income developing countries **(Table 7-5)**, Thailand spent (2016 data in adjusted USD) $221 annually per person, Kazakhstan spent $262, Colombia spent $340, Malaysia spent $361, Botswana spent $379, China spent $398, Mexico spent $461, and Turkey spent $468. Among low-income developing countries **(Table 7-6)**, Ethiopia spent $27 per person annually, Nepal spent $45, India spent $62, and Nigeria spent $79, whereas Honduras spent $199.

China provides an interesting example of financing and service delivery development in middle-income developing countries. Financing reforms replaced fully publicly funded services with three new arrangements tied to work status and residence: (1) Urban Employee Basic Medical Insurance in 1998 (incorporating privately funded medical savings accounts—a concept pioneered in Singapore); (2) Urban Resident Basic Medical Insurance in 2007; and (3) New Rural Cooperative Medical Scheme in 2007. The urban employee program is an SHI model reflecting the rapid rate of economic growth and increasing incomes for urban workers. Starting in 2013, the Chinese government increasingly emphasized the development of new private hospitals and promotion of private insurance in urban areas. These and other health sector reforms became possible as continued strong economic growth over 30 years raised an estimated 300 million Chinese into the middle class, generating the requisite private as well as public revenues to underpin major structural health sector change.

Service delivery in developing countries varies widely in access, quality, and outcomes across and also within many developing countries. Medical services and tertiary institutions in urban areas of China, for example, operate at a substantially higher standard of service than those typically available in poorer rural regions. Similar disparities exist in wealthier parts of India such as Rajasthan, whereas in poorer states such as Bihar, primary care is mostly delivered by community "volunteers" with basic medical training, supervised by a GP.

Two critical challenges for all developing country health systems are contingent on generating adequate future funding flows. First, the current push from United Nations agencies to achieve universal health coverage will require additional public and private sector funding to pay for the necessary new providers and services. Second, available funding will need to be more effectively targeted on needed and appropriate services, with minimized managerial inefficiencies and substantially less political corruption.

Both forms of expanded funding will be dependent on strong national and global economic growth, which in turn will require continued country-level economic and political reforms. Achieving both funding-related objectives will require considerable international as well as national effort.

TABLE 7-5 Middle-Income Developing Countries: Per Capita Health Expenditures	
Middle-Income Developing Countries	
Thailand	$221
Kazakhstan	$262
Colombia	$340
Malaysia	$361
Botswana	$379
China	$398
Mexico	$461
Turkey	$468

8 The Safety and Quality of Health Care

David W. Bates

Safety and quality are two of the central dimensions of health care. In recent years, it has become easier to measure safety and quality, and it is increasingly clear that performance in both dimensions could be much better. The public is—with good justification—demanding measurement and accountability, and payment for services will increasingly be based on performance in these areas. Thus, physicians must learn about these two domains, how they can be improved, and the relative strengths and limitations of the current ability to measure them.

Safety and quality are closely related but do not completely overlap. The Institute of Medicine has suggested in a seminal series of reports that safety is the first part of quality and that the health care system must first and foremost guarantee that it will deliver safe care, although quality is also pivotal. In the end, it is likely that more net clinical

benefit will be derived from improving quality than from improving safety, though both are important and safety is in many ways more tangible to the public. The first section of this chapter will address issues relating to the safety of care and the second will cover quality of care.

SAFETY IN HEALTH CARE

Safety Theory and Systems Theory *Safety theory* clearly points out that individuals make errors all the time. Think of driving home from the hospital: you intend to stop and pick up a quart of milk on the way home but find yourself entering your driveway without realizing how you got there. Everybody uses low-level, semiautomatic behavior for many activities in daily life; this kind of error is called a *slip*. Slips occur often during care delivery—e.g., when people intend to write an order but forget because they must complete another action first. *Mistakes*, by contrast, are errors of a higher level; they occur in new or nonstereotypic situations in which conscious decisions are being made. An example would be dosing of a medication with which a physician is not familiar. The strategies used to prevent slips and mistakes are often different.

Systems theory suggests that most accidents occur as the result of a series of small failures that happen to line up in an individual instance so that an accident can occur **(Fig. 8-1)**. It also suggests that most individuals in an industry such as health care are trying to do the right thing (e.g., deliver safe care) and that most accidents thus result from defects in systems. Systems should be designed both to make errors less likely and to identify those that do inevitably occur.

Factors That Increase the Likelihood of Errors Many factors ubiquitous in health care systems can increase the likelihood of errors, including fatigue, stress, interruptions, complexity, and transitions. The effects of fatigue in other industries are clear, but its effects in health care have been more controversial until recently. For example, the accident rate among truck drivers increases dramatically if they work over a certain number of hours in a week, especially with prolonged shifts. A recent study of house officers in the intensive care unit demonstrated that they were about one-third more likely to make errors when they were on a 24-h shift than when they were on a schedule that allowed them to sleep 8 h the previous night. The American College of Graduate Medical Education has moved to address this issue by putting in place the 80-h workweek. Although this stipulation is a step forward, it does not address the most important cause of fatigue-related errors: extended-duty shifts. High levels of stress and heavy workloads also can increase error rates. Thus, in extremely high-pressure situations, such as cardiac arrests, errors are more likely to occur. Strategies such as using protocols in these settings can be helpful, as can simple recognition that the situation is stressful.

Interruptions also increase the likelihood of error and occur frequently in health care delivery. It is common to forget to complete an action when one is interrupted partway through it by a page, for example. Approaches that may be helpful in this area include minimizing interruptions and setting up tools that help define the urgency of an interruption.

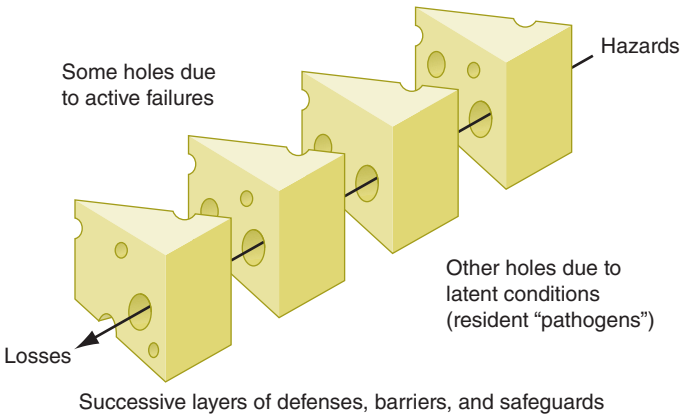

FIGURE 8-1 "Swiss cheese" diagram. Reason argues that most accidents occur when a series of "latent failures" are present in a system and happen to line up in a given instance, resulting in an accident. Examples of latent failures in the case of a fall might be that the unit is unusually busy and the floor happens to be wet. *(Adapted from J Reason: BMJ 320:768, 2000.)*

Complexity represents a key issue that contributes to errors. Providers are confronted by streams of data (e.g., laboratory tests and vital signs), many of which provide little useful information but some of which are important and require action or suggest a specific diagnosis. Tools that emphasize specific abnormalities or combinations of abnormalities may be helpful in this area.

Transitions between providers and settings are also common in health care, especially with the advent of the 80-h workweek, and generally represent points of vulnerability. Tools that provide structure in exchanging information—for example, when transferring care between providers—may be helpful.

The Frequency of Adverse Events in Health Care Most large studies focusing on the frequency and consequences of adverse events have been performed in the inpatient setting; some data are available for nursing homes, but much less information is available about the outpatient setting. The Harvard Medical Practice Study, one of the largest studies to address this issue, was performed with hospitalized patients in New York. The primary outcome was the adverse event: an injury caused by medical management rather than by the patient's underlying disease. In this study, an event either resulted in death or disability at discharge or prolonged the length of hospital stay by at least 2 days. Key findings were that the adverse event rate was 3.7% and that 58% of the adverse events were considered preventable. Although New York is not representative of the United States as a whole, the study was replicated later in Colorado and Utah, where the rates were essentially similar. Since then, other studies using analogous methodologies have been performed in various developed nations, and the rates of adverse events in these countries appear to be ~10%. Rates of safety issues appear to be even higher in developing and transitional countries; thus, this is clearly an issue of global proportions.

In the Harvard Medical Practice Study, adverse drug events (ADEs) were most common, accounting for 19% of all adverse events, and were followed in frequency by wound infections (14%) and technical complications (13%). Almost half of adverse events were associated with a surgical procedure. Among nonoperative events, 37% were ADEs, 15% were diagnostic mishaps, 14% were therapeutic mishaps, 13% were procedure-related mishaps, and 5% were falls.

ADEs have been studied more than any other error category. Studies focusing specifically on ADEs have found that they appear to be much more common than was suggested by the Harvard Medical Practice Study, although most other studies use more inclusive criteria. Detection approaches in the research setting include chart review and the use of a computerized ADE monitor, a tool that explores the database and identifies signals that suggest an ADE may have occurred. Studies that use multiple approaches find more ADEs than does any individual approach, and this discrepancy suggests that the true underlying rate in the population is higher than would be identified by a single approach. About 6–10% of patients admitted to U.S. hospitals experience an ADE.

Injuries caused by drugs are also common in the outpatient setting. One study found a rate of 21 ADEs per every 100 patients per year when patients were called to assess whether they had had a problem with one of their medications. The severity level was lower than in the inpatient setting, but approximately one-third of these ADEs were preventable.

The period immediately after a patient is discharged from the hospital appears to be very risky. A recent study of patients hospitalized on a medical service found an adverse event rate of 19%; about one-third of those events were preventable, and another one-third were ameliorable (i.e., they could have been made less severe). ADEs were the single leading error category.

Prevention Strategies Most work on strategies to prevent adverse events has targeted specific types of events in the inpatient setting, with nosocomial infections and ADEs having received the most attention. Nosocomial infection rates have been reduced greatly in intensive care

settings, especially by using checklists. For ADEs, several strategies have been found to reduce the medication error rate, although it has been harder to demonstrate that they reduce the ADE rate overall, and no studies with adequate power to show a clinically meaningful reduction have been published.

Implementation of checklists to ensure that specific actions are carried out has had a major impact on rates of catheter-associated bloodstream infection and ventilator-associated pneumonia, two of the most serious complications occurring in intensive care units. The checklist concept is based on the premise that several specific actions can reduce the frequency of these issues; when these actions are all taken for every patient, the result has been an extreme reduction in the frequency of the associated complication. These practices have been disseminated across wide areas in the state of Michigan.

Computerized physician order entry (CPOE) linked with clinical decision support reduces the rate of serious medication errors, defined as those that harm someone or have the potential to do so. In one study, CPOE, even with limited decision support, decreased the serious medication error rate by 55%. CPOE can prevent medication errors by suggesting a default dose, ensuring that all orders are complete (e.g., that they include dose, route, and frequency), and checking orders for allergies, drug–drug interactions, and drug–laboratory issues. In addition, clinical decision support can suggest the right dose for a patient, tailoring it to the level of renal function and age. In one study, patients with renal insufficiency received the appropriate dose only one-third of the time without decision support, whereas that fraction increased to approximately two-thirds with decision support; moreover, with such support, patients with renal insufficiency were discharged from the hospital half a day earlier. As of 2019, over 95% of U.S. hospitals had implemented CPOE, although the decision support often is still limited.

Another technology that can improve medication safety is bar coding linked with an electronic medication administration record. Bar coding can help ensure that the right patient gets the right medication at the right time. Electronic medication administration records can make it much easier to determine what medications a patient has received. Studies to assess the impact of bar coding on medication safety are under way, and the early results are promising. Another technology to improve medication safety is "smart pumps." These pumps can be set according to which medication is being given and at what dose; the health care professional will receive a warning if too high a dose is about to be administered.

The National Safety Picture Several organizations, including the National Quality Forum and The Joint Commission, have made recommendations for improving safety. The National Quality Forum has released recommendations to U.S. hospitals about what practices will most improve the safety of care, and all hospitals are expected to implement these recommendations. Many of these practices arise frequently in routine care. One example is "readback," the practice of recording all verbal orders and immediately reading them back to the physician to verify the accuracy of what was heard. Another is the consistent use of standard abbreviations and dose designations; some abbreviations and dose designations are particularly prone to error (e.g., 7U may be read as 70).

Measurement of Safety Measuring the safety of care is difficult and expensive, since adverse events are, fortunately, rare. Most hospitals rely on spontaneous reporting to identify errors and adverse events, but the sensitivity of this approach is very low, with only ~1 in 20 ADEs reported. Promising research techniques involve searching the electronic record for signals suggesting that an adverse event has occurred. These methods are not yet in wide use but will probably be used routinely in the future. Claims data have been used to identify the frequency of adverse events; this approach works much better for surgical care than for medical care and requires additional validation. The net result is that, except for a few specific types of events (e.g., falls and nosocomial infections), hospitals have little idea about the true frequency of safety issues.

Nonetheless, all providers have the responsibility to report problems with safety as they are identified. All hospitals have spontaneous reporting systems, and if providers report events as they occur, those events can serve as lessons for subsequent improvement.

Conclusions about Safety It is abundantly clear that the safety of health care can be improved substantially. As more areas are studied closely, more problems are identified. Much more is known about the epidemiology of safety in the inpatient setting than in outpatient settings. A number of effective strategies for improving inpatient safety have been identified and are increasingly being applied. Some effective strategies are also available for the outpatient setting. Transitions appear to be especially risky. The solutions to improving care often entail the consistent use of systematic techniques such as checklists and often involve leveraging of information technology. Nevertheless, solutions will also include many other domains, such human factors techniques, team training, and a culture of safety.

QUALITY IN HEALTH CARE

Assessment of quality of care has remained somewhat elusive, although the tools for this purpose have increasingly improved. Selection of health care and measurement of its quality are components of a complex process.

Quality Theory Donabedian has suggested that quality of care can be categorized by type of measurement into structure, process, and outcome. *Structure* refers to whether a particular characteristic is applicable in a particular setting—e.g., whether a hospital has a catheterization laboratory or whether a clinic uses an electronic health record. *Process* refers to the way care is delivered; examples of process measures are whether a Pap smear was performed at the recommended interval or whether an aspirin was given to a patient with a suspected myocardial infarction. *Outcome* refers to what happens—e.g., the mortality rate in myocardial infarction. It is important to note that good structure and process do not always result in a good outcome. For instance, a patient may present with a suspected myocardial infarction to an institution with a catheterization laboratory and receive recommended care, including aspirin, but still die because of the infarction.

Quality theory also suggests that overall quality will be improved more in the aggregate if the performance level of all providers is raised rather than if a few poor performers are identified and punished. This view suggests that systems changes are especially likely to be helpful in improving quality, since large numbers of providers may be affected simultaneously.

The theory of *continuous quality improvement* suggests that organizations should be evaluating the care they deliver on an ongoing basis and continually making small changes to improve their individual processes. This approach can be very powerful if embraced over time.

Several specific tools have been developed to help improve process performance. One of the most important is the Plan-Do-Check-Act cycle **(Fig. 8-2)**. This approach can be used for "rapid cycle" improvement of a process—e.g., the time that elapses between a diagnosis of pneumonia and administration of antibiotics to the patient. Some statistical tools, such as control charts, are often used in conjunction to determine whether progress is being made. Because most medical care includes one or many processes, this tool is especially important for improvement.

Factors Relating to Quality Many factors can decrease the level of quality, including stress to providers, high or low levels of production pressure, and poor systems. Stress can have an adverse effect on quality because it can lead providers to omit important steps, as can a high level of production pressure. Low levels of production pressure sometimes can result in worse quality, as providers may be bored or have little experience with a specific problem. Poor systems can have a tremendous impact on quality, and even extremely dedicated providers typically cannot achieve high levels of performance if they are operating within a poor system.

Data about the Current State of Quality A study published by the RAND Corporation in 2006 provided the most complete picture of

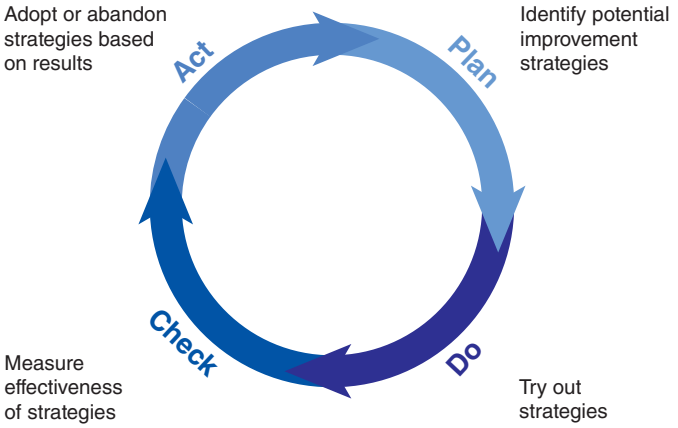

FIGURE 8-2 Plan-Do-Check-Act cycle. This approach can be used to improve a specific process rapidly. First, planning is undertaken, and several potential improvement strategies are identified. Next, these strategies are evaluated in small "tests of change." "Checking" entails measuring whether the strategies have appeared to make a difference, and "acting" refers to acting on the results.

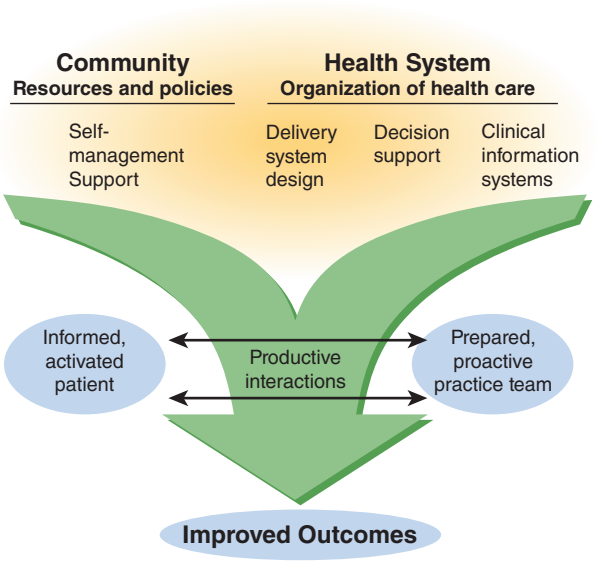

FIGURE 8-3 The Chronic Care Model, which focuses on improving care for chronic diseases, suggests that (1) delivery of high-quality care requires a range of strategies that must closely involve and engage the patient and (2) team care is essential. *(From EH Wagner et al: Eff Clin Pract 1:2, 1998.)*

quality of care delivered in the United States to date. The results were sobering. The authors found that, across a wide range of quality parameters, patients in the United States received only 55% of recommended care overall; there was little variation by subtype, with scores of 54% for preventive care, 54% for acute care, and 56% for care of chronic conditions. The authors concluded that, in broad terms, the chances of getting high-quality care in the United States were little better than those of winning a coin flip.

Work from the Dartmouth Atlas of Health Care evaluating geographic variation in use and quality of care demonstrates that, despite large variations in utilization, there is no positive correlation between the two variables at the regional level. An array of data demonstrate, however, that providers with larger volumes for specific conditions, especially for surgical conditions, do have better outcomes.

Strategies for Improving Quality and Performance Many specific strategies can be used to improve quality at the individual level, including rationing, education, feedback, incentives, and penalties. *Rationing* has been effective in some specific areas, such as persuading physicians to prescribe within a formulary, but it generally has been resisted. *Education* is effective in the short run and is necessary for changing opinions, but its effect decays fairly rapidly with time. *Feedback* on performance can be given at either the group or the individual level. Feedback is most effective if it is individualized and is given in close temporal proximity to the original events. *Incentives* can be effective, and many believe that they will prove to be a key to improving quality, especially if pay-for-performance with sufficient incentives is broadly implemented (see below). *Penalties* produce provider resentment and are rarely used in health care.

Another set of strategies for improving quality involves changing the systems of care. An example would be introducing reminders about which specific actions need to be taken at a visit for a specific patient—a strategy that has been demonstrated to improve performance in certain situations, such as the delivery of preventive services. Another approach that has been effective is the development of "bundles" or groups of quality measures that can be implemented together with a high degree of fidelity. Many hospitals have implemented a bundle for ventilator-associated pneumonia in the intensive care unit that includes five measures (e.g., ensuring that the head of the bed is elevated). These hospitals have been able to improve performance substantially. Another technique is SCAMPs, or Standardized Clinical Assessment and Management Plans. These are care guidelines developed by clinicians who identify key steps in workflow and decisions to help improve the process outcomes.

Perhaps the most pressing need is to improve the quality of care for chronic diseases. The Chronic Care Model has been developed by Wagner and colleagues **(Fig. 8-3)**; it suggests that a combination of strategies is necessary (including self-management support, changes in delivery system design, decision support, and information systems) and that these strategies must be delivered by a practice team composed of several providers, not just a physician.

Available evidence about the relative efficacy of strategies in reducing hemoglobin A_{1c} (HbA_{1c}) in outpatient diabetes care supports this general premise. It is especially notable that the outcome was the HbA_{1c} level, as it has generally been much more difficult to improve outcome measures than process measures (such as whether HbA_{1c} was measured). In this meta-analysis, a variety of strategies were effective, but the most effective ones were the use of team changes and the use of a case manager. When cost-effectiveness is considered in addition, it appears likely that an amalgam of strategies will be needed. However, the more expensive strategies, such as the use of case managers, probably will be implemented widely only if pay-for-performance takes hold.

The evidence linking better performance on quality metrics assessing process and outcomes varies greatly by condition. For example, there is strong evidence that performing Pap smears results in better outcomes in patients who develop cervical cancer, but the evidence for many other conditions is far more tenuous.

National State of Quality Measurement In the inpatient setting, quality measurement is now being performed by a very large proportion of hospitals for several conditions, including myocardial infarction, congestive heart failure, pneumonia, and surgical infection prevention; 20 measures are included in all. This is the result of the Hospital Quality Initiative, which represents a collaboration among many entities, including the Hospital Quality Alliance, The Joint Commission, the National Quality Forum, and the Agency for Healthcare Research and Quality. The data are housed at the Centers for Medicare and Medicaid Services, which publicly releases performance data on the measures on a website called *Hospital Compare* (*www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/HospitalQualityInits/HospitalCompare.html*). These data are reported voluntarily and are available for a very high proportion of the nation's hospitals. Analyses demonstrate substantial regional variation in quality and important differences among hospitals. Analyses by The Joint Commission for similar indicators reveal that performance on measures by hospitals has improved over time and that, as might be hoped, lower performers have improved more than higher performers.

Public Reporting Overall, public reporting of quality data is becoming increasingly common. There are now commercial websites that have quality-related data for most regions of the United States, and

these data can be accessed for a fee. Similarly, national data for hospitals are available. The evidence to date indicates that patients have not made much use of such data, but that the data have had an important effect on provider and organization behavior. Instead, patients have relied on provider reputation to make choices, partly because little information was available until very recently and the information that was available was not necessarily presented in ways that were easy for patients to access. Problems still exist with quality metrics; many can be "gamed," and even though providers are now nearly universally using electronic health records (EHRs), most metrics come from claims that include many inaccuracies. More metrics that leverage EHRs are sorely needed. However, many authorities think that, as more information about quality becomes available, it will become increasingly central to patients' choices about where to access care.

Pay-for-Performance Currently, providers in the United States get paid the same amount for a specific service, regardless of the quality of care delivered. The pay-for-performance theory suggests that, if providers are paid more for higher-quality care, they will invest in strategies that enable them to deliver that care. The current key issues in the pay-for-performance debate relate to (1) how effective it is, (2) what levels of incentives are needed, and (3) what perverse consequences are produced. The evidence on effectiveness is limited, although a number of studies are ongoing. With respect to incentive levels, most quality-based performance incentives have accounted for merely 1–2% of total payment in the United States to date. In the United Kingdom, however, 40% of general practitioners' salaries have been placed at risk according to performance across a wide array of parameters; this approach has been associated with substantial improvements in reported quality performance, although it is still unclear to what extent this change represents better performance versus better reporting. The potential for perverse consequences exists with any incentive scheme. One problem is that, if incentives are tied to outcomes, there may be a tendency to transfer the sickest patients to other providers and systems. Another concern is that providers will pay too much attention to quality measures with incentives and ignore the rest of the quality picture. The validity of these concerns remains to be determined. Nonetheless, it appears likely that, under health care reform, the use of various pay-for-performance schemes is likely to increase.

CONCLUSIONS

The safety and quality of care in the United States could be improved substantially. A number of available interventions have been shown to improve the safety of care and should be used more widely; others are undergoing evaluation or soon will be. Quality also could be dramatically better, and the science of quality improvement continues to mature. Implementation of value-based approaches such as accountable care that include pay-for-performance related to safety and quality should make it much easier for organizations to justify investments in improving safety and quality parameters, including health information technology. However, many improvements will also require changing the structure of care—e.g., moving to a more team-oriented approach and ensuring that patients are more involved in their own care. Payment reform focusing on value seems very likely to progress and will likely include both positive incentives and penalties related to safety and quality performance. Measures of safety are still relatively immature and could be made much more robust; it would be particularly useful if organizations had measures they could use in routine operations to assess safety at a reasonable cost, and substantial research is addressing this. Although the quality measures available are more robust than those for safety, they still cover a relatively small proportion of the entire domain of quality, and more measures need to be developed. The public and payers are demanding better information about safety and quality as well as better performance in these areas. The clear implication is that these domains will have to be addressed directly by providers.

9 Diagnosis: Reducing Errors and Improving Quality

Gordon Schiff

Diagnosing patients' illnesses is the essence of medicine. Patients present to doctors seeking an answer to the question, "What is wrong with me?" Ideally, no clinician would want to treat a patient without knowing the diagnosis or, worse yet, erroneously treat a misdiagnosed illness. From the earliest moments of medical school, the defining quest toward becoming a knowledgeable and proficient physician is learning how to put a diagnostic label on patients' symptoms and physical findings, and clinicians pride themselves on being "good diagnosticians." Yet the centuries-old paradigm of mastering a long list of diseases, understanding their pathophysiology, and knowing the cardinal ways they manifest themselves in signs and symptoms, while still of fundamental importance, is being challenged by new insights illuminated by the glaring spotlight of diagnostic errors. Basic internal medicine diseases, such as asthma, pulmonary embolism, congestive heart failure, seizures, strokes, ruptured aneurysms, depression, and cancer, are misdiagnosed at shockingly high rates, often with 20–50% of patients either being mislabeled as having these conditions (false-positive diagnoses) or having their diagnosis missed or delayed (false negatives). How and why do physicians so often get it wrong, and what can we do to both diagnose and treat the problem of delayed diagnosis or misdiagnosis?

Diagnosis is both an ancient art and a modern science. The current science of diagnosis, however, goes far beyond what typically comes to clinicians' and patients' minds when they conjure up images of state-of-the-art molecular, genetic, or imaging technologies. Improvements in diagnosis are just as likely to come from other areas, many with origins outside of medicine, as they are from advanced diagnostic testing modalities. These diverse sciences that the field of diagnostic safety has, and must, draw from include systems and human factors

engineering, reliability science, cognitive psychology, decision sciences, forensic science, clinical epidemiology, health services research, decision analysis, network medicine, learning health systems theory, medical sociology, team dynamics and communication, risk assessment and communication, information and knowledge management, and health information technology, especially artificial intelligence and clinical decision support. A clinician reading this chapter is likely to find this list of overlapping and intersecting domains quite daunting. However, rather than feeling overwhelmed, we urge readers to view them as the basic science supports that will ultimately make their lives easier and diagnosis more accurate and timely. Rather than feeling intimidated, clinicians should feel a sense of relief and assurance in understanding that good diagnosis does not rest entirely on their shoulders. Instead, it is a systems property, where an infrastructure and a team, one that especially includes the patient, can in a coordinated way work together to achieve more reliable and optimal diagnosis.

EMERGENCE OF DIAGNOSIS ERROR AS AN IMPORTANT PATIENT SAFETY ISSUE

Over the past decade, a series of studies culminating in a landmark report from the U.S. National Academy of Medicine (NAM), *Improving Diagnosis in Health Care,* have shone a spotlight on diagnostic errors. Reports from patient surveys, malpractice claims, and safety organizations, such as the ECRI and the National Patient Safety Foundation (now part of Institute for Healthcare Improvement), have found that diagnostic errors are the leading type of medical error. Although errors in diagnosis are defined in various ways, the NAM Committee defined diagnostic error as "the failure to (a) establish an accurate and timely explanation of the patient's health problem(s) or (b) communicate that explanation to the patient." One way to visualize diagnostic errors is through a Venn diagram **(Fig. 9-1)**, which illustrates the fact that many things can go wrong in the diagnostic process (e.g., failure to ask an important history question, physical examination sign overlooked, laboratory specimen erroneously switched between two patients, x-ray not followed up), but this usually does not result in a wrong diagnosis or patient harm. Similarly, a patient can be misdiagnosed but unharmed, without any identifiable error in the care received. Our greatest concern is where these three circles intersect, with conservative estimates suggesting that 40,000–80,000 patients die each year in U.S. hospitals alone from diagnostic errors. The NAM report outlined eight recommendations that are the foundation for this chapter **(Table 9-1)**.

NEW WAYS TO THINK ABOUT DIAGNOSIS AND DIAGNOSTIC ERRORS

Medical textbooks have historically given attention to "clinician reasoning" and associated cognitive heuristics and biases. Errors in clinical reasoning can be summarized in three broad groups: (1) hasty judgments, (2) biased judgments, and (3) inaccurate probability estimates. Research from cognitive psychology has identified scores of common mental shortcuts or "heuristics" humans are prone to use in everyday life, many of which are useful for efficient diagnosis but

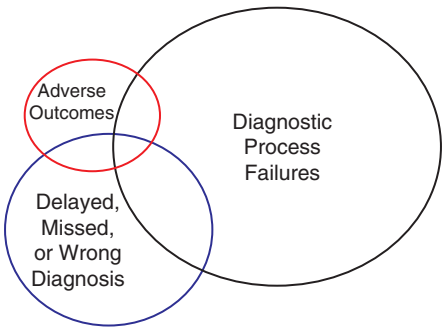

FIGURE 9-1 What is a diagnosis error? *(Adapted from GD Schiff et al: Diagnosing diagnosis errors: Lessons from a multi-institutional collaborative project, in Advances in Patient Safety: from Research to Implementation. Vol. 2 Concepts and Methodology, Rockville, MD, 2005, pp. 255-278, and GD Schiff, L Leape: Acad Med 87:135, 2012.)*

TABLE 9-1 National Academy of Medicine Recommendations for Improving Diagnosis in Health Care

1. Facilitate more effective teamwork in the diagnostic process among health care professionals, patients, and their families.
2. Enhance professional education and training in the diagnostic process in areas such as clinical reasoning; teamwork; communication with patients, families, and other health care professionals; and appropriate use of diagnostic tests.
3. Ensure that health information technologies support patients and health care professionals in the diagnostic process.
4. Develop and deploy approaches to identify, learn from, and reduce diagnostic errors and near misses in clinical practice including providing systematic feedback on diagnostic performance.
5. Establish a work system and culture that supports the diagnostic process and improvements in diagnostic performance.
6. Develop a reporting environment and medical liability system that facilitates improved diagnosis by learning from diagnostic errors and near misses.
7. Design a payment and care delivery environment that supports the diagnostic process.
8. Provide dedicated funding for research on the diagnostic process and diagnostic errors.

can also lead to biases and errors. **Table 9-2** lists some of the common cognitive biases that can lead diagnosis astray (this topic is discussed further in **Chap. 4**).

However, clinicians will also benefit from having a better understanding of diagnosis as a "system" rather than just what takes place in clinicians' minds. Classic teaching exhorting trainees and practicing physicians to have a broad differential and "high index of suspicion" for various diseases is challenged not only by these unconscious biases but also by limitations of human memory, information shortfalls, constrained encounter time, system process failures, and the myriad nonspecific symptoms that patients bring to clinicians. Many symptoms are self-limited, defy a precise diagnosis or etiology, and do not portend harmful outcomes. Insights from safety and cognitive sciences call for rethinking traditional approaches to diagnosis and suggest new approaches to overcome current limitations **(Table 9-3)**.

UNCERTAINTY IN DIAGNOSIS

Given variations and overlap in ways patients present, illnesses evolve, and tests perform, it is often not possible or practical to "make" a definitive diagnosis, particularly in the primary care setting early in the course of a patient's illness. Clinicians need to harness these uncertainties to both engineer situational awareness of where things

TABLE 9-2 Selected Cognitive Biases Contributing to Diagnostic Errors

1. Premature closure: accepting a diagnosis before it has been fully verified
2. Anchoring: tendency to fixate on a specific symptom or piece of information early in the diagnostic process with subsequent failure to appropriately adjust
3. Confirmation bias: tendency to look for confirming evidence to support one's diagnostic hypothesis, rather than disconfirming evidence to refute it
4. Search satisficing: tendency to call off a search, satisfied once a piece of data or presumed explanation is found, and not considering/searching for additional findings or diagnoses
5. Availability bias: tendency to give too much weight to diagnoses that come more readily to mind (e.g., recent dramatic case)
6. Base-rate neglect: failing to adequately take into account prevalence of a particular disease (e.g., erroneously interpreting a positive test as indicating disease in a low-prevalence population using a test with 5% false-positive rate)
7. Knowledge deficit (on part of provider, with accompanying lack of awareness)
8. Framing bias: Judgement overly influenced by the way the problem was presented (how it was framed in words, settings, situations)
9. Social/demographic/stereotype bias: biases from personal or cultural beliefs about women, minorities, or other patient groups for whom prejudices may distort diagnostic assessment

TABLE 9-3 New Models for Conceptualizing Diagnosis and Diagnosis Improvement

TRADITIONAL WAYS OF THINKING ABOUT DIAGNOSIS AND DIAGNOSTIC ERROR	NEW PARADIGMS/BETTER WAYS TO THINK ABOUT DIAGNOSIS AND IMPROVING DIAGNOSIS
General	
A good diagnostician gets it right the first time, almost all of the time	Diagnosis is an inexact science with inherent uncertainties Goal is to minimize errors and delays via more reliable systems and follow-up
Lore of masterful/skillful academic expert diagnostician who knows/recalls everything; need to look to them if seeking diagnostic excellence	Less reliance on (fallible) human memory Quality diagnosis is based on well-coordinated distributed network/team of people and reliable processes All patients entitled to receive quality diagnosis, regardless of where and from whom they receive care
Diagnosis is the doctor's job	Co-production of diagnosis among clinicians (including lab, radiology, specialists, nurses, social workers) and, especially, the patient and family
Patients often viewed as overly anxious, exaggerating, time-consuming, questioning, with sometimes unreasonable demands and expectations	Patients are key allies in diagnosis; hold key information Need to address understandable/legitimate fears, desires for explanations Leveraging patient questions and questioning of diagnosis to stimulate rethinking the diagnosis where needed
Diagnosis and treatment as separate stages in patient care (i.e., make a diagnosis, then treat)	Prioritizing diagnostic efforts to target treatable conditions More integrated strategies and timing for testing and treatment depending on urgency for treatment
Clinical practices	
Order lots of tests to avoid missing diagnoses	Judicious ordering: targeted, well-organized data and testing Appreciation of test limitations (false positive or negative, incidental findings, overdiagnosis, test risks) and resulting harms
More referrals to avoid missing rarer/specialized diagnoses; concomitant utilization barriers (copays, prior authorization) to minimize overuse	"Pull systems" to lower barriers and make it easier to pose questions, obtain real-time virtual consults Co-management approaches to enable collaborative watch-and-wait conservative strategies where appropriate
Frequent empirical drug trials when uncertain of diagnosis	Conservative use of drugs to avoid confusing clinical picture or labeling patients with diseases they may not have
Physician attention/efforts to ensure disease screening	Automating, delegating clerical functions; teamwork to free up physician cognitive time
Diagnosis errors and challenges	
Diagnostic error viewed as a personal failing Errors classified as either "system" or "cognitive"	Many errors/delays rooted in processes and system design/failures Errors multifactorial with interwoven, interacting, and inseparable cognitive and system factors
Errors are infrequent; hit-and-miss ways to learn about errors	Errors are common; systematic proactive follow-up is needed to recognize potential for errors Surveilling of high-risk situations and one's own diagnostic performance and outcomes
Clinicians' reactions: denial, defensive, others to blame, pointing to others also making similar errors	Culture of actively and nondefensively seeking to uncover, dig deep to learn from, and share errors and lessons
Dreading complex, frustrating diagnostic dilemmas	Welcoming/enjoying intellectual/professional challenges Adequate support (time, help, consultations) for more complex patients
Diagnoses as distinct labels, events	Diagnoses can be indistinct, interacting comorbidities, socially constructed, multifactorial, evolving over time, or have overlapping genotype-phenotype expressions
Documentation/communication	
Viewed as time-consuming, mindless, primarily to document for billing code and/or bulwark against malpractice claims	Documentation as useful tool for reflecting, crafting, sharing assessments, differential diagnosis, reflecting about unanswered questions Opportunities for decision support interacting with computer Notes open for patients to read to help understand and critique diagnosis
Say and write as little as possible about uncertainties, lest it be used against you in malpractice allegation	Share uncertainties to maximize communication and engagement with other caregivers, patients
Don't let patient know about errors so they don't become angry, mistrustful, or sue	Patients have right to honest disclosure; often find out about errors anyway (e.g., cancer evolves); anticipate, engage their concerns
Patients advised to call if not better; no news is good news (test results: "We'll call if anything is abnormal.")	Systematic proactive follow-up to close loop on tests and symptoms, to check how patient is doing, monitor outcomes
Global remedies	
Knowing/memorizing more medical knowledge	Knowing more about the patient (including psychosocial, past history, environmental contexts)
Attention to the "objective" data (physical exam, tests) to reliably make diagnoses	Renewed emphasis on history, history-taking, listening Acknowledgement of ubiquitous subjective cognitive biases; efforts to anticipate, recognize, counteract
Exhortations to have "high index of suspicion" of various diagnoses	Less reliance on memory recall of lectures/reading; more just-in-time info look-up Affordances, alerts to red flags engineered into workflow Delineation of "don't miss" diagnoses with design of context-relevant decision support reminders
Ensuring physician is copied on everything, thorough/voluminous notes, widespread reminders/alerts	Biggest problem is no longer lack of access to information, but rather information overload; strategies to organize, minimize
Continuing medical education (CME) courses to expand medical knowledge	Real-time, context-aware reminders of pitfalls, critical differential diagnoses, and key differentiating features. Ready access to medical references, second opinions

(*Continued*)

TABLE 9-3 New Models for Conceptualizing Diagnosis and Diagnosis Improvement (Continued)

TRADITIONAL WAYS OF THINKING ABOUT DIAGNOSIS AND DIAGNOSTIC ERROR	NEW PARADIGMS/BETTER WAYS TO THINK ABOUT DIAGNOSIS AND IMPROVING DIAGNOSIS
Redundancies, double-checks	Recognition that single, highly reliable systems are often better than multiple halfway solutions. Clear delineation of responsibilities for follow-up tasks
Fear of malpractice suits to motivate physicians to be more careful and practice defensive medicine	Drive out fear, making it safe to learn from and share errors Shared situational awareness of where pitfalls lurk
More accountability, financial incentives, and penalties tied to performance metrics	Clinician engagement in improvement based on trust, collaboration, professionalism, financial neutrality Metric modesty, recognizing many best practices yet to be defined/proven
More rules, requirements; target outliers for better compliance	Standardization with flexibility; learning from deviations
More time with patients	Better time spent with patients: offloading distractions, more efficient history collection/organization, longitudinal continuity, and, where needed, additional time to talk/think/explain during, before, or after visits Easier access for patients to reach or be seen by clinicians when experiencing symptoms
Reflex changes in response to errors	Avoiding "tampering," which entails understanding/diagnosing difference between "special cause" versus "common cause" (random) variation

Source: Modified from GD Schiff: Quality and Safety in Health Care 2013.

can go wrong and create safety nets to protect patients against harms from delayed diagnosis and misdiagnosis. Terms such as *preliminary diagnosis*, *working diagnosis*, *differential diagnosis*, *deferred diagnosis*, *undiagnosed illness*, *diagnoses with uncertain or multifactorial etiologies*, *intermittent diagnoses*, *multiple/dual diagnoses*, *self-diagnosis*, or at times *contested diagnosis* need to be part of our vocabulary, thinking, and communications with patients to convey that diagnosis is often imprecise. Anxious patients worried about a condition, for example, cancer, COVID-19 infection, or a diagnosis to which a relative or a friend has recently succumbed, come seeking reassurance and may not welcome an uncertain answer. Thus, we have to work with patients, listen to and respect their concerns, and take their symptoms seriously yet modestly acknowledge our limitations. We need to tailor this approach to patients' differing levels of health literacy, trust in our clinical advice, and experiences with the health system.

DON'T MISS DIAGNOSES AND RED FLAGS

Uncertainty should not be a license for complacency. Particularly for diseases that (1) progress rapidly, (2) require specific treatments that depend on making the correct diagnosis, or (3) have public health or contagion implications, clinicians need to be poised, and systems designed, to consider and, where appropriate, pursue critical "don't miss" diagnoses. While clinicians are generally aware of more common "don't miss" diagnoses (e.g., acute myocardial infarction, sepsis), Table 9-4 illustrates examples of less common diagnoses that warrant similar consideration. Throughout this textbook, readers should orient themselves to recognize such critical diagnoses and think about presentations and syndromes where they may be lurking.

An important related concept is so-called "red flags" or "alarm symptoms." This construct has its origins in guidelines for back pain but has increasingly been applied to many other problems, such as headache, red eye, swollen joint, or even abdominal pain and chest pain. Examples of widely cited red flags for back pain that should trigger consideration of more serious etiologies include fever, weight loss, history of malignancy or intravenous drug use, or neurologic signs and symptoms. In theory, many presenting syndromes could benefit from identification of such clues to more serious diagnoses. Evidence-based medicine calls for better data on the sensitivity, specificity, yield, and discriminatory ability of various clinical "red flag" clues; yet, few have been rigorously evaluated. Nonetheless, clinicians find them useful as simple ways to reassure themselves and their patients that a common symptom such as back pain or headache is, or is not, likely an indicator of more urgent or serious pathology.

Interwoven with the challenges of not missing critical diagnoses is the problem of overtesting and overdiagnosis—performing unnecessary and even potentially harmful tests whose benefit does not justify the risks or costs or that may lead to diagnoses that would have never caused any symptoms or problems. Thoughtful diagnosticians need to weigh carefully this "other side of the coin" of missed diagnosis to avoid such harms and expenses.

DIAGNOSTIC PITFALLS

One of the important ways of learning in medicine is learning from the missteps of those who have walked the path ahead of us. By learning about commonly missed diagnoses and the ways accurate, timely diagnosis went astray, we can avoid making similar mistakes. Anticipating the potential for similar types of errors can both create situational awareness of traps to avoid and contribute to learning from our own personal and collective patterns of mistakes. Several studies have examined common or recurring pitfalls in diagnosis. An example of a common disease-specific diagnostic pitfall in breast cancer diagnosis is ordering a mammogram for a woman with a palpable breast lump and, when the mammogram returns as normal, reassuring her that cancer has been "ruled out" by the negative test. Any mass or lesion palpable

TABLE 9-4 Examples of "Don't Miss" Diagnoses

INFECTIONS/ INFLAMMATION	CARDIAC/ISCHEMIC/ BLEEDING	METABOLIC/ HEMATOLOGIC/ ENVIRONMENTAL
Spinal epidural abscess	Aortic dissection Leaking/ruptured abdominal aortic aneurysm	Diabetes ketoacidosis Hyperosmolar hyperglycemia
Necrotizing fasciitis	Pericardial tamponade	Myxedema/ thyrotoxicosis
Meningitis	Wolff-Parkinson-White Prolonged QT	Addison's disease
Endocarditis	Pulmonary embolism	B_{12} deficiency anemia
Peritonsillar abscess	Tension pneumothorax	von Willebrand's disease
Tuberculosis-active pulmonary, other	Acute mesenteric ischemia Sigmoid volvulus	Hemochromatosis
COVID-19 infection	Esophageal, bowel perforation	Celiac sprue
Guillain-Barré syndrome	Cerebellar hemorrhage	Carbon monoxide poisoning
Ebola infection	Spinal cord compression	Food poisoning
Temporal arteritis	Testicular, ovarian torsion	Malignant hyperthermia
Rhabdomyolysis	Ectopic pregnancy	Alcohol, benzodiazepine, barbiturate withdrawal
Angioedema	Retroperitoneal hemorrhage	Tumor lysis syndrome Hypo-/hypercalcemia

TABLE 9-5 Generic Types of Diagnostic Pitfalls

PITFALL	EXAMPLES
Disease A mistaken for disease B Diseases often mistaken/misdiagnosed with each other	• Aortic dissection misdiagnosed as acute myocardial infarction • Bipolar disorder misdiagnosed as depression
Misinterpretation of test result(s) False-positive or false-negative results with failure to recognize test limitations	• Breast lump dismissed after negative mammogram • Negative COVID-19 test early or late in course
Failure to recognize atypical presentation, signs, and symptoms	• Apathetic hyperthyroidism • Sepsis in elderly patient who is afebrile or hypothermic
Failure to assess appropriately the urgency of diagnosis Urgency of the clinical situation was not appreciated and/or delays critical diagnoses	• Compartment syndrome • Pericardial tamponade • Tension pneumothorax
Perils of intermittent symptoms or misleading evolution Intermittent symptoms dismissed due to normal findings (exam, lab, electrocardiogram) when initially seen	• "Lucid interval" in traumatic epidural hematoma • Paroxysmal arrhythmias • Intermittent hydrocephalus (Bruns' syndrome)
Confusion arising from response/masking by empiric treatment	• Empiric treatment with steroids, proton pump inhibitors, antibiotics, pain medication erroneously masking serious diagnosis
Chronic disease or comorbidity presumed to account for new symptoms Especially in medically complex patients	• Septic joint signs misattributed to chronic rheumatoid arthritis • Mental status change due to infection or medication misattributed to underlying dementia
Rare diagnosis: failure to consider or know	• Many; fortunately, by definition, rare, but still warrant consideration especially if urgent or treatable
Drug or environmental factor not considered/overlooked Underlying etiology causing/contributing to symptoms, or disease progression not sought, uncovered	• Ventricular arrhythmia related to QT-prolonging drug • Achilles tendon rupture related to quinolone drugs
Failure to appreciate risk factors for particular disease	• Family history of breast, colorectal cancer not solicited and/or weighed in diagnostic evaluation or screening
Failure to appreciate limitations of physical exam Now with ↑ telemedicine, missing physical exam entirely	• Overweighing absence of tenderness, swelling in deep vein thrombosis • Missing pill-rolling tremor during telemedicine visit

on physical examination probably needs more careful assessment proceeding all the way to invasive biopsy, if necessary. Diagnostic pitfalls can be classified into a number of generic scenarios **(Table 9-5)**. We now have large databases that have the potential to track "diagnoses outcomes"—i.e., whether a new diagnosis emerges that suggests an initial diagnosis was incorrect or a diagnosis of a patient's symptoms was suboptimally delayed. This should, in the future, allow us to more rigorously focus on these cases, to identify contributing factors and recurring patterns, and to help point the way for systemwide improvement strategies.

DIAGNOSIS SAFETY CULTURE

Just as diagnosing bacterial infections relies on a proper culture medium to grow and identify etiologic organisms, good diagnosis also requires a healthy safety culture that will allow it to grow and flourish. While clinicians may be inclined to view "safety culture" as something too subjective to be important in their quest to make a definitive diagnosis, this view is misguided. Multiple studies have demonstrated adverse consequences resulting from organizational cultures that inhibit openness, learning, and sharing and create a climate where staff and patients are afraid to speak up when they observe problems or have questions. Most importantly, patients need to be encouraged to question diagnoses and be heard, particularly when they are not responding to treatment as expected or developing symptoms that are either not consistent with the diagnosis or represent possible red flags for other diagnoses or complications.

Studies examining "high-reliability organizations" outside of medicine and "learning health care organizations" have distilled a series of fundamental properties that are correlated with more reliable and safer outcomes. Just as a thermometer or recording of a pulse can suggest how ill a patient is, we now have instruments that can measure safety culture. These safety measurement tools typically are validated staff surveys that assess (1) communication about errors with staff willingness to report mistakes because they do not feel these mistakes are held against them; (2) openness and encouragement to talk about hospital/office problems; (3) existence of a learning culture that seeks to learn from errors and improve based on lessons learned; (4) leadership commitment to safety, prioritizing safety over production speed and the "bottom line" by providing adequate staffing and resources to operate safely; and (5) accountability and transparency for following up safety events and concerns. Each of these generic culture attributes translates into specific implications for diagnostic safety. These include the following:

- Making it "safe" for clinicians to admit and share diagnostic errors
- Proactive identification, ownership, and accountability regarding error-prone diagnostic workflow processes (particularly around test results, referrals, and patient follow-up)
- Leadership making diagnosis improvement a top priority based on recognition that patients and malpractice insurers report that diagnostic errors are the leading patient safety problem
- Mutual trust and respect for challenges that clinicians often face in making diagnoses and caution in applying the lens of hindsight bias in judging what in retrospect might seem like an "obvious" diagnosis that a clinician initially missed

HEALTH INFORMATION TECHNOLOGY AND THE FUTURE OF DIAGNOSIS

Clinicians now spend more time interacting with computers than they do interacting with patients. This is especially true for diagnosis and will likely be even more so in the future. Interactions with patients, consultants, and other staff are increasingly mediated through the computer. Key activities, such as collecting patients' history (past and current), interpreting data to make a diagnosis, conveying diagnostic assessments (to others on the team and, increasingly, to the patient via open notes), and tracking diagnostic trajectories as they evolve over time, are now computer based. With the rise of telemedicine, even elements of the physical examination have been rerouted to electronic encounters.

While many complain the computer has "gotten in the way" of good diagnosis, distracting clinicians from quality time listening to patients and miring doctors in reading and writing notes filled with copied/pasted/templated information of questionable currency and accuracy, medicine needs to harness the computer's capabilities to improve diagnosis **(Table 9-6)**. Although these basic diagnosis-supporting capabilities should be the foundation of the design of health information technology and everyday workflow, electronic medical records have historically been largely designed around other needs, such as ordering medications and billing and malpractice documentation. They need to be radically redesigned to better support diagnostic processes, as well as save, rather than squander, clinicians' time.

DIAGNOSIS OF DIAGNOSIS ERRORS AND SAFETY: PRACTICAL CONCLUSIONS

In practice, there are frequent and meaningful opportunities for improving diagnosis in each of the three NAM-defined areas to make it a) more reliable, b) timely, and c) to improve diagnosis-related communication with patients. Clinicians in training, practicing physicians, nurses, and others should develop the habit of regularly asking

TABLE 9-6 Areas Where Health Information Technology Has Potential to Help Improve Diagnosis and Reduce Errors

FUNCTION	EXAMPLES
Facilitate collection/ gathering of information	• Quickly access past history from prior care at same and outside institutions • Electronic collection of history of present illness, review of systems, and social determinant risks in advance of visits
Enhanced information entry, organization, and display	• Visually enhanced flowsheets showing trends, relationships to treatment • Reorganized notes to facilitate summarization and simplification and prevent items from getting lost
Generating differential diagnosis	• Automated creation of lists of diagnoses to consider based on patient's symptoms, demographics, risks
Weighing diagnoses likelihoods	• Tools to assist in calculation of posttest (Bayesian) probabilities
Aids for formulating diagnostic plan, intelligent test ordering	• Entering a diagnostic consideration (e.g., celiac disease, pheochromocytoma) and computer suggests most appropriate diagnostic test(s) and how to order
Access to diagnostic reference information	• Info-buttons instantly linking symptom or diagnosis relevant questions to Harrison's, Up-to-Date chapters, references
Ensuring more reliable follow-up	• Hardwiring "closed loops" to ensure abnormal labs, missed referrals, worrisome symptoms are tracked and followed up
Support screening for early detection	• Collaborative tools that patients, clinicians, and offices can use to know when due, order and track screening based on individualized demographics, risk factors, prior tests
Collaborative diagnosis; access to specialist	• Real-time posing/answering of questions • Electronic consults; virtual co-management
Facilitating feedback on diagnoses	• Feeding back new diagnoses (from downstream providers, patients) that emerge suggesting potential misdiagnosis/errors to clinicians, ERs who saw patient previously

Abbreviation: ERs, emergency rooms.

Source: Modified from G Schiff, DW Bates: N Engl J Med 362:1066, 2010, and R El-Karah et al: BMJ Qual Saf Suppl 2:ii40, 2013.

themselves three questions about individual patients in their care, and another three questions regarding the systems in which they work. For each patient being assessed, clinicians should ask:

1. What else might this be? (forcing a differential diagnosis to be made)
2. What doesn't fit? (making sure unexplained abnormal findings are not dismissed)
3. What critical diagnoses are important not to miss? (injecting consideration of "don't miss" diagnoses, red flags, and known pitfalls)

and to diagnose safely, each practitioner must recognize that he or she is working within a larger system. Questions to be asking continually, ensuring we are maximizing reliability and timeliness and minimizing potential for errors, include:

1. Do we have reliable "closed loop" systems to provide reliable, ideally automated tracking and following up of patients' symptoms, abnormal laboratory or imaging findings, and critical referrals that we order?
2. What is the culture-of-safety climate in our organization, office, or clinic?
3. How does the electronic (or even paper) medical record as currently implemented help versus impair efficient, timely, accurate, and fail-safe diagnosis, and how can it be improved?

To take these questions to the next stage, an international movement dedicated to studying and improving diagnosis has emerged. These efforts include annual conferences of clinicians, researchers, and patients; the formation of the Society for Improving Diagnosis in Medicine (SIDM); and convening of a broad coalition of organizations, including the American Board of Internal Medicine (ABIM), the American College of Physicians (ACP), and the Society of Hospital Medicine (SHM), committed to increasing awareness and action. Ultimately, collectively tackling the challenges of improving the quality of diagnosis will transform the way clinicians and patients work together to co-produce better diagnoses.

10 Racial and Ethnic Disparities in Health Care

Lenny López, Joseph R. Betancourt

Over the course of its history, the United States has experienced dramatic improvements in overall health and life expectancy, largely as a result of initiatives in public health, health promotion, disease prevention, and chronic care management. Our ability to prevent, detect, and treat diseases in their early stages has allowed us to target and reduce rates of morbidity and mortality. Despite interventions that have improved the overall health of the majority of Americans, racial and ethnic minorities (blacks, Hispanics/Latinos, Native Americans/Alaskan Natives, Asian/Pacific Islanders) have benefited less from these advances than whites and have suffered poorer health outcomes from many major diseases, including cardiovascular disease, cancer, and diabetes. These disparities highlight the importance of recognizing and addressing the multiple factors that impact health outcomes, including structural racism, *social determinants of health* (SDOH), access to care, and health care quality. On this last point, research has revealed that minorities may receive less care and lower-quality care than whites, even when confounders such as stage of presentation, comorbidities, and health insurance are controlled. These differences in quality are called *racial and ethnic disparities in health care*. These health care disparities have taken on greater importance with the significant transformation of the U.S. health care system and value-based purchasing. The shift toward creating financial incentives and disincentives to achieve quality goals makes focusing on those who receive lower-quality care more important than ever before. This chapter will provide an overview of racial and ethnic disparities in health and health care, identify root causes, and provide key recommendations to address these disparities at both the clinical and health system levels.

NATURE AND EXTENT OF DISPARITIES

Life expectancy at birth is an important measure of the health of a nation's population. Although the overall life expectancy in the United States has been increasing since 1900, differences due to

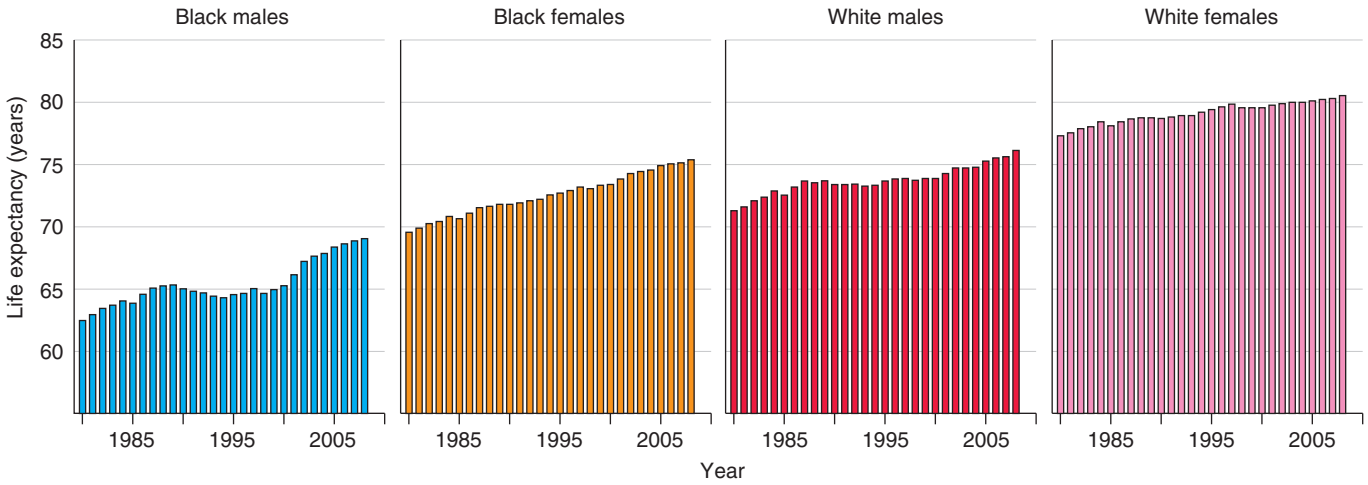

FIGURE 10-1 Life expectancy at birth among black and white males and females in the United States, 1975–2003. *(Adapted from S Harper, J Lynch, S Burris, GD Smith: Trends in the black-white life expectancy gap in the United States, 1983-2003. JAMA 297:1224, 2007.)*

race/ethnicity, education, and socioeconomic status have persisted. For example, at every level of education and income, African Americans have lower life expectancy at age 25 than whites and Hispanics/Latinos. Blacks with a college degree or more education have lower life expectancy than whites and Hispanics who graduated from high school. Blacks have had lower life expectancy compared to whites for as long as data have been collected. From 1975 to 2003, the largest difference in life expectancy between blacks and whites was substantial (6.3 years for males and 4.5 years for females) **(Fig. 10-1)**. The gap in life expectancy between the black and white populations decreased by 2.3 years between 1999 and 2013 from 5.9 to 3.6 years (4.4 years for males and 3.0 years for women) **(Fig. 10-2)**.

The life expectancy gap is augmented by worse health and higher disease burden. Cardiovascular-related diseases remain the leading cause of black-white differences in life expectancy. If all cardiovascular causes and diabetes are considered together, they account for 35% and 52% of the gap for males and females, respectively. Finally, place matters for health. Analysis of data from 2010 to 2015 demonstrate large geographic life expectancy gap variation at the census tract level **(Fig. 10-3)**. Socioeconomic and race/ethnicity factors, behavioral and metabolic risk factors (prevalence of obesity, leisure-time physical inactivity, cigarette smoking, hypertension, diabetes), and health care factors (percentage of the population younger than 65 years who are insured, primary care access and quality, number of physicians per capita) explained 60%, 74%, and 27% of county-level variation in life expectancy, respectively. Combined, these factors explained 74% of this variation. Most of the association between socioeconomic and race/ethnicity factors and life expectancy was mediated through behavioral and metabolic risk factors.

In addition to racial and ethnic disparities in *health*, there are racial and ethnic disparities in the *quality of care* for persons with access to the health care system. Seminal studies over several decades have consistently documented disparities in health care. For instance, studies have documented disparities in the treatment of pneumonia and congestive heart failure, with blacks receiving less optimal care than whites when hospitalized for these conditions. Moreover, blacks with end-stage renal disease are referred less often to the transplant list than are their white counterparts **(Fig. 10-4)**. Disparities have been found, for example, in the use of cardiac diagnostic and therapeutic procedures (with blacks being referred less often than whites for cardiac catheterization and bypass grafting), prescription of analgesia for pain control (with blacks and Hispanics/Latinos receiving less pain medication than whites for long-bone fractures and cancer), and surgical treatment of lung cancer (with blacks receiving less curative surgery than whites for non-small-cell lung cancer). Again, many of these disparities have occurred even when variations in factors such as insurance status, income, age, comorbid conditions, and symptom expression are taken into account. Finally, disparities in the quality of care provided at the sites where minorities tend to receive care have been shown to be an important additional contributor to overall disparities.

The 2019 National Healthcare Quality and Disparities Report, released by the Agency for Healthcare Research and Quality, tracks about 250 health care process, outcome, and access measures, across many diseases and settings. This annual report is particularly important because most studies of disparities have not been longitudinally repeated with the same methodology to document trends and changes in disparities over time. This report found that some disparities were getting smaller from 2000 through 2016–2018, but disparities persisted and some even worsened, especially for poor and uninsured populations. For about 40% of quality measures, blacks (82 of 202 measures) and American Indians and Alaska Natives (47 of 116 measures) received worse care than whites. For more than one-third of quality measures, Hispanics (61 of 177 measures) received worse care than whites. Asians and Native Hawaiians/Pacific Islanders received worse care than whites for about 30% of quality measures, but Asians also received better care for about 30% of quality measures **(Fig. 10-5)**. Of note, for those quality measures that demonstrated disparities at baseline, >90% of these measures showed no improvement since 2000 **(Fig. 10-6)**.

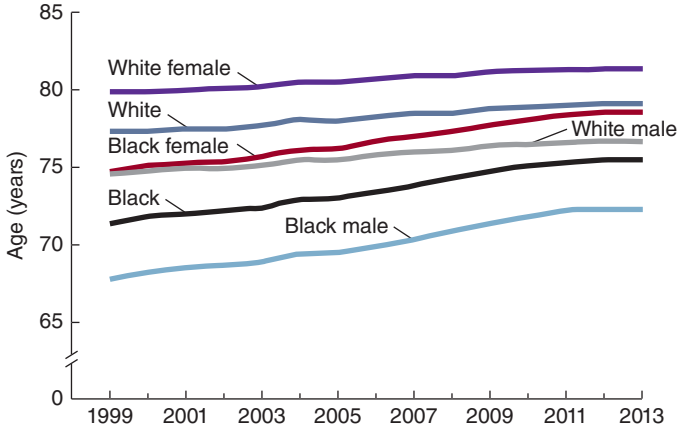

FIGURE 10-2 Life expectancy, by race and sex: United States, 1999–2013. *(From KD Kochanek et al: NCHS Data Brief 218:1, 2015.)*

ROOT CAUSES OF DISPARITIES

Race, Racism, and Health Race and racism are core elements of any explanatory model on racial and ethnic disparities in health and health care. Our nation's history of slavery, segregation, separate but "equal" health care, and medical experimentation, among a myriad of other ways in which racism has manifested in the United States, has played a key role in the existence and persistence of these disparities. It is now well accepted that race is a social category without biologic foundation and a product of historical racism. Nevertheless, it is clear that racism has a biologic impact as a form of psychosocial stress. It is now well established

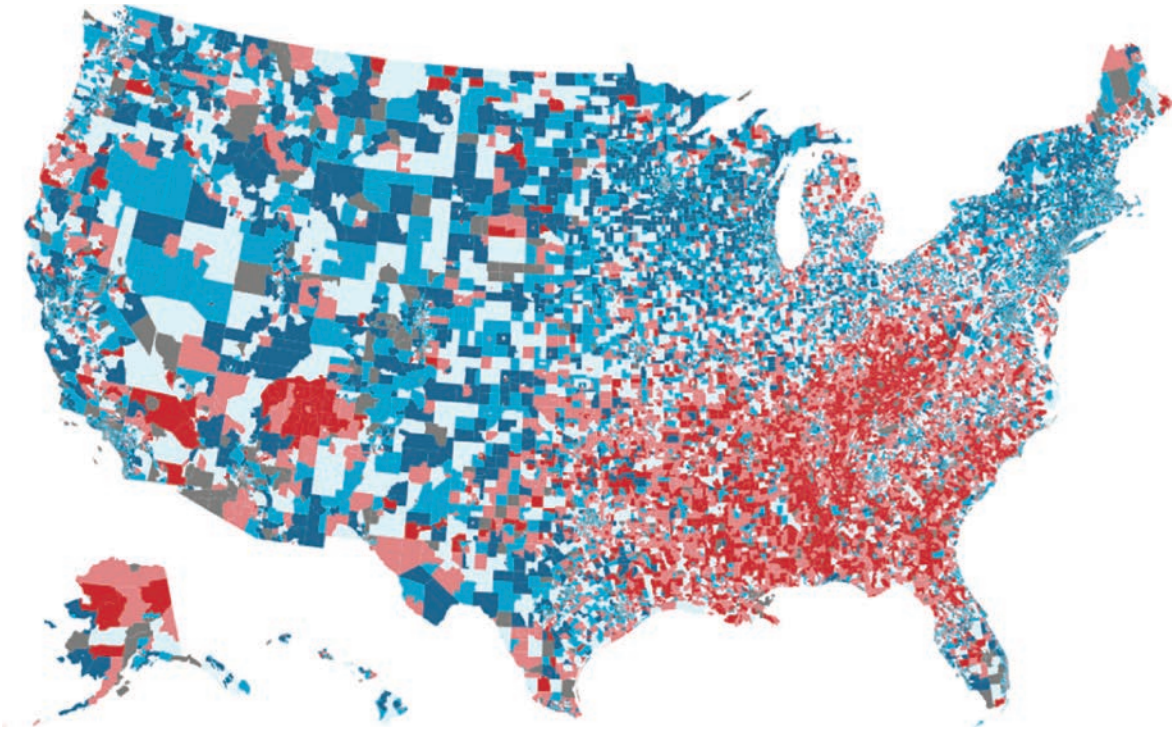

FIGURE 10-3 Life expectancy at birth for U.S. census tracts, 2010-2015. *(A New View of Life Expectancy, Surveillance and Data - Blogs and Stories, Centers for Disease Control and Prevention. Retrieved from https://www.cdc.gov/surveillance/blogs-stories/life-expectancy.html.)*

that psychosocial stress negatively impacts health through psychophysiologic reactivity causing hyperstimulation of the sympathetic-adrenal-medullary system and the hypothalamic-pituitary-adrenal axis, leading to vascular inflammation, endothelial dysfunction, and neurohormonal dysregulation causing an acceleration of cardiovascular disease. Behavioral changes occurring as adaptations or coping responses to stressors such as increased smoking, decreased exercise and sleep, and poorer adherence to medical regimens provide an additional important pathway through which stressors influence disease risk. This accelerated disease risk, aging, and premature death has been termed the *weathering effect*.

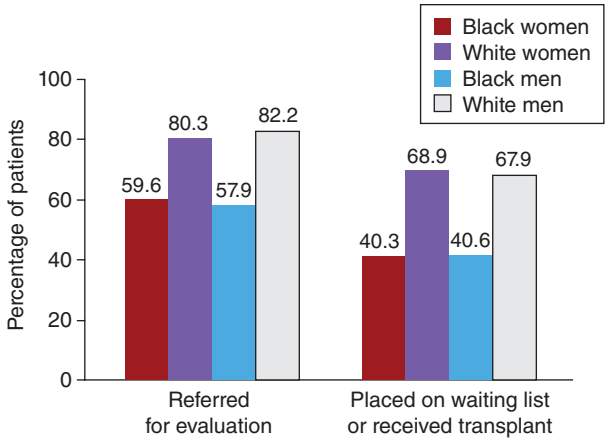

FIGURE 10-4 Referral for evaluation at a transplantation center or placement on a waiting list/receipt of a renal transplant within 18 months after the start of dialysis among patients who wanted a transplant, according to race and sex. The reference population consisted of 239 black women, 280 white women, 271 black men, and 271 white men. Racial differences were statistically significant among both the women and the men ($p < .0001$ for each comparison). *(From JZ Ayanian, PD Cleary, JS Weissman, AM Epstein: The effect of patients' preferences on racial differences in access to renal transplantation. N Engl J Med 341:1661,1999. Copyright © 1999 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

While most empiric research focuses on interpersonal racial/ethnic discrimination, structural racism (sometimes called institutional racism) provides a more holistic framework. Structural racism refers to the totality of ways that a society fosters, sustains, and reinforces discrimination through sociopolitical, legal, economic, and health structures that determine differential access to risks, opportunities, and resources that drive health and health care disparities. Structural racism explains how racism's structure and ideology can persist in governmental and institutional policies in the absence of individual actors who are explicitly racially prejudiced. For example, the history of residential segregation has had lasting negative effects generationally on equal access for racial/ethnic minorities to employment, banking, earnings, high-quality education, and health care. Policies that do not address root structural causes will not address health and health care inequities.

With the promise of individualizing clinical decisions, the use of race in clinical and risk assessment algorithms has long been a part of modern medicine. The evidence is now clear that race is not a reliable proxy for genetic difference and that race adjustment has the potential to create inadvertent disparities in health care. One clinical example is from nephrology. Blacks have higher rates of end-stage kidney disease and death due to kidney failure than the overall population. The most widely used cohort-derived equation to estimate glomerular filtration rate (GFR), the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, has the limitation that it produces 80–90% estimated GFR (eGFR) values that are within ±30% of a patient's measured GFR. In addition, this equation uses a black race-related factor, which increases eGFR for any given serum creatinine by 15.9% compared to a nonblack patient with the same age, sex, and serum creatinine. The increase in eGFR is likely to disadvantage blacks for early referral to a nephrologist, early treatment of advanced chronic kidney disease, and

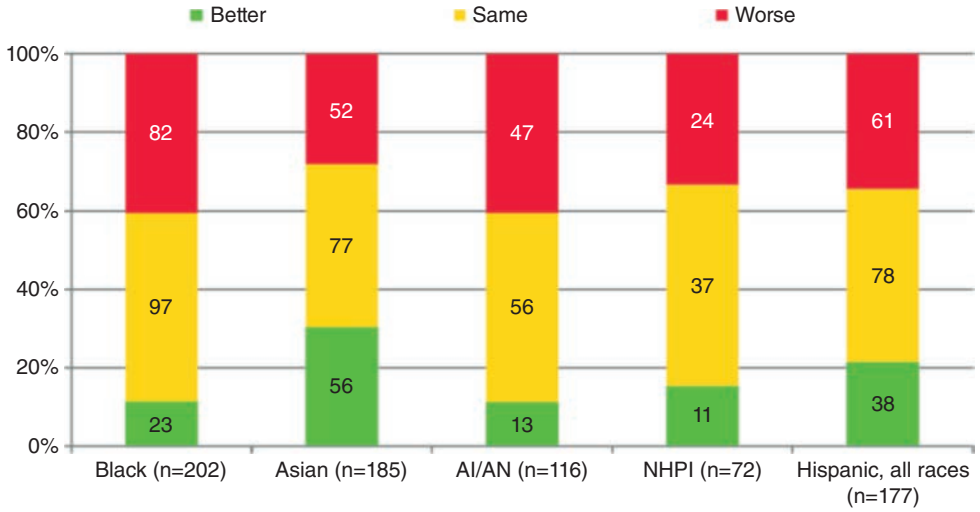

FIGURE 10-5 Number and percentage of quality measures for which members of selected groups experienced better, same, or worse quality of care compared with reference group (white) for the most recent data year, 2014, 2016, 2017, or 2018. AI/AN, American Indian or Alaska Native; NHPI, Native Hawaiian/Pacific Islander *(From 2019 National Healthcare Quality and Disparities Report. Rockville, MD: Agency for Healthcare Research and Quality; December 2020. AHRQ Pub. No. 20(21)-0045-EF.)*

kidney transplantation. It is also not clear how to apply the race factor when the patient's race is unknown and/or ambiguous, as in those who are multiracial. This disparity-inducing scenario could be avoided through the use of cystatin C–based eGFR estimation, which has been demonstrated to be more accurate than the CKD-EPI equation and for which race is not required in estimation.

The application of artificial intelligence (AI) analytics to large amounts of clinical electronic data—big data—holds the promise to better understand health care costs, utilization, resource allocation, and population health monitoring. Machine learning models can identify the statistical patterns in large amounts of historically collected data. These data naturally contain the patterning of preexisting health care disparities created by socially and historically structured inequities. This biased patterning can lead to incorrect predictions, withholding of resources, and worse outcomes for vulnerable populations. Recently, analysis of a commercial, national, proprietary prediction algorithm, affecting millions of patients, exhibited racial bias. Historical cost data were used to predict clinical risk and allocate additional clinical services for high-cost patients. Algorithmic bias arose because black patients historically have less access to health care and thus less money is spent on their care compared to white patients. Thus, blacks, who tended to be sicker than white patients, received lower clinical risk scores and thus were less likely to receive additional clinical services. The observed allocation bias was remedied using direct measures of illness and illness severity. Thus, machine learning algorithms are not inherently free of bias and should be assessed for accuracy and fairness.

In summary, there are many ways in which racism has contributed and does and will continue to contribute to racial and ethnic disparities in health and health care.

SOCIAL DETERMINANTS OF HEALTH

Minority Americans have poorer health outcomes than whites from preventable and treatable conditions such as cardiovascular disease, diabetes, asthma, cancer, and HIV/AIDS. Multiple factors contribute to these racial and ethnic disparities in health. The landmark National Academy of Medicine (formerly, the Institute of Medicine [IOM]) report, *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care*, published in 2002, summarized the scientific evidence on health disparities and provided an important framework for conceptualizing and defining racial/ethnic disparities. Since the *Unequal Treatment* report, there has been a growing empiric evidence base on how racism and the SDOH, often working in synergy, create and sustain disparities. Mechanistically, the biopsychosocial model brings together the social and physical characteristics of the environment with individual physical and psychological attributes. These environmental and individual characteristics, in turn, influence health behaviors and stress-related physiologic pathways that directly impact health. The National Institute on Minority Health and Health Disparities SDOH model builds on prior models and adds the time element across the life course of the individual in recognition of the long-lasting health effects of socioeconomic exposures **(Fig. 10-7)**. The resulting matrix has the domains of influence of health (biological, behavioral, physical and built environment, sociocultural environment, health care system) along the y-axis and the levels of influence on health (individual, interpersonal, community, societal) along the x-axis. Cells are not mutually exclusive, and examples of factors within each cell are illustrative and not comprehensive. This framework emphasizes the complex multidomain etiologies of disparities across the factors in the conceptual matrix thus highlighting the limitation of individual-level focused research and policy.

In addition to race and racism, *Unequal Treatment* identified a set of root causes that included health system, provider-level, and patient-level factors.

Health System Factors • HEALTH SYSTEM COMPLEXITY Even among persons who are insured and educated and who have a high degree of health literacy, navigating the U.S. health care system can be complicated and confusing. Some individuals may be at higher risk for receiving substandard care because of their difficulty navigating the system's complexities. These individuals may include those from cultures

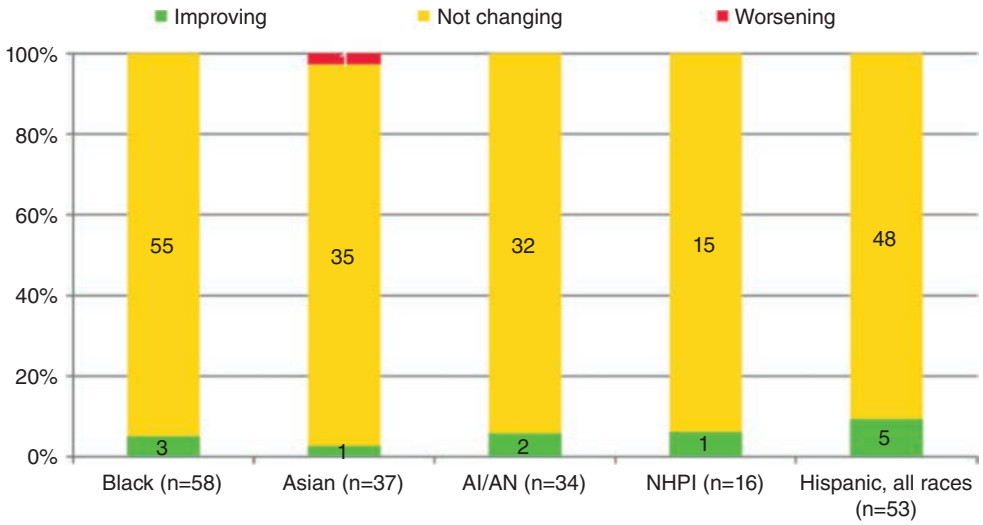

FIGURE 10-6 Number and percentage of quality measures with disparity at baseline for which disparities related to race and ethnicity were improving, not changing, or worsening over time, 2000 through 2014, 2015, 2016, 2017, or 2018. AI/AN, American Indian or Alaska Native; NHPI, Native Hawaiian/Pacific Islander. *(From 2019 National Healthcare Quality and Disparities Report. Retrieved from https://www.nimhd.nih.gov/about/overview/research-framework.html.)*

unfamiliar with the Western model of health care delivery, those with limited English proficiency, those with low health literacy, and those who are mistrustful of the health care system. These individuals may have difficulty knowing how and where to go for a referral to a specialist; how to prepare for a procedure such as a colonoscopy; or how to follow up on an abnormal test result such as a mammogram. Since people of color in the United States tend to be overrepresented among the groups listed above, the inherent complexity of navigating the health care system has been seen as a root cause for racial/ethnic disparities in health care.

OTHER HEALTH SYSTEM FACTORS Racial/ethnic disparities are due not only to differences in care provided within hospitals but also to where and from whom minorities receive their care; i.e., certain specific providers, geographic regions, or hospitals are lower-performing on certain aspects of quality. For example, one study showed that 25% of hospitals cared for 90% of black Medicare patients in the United States and that these hospitals tended to have lower performance scores on certain quality measures than other hospitals. That said, health systems generally are not well prepared to measure, report, and intervene to reduce disparities in care. Few hospitals or health plans stratify their quality data by race/ethnicity or language to measure disparities, and even fewer use data of this type to develop disparity-targeted interventions. Similarly, despite regulations concerning the need for professional interpreters, research demonstrates that many health care organizations and providers fail to routinely provide this service for patients with limited English proficiency. Despite the link between limited English proficiency and health care quality and safety, few providers or institutions monitor performance for patients in these areas.

Provider-Level Factors • PROVIDER–PATIENT COMMUNICATION

Significant evidence highlights the impact of sociocultural factors, race, ethnicity, and limited English proficiency on health and clinical care. Health care professionals frequently care for diverse populations with varied perspectives, values, beliefs, and behaviors regarding health and well-being. The differences include variations in the recognition of symptoms, thresholds for seeking care, comprehension of management strategies, expectations of care (including preferences for or against diagnostic and therapeutic procedures), and adherence to preventive measures and medications. In addition, sociocultural differences between patient and provider influence communication and clinical decision-making and are especially pertinent: evidence clearly links provider–patient communication to improved patient satisfaction, regimen adherence, and better health outcomes **(Fig. 10-8)**. Thus, when sociocultural differences between patient and provider are not appreciated, explored, understood, or communicated effectively during the medical encounter, patient dissatisfaction, poor adherence, poorer health outcomes, and racial/ethnic disparities in care may result.

A survey of 6722 Americans ≥18 years of age is particularly relevant to this important link between provider–patient communication and health outcomes. Whites, African Americans, Hispanics/Latinos, and Asian Americans who had made a medical visit in the past 2 years were asked whether they had trouble understanding their doctors; whether they felt the doctors did not listen; and whether they had medical questions they were afraid to ask. The survey found that 19% of all patients experienced one or more of these problems, yet whites experienced them 16% of the time as opposed to 23% of the time for African Americans, 33% for Hispanics/Latinos, and 27% for Asian Americans **(Fig. 10-9)**.

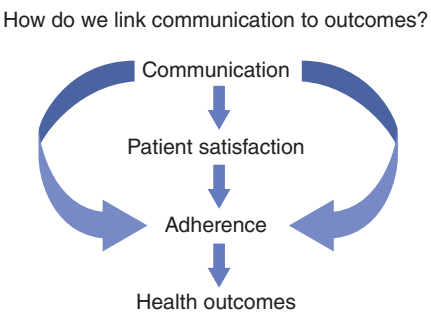

FIGURE 10-8 The link between effective communication and patient satisfaction, adherence, and health outcomes. *(Institute of Medicine. 2003. Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care. https://doi.org/10.17226/12875. Adapted and reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.)*

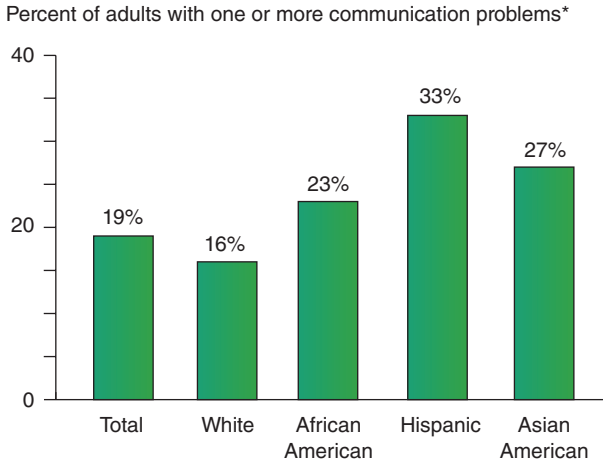

FIGURE 10-9 Communication difficulties with physicians, by race/ethnicity. The reference population consisted of 6722 Americans ≥18 years of age who had made a medical visit in the previous 2 years and were asked whether they had had trouble understanding their doctors, whether they felt that the doctors had not listened, and whether they had had medical questions they were afraid to ask. *(Reproduced with permission from the Commonwealth Fund Health Care Quality Survey, 2001.)*

In addition, in the setting of even a minimal language barrier, provider–patient communication without an interpreter is recognized as a major challenge to effective health care delivery. These communication barriers for patients with limited English proficiency lead to frequent misunderstanding of diagnosis, treatment, and follow-up plans; inappropriate use of medications; lack of informed consent for surgical procedures; high rates of adverse events with more serious clinical consequences; and a lower-quality health care experience than is provided to patients who speak fluent English. Physicians who have access to trained interpreters report a significantly higher quality of patient–physician communication than physicians who use other methods. Communication issues related to discordant language disproportionately affect minorities and likely contribute to racial/ethnic disparities in health care.

CLINICAL DECISION-MAKING Theory and research suggest that variations in clinical decision-making may contribute to racial and ethnic disparities in health care. Two factors are central to this process: clinical uncertainty and stereotyping.

First, a doctor's decision-making process is nested in *clinical uncertainty*. Doctors depend on inferences about severity based on what they understand about illness and the information obtained from the patient. A doctor caring for a patient whose symptoms he or she has difficulty understanding and whose "signals"—the set of clues and indications that physicians rely on to make clinical decisions—are hard to read may make a decision different from the one that would be made for another patient who presents with exactly the same clinical condition. Given that the expression of symptoms may differ among cultural and racial groups, doctors—the overwhelming majority of whom are white—may understand symptoms best when expressed by patients of their own racial/ethnic groups. The consequence is that white patients may be treated differently from minority patients. Differences in clinical decisions can arise from this mechanism even when the doctor has the same regard for each patient (i.e., is not prejudiced).

Second, the literature on social cognitive theory highlights how natural tendencies to stereotype may influence clinical decision-making. *Stereotyping* can be defined as the way in which people use social categories (e.g., race, gender, age) in acquiring, processing, and recalling information about others. Faced with enormous information loads and the need to make many decisions, people often subconsciously simplify the decision-making process and lessen cognitive effort by using "categories" or "stereotypes" that bundle information into groups or types that can be processed more quickly. Although functional, stereotyping can be systematically biased, as people are automatically classified into social categories based on dimensions such as *race*, *gender*, and *age*. Many people may not be aware of their attitudes, may not consciously endorse specific stereotypes, and paradoxically may consider themselves egalitarian and not prejudiced.

Stereotypes may be strongly influenced by the messages presented consciously and unconsciously in society. For instance, if the media and our social/professional contacts tend to present images of minorities as being less educated, more violent, and nonadherent to health care recommendations, these impressions may generate stereotypes that unnaturally and unjustly impact clinical decision-making. As signs of racism, classism, gender bias, and ageism are experienced (consciously or unconsciously) in our society, stereotypes may be created that impact the way doctors manage patients from these groups. On the basis of training or practice location, doctors may develop certain perceptions about race/ethnicity, culture, and class that may evolve into stereotypes. For example, many medical students and residents are trained—and minorities cared for—in academic health centers or public hospitals located in socioeconomically disadvantaged areas. As a result, doctors may begin to equate certain races and ethnicities with specific health beliefs and behaviors (e.g., "these patients" engage in risky behaviors, "those patients" tend to be noncompliant) that are more associated with the social environment (e.g., poverty) than with a patient's racial/ethnic background or cultural traditions. This "conditioning" phenomenon may also be operative if doctors are faced with certain racial/ethnic patient groups who frequently do not choose aggressive forms of diagnostic or therapeutic intervention. The result over time may be that doctors begin to believe that "these patients" do not like invasive procedures; thus, they may not offer these procedures as options. A wide range of studies have documented the potential for provider biases to contribute to racial/ethnic disparities in health care. For example, one study measured physicians' unconscious (or implicit) biases and showed that these were related to differences in decisions to provide thrombolysis for a hypothetical black or white patient with a myocardial infarction.

It is important to differentiate stereotyping from prejudice and discrimination. *Prejudice* is a conscious prejudgment of individuals that may lead to disparate treatment, and *discrimination* is conscious and intentional disparate treatment. All individuals *stereotype* subconsciously, yet, if left unquestioned, these subconscious assumptions may lead to lower-quality care for certain groups because of differences in clinical decision-making or differences in communication and patient-centeredness. For example, one study tested physicians' unconscious racial/ethnic biases and showed that patients perceived more biased physicians as being less patient-centered in their communication. What is particularly salient is that stereotypes tend to be activated most in environments where the individual is stressed, multitasking, and under time pressure—the hallmarks of the clinical encounter. In fact, in a survey of close to 16,000 physicians, 42% admitted that bias—including by race and ethnicity—impacted their clinical decision-making. Interestingly, emergency medicine physicians, who work in environments of stress, time pressure, risk, and where they are multitasking, topped the list by discipline at 62%.

Patient-Level Factors Lack of trust has become a major concern for many health care institutions today. For example, an IOM report, *To Err Is Human: Building a Safer Health System*, documented alarming rates of medical errors that made patients feel vulnerable and less trustful of the U.S. health care system. The increased media and academic attention to problems related to quality of care (and of disparities themselves) has clearly diminished trust in doctors and nurses.

Trust is a crucial element in the therapeutic alliance between patient and health care provider. It facilitates open communication and is directly correlated with adherence to the physician's recommendations and the patient's satisfaction. In other words, patients who mistrust their health care providers are less satisfied with the care they receive, and mistrust of the health care system greatly affects patients' use of services. Mistrust can also result in inconsistent care, "doctor-shopping,"

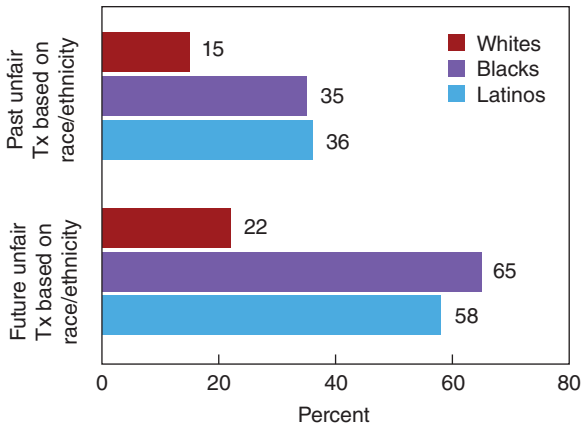

FIGURE 10-10 Patient perspectives regarding unfair treatment (Tx) based on race/ethnicity. The reference population consisted of 3884 individuals surveyed about how fairly they had been treated in the health care system in the past and how fairly they felt they would be treated in the future on the basis of their race/ethnicity. *(From Race, Ethnicity & Medical Care: A Survey of Public Perceptions and Experiences. Kaiser Family Foundation, 2005.)*

self-medication, and an increased demand by patients for referrals and diagnostic tests.

On the basis of historic factors such as discrimination, segregation, and medical experimentation, blacks may be especially mistrustful of providers. The exploitation of blacks by the U.S. Public Health Service during the Tuskegee syphilis study from 1932 to 1972 left a legacy of mistrust that persists even today among this population. Other populations, including Native Americans/Alaskan Natives, Hispanics/Latinos, and Asian Americans, also harbor significant mistrust of the health care system. A national survey conducted by the Kaiser Family Foundation found that there is significant mistrust for the health care system among minority populations. Of the 3884 individuals surveyed, 36% of Hispanics and 35% of blacks (compared to 15% of whites) felt they were treated unfairly in the health care system in the past based on their race and ethnicity. Perhaps even more alarming—65% of blacks and 58% of Hispanics (compared to 22% of whites) were afraid of being treated unfairly in the future based on their race/ethnicity **(Fig. 10-10)**.

This mistrust may contribute to wariness in accepting or following recommendations, undergoing invasive procedures, or participating in clinical research, and these choices, in turn, may lead to misunderstanding and the perpetuation of stereotypes among health professionals.

KEY RECOMMENDATIONS TO ADDRESS RACIAL/ETHNIC DISPARITIES IN HEALTH CARE

Unequal Treatment provides recommendations to address the root causes of racial/ethnic disparities organized as *health system interventions*, *provider interventions*, *patient interventions*, and *general recommendations*.

Health System Interventions

COLLECTING, REPORTING, AND TRACKING OF DATA ON HEALTH CARE ACCESS AND USE, BY PATIENTS' RACE/ETHNICITY *Unequal Treatment* found that the appropriate systems to track and monitor racial and ethnic disparities in health care are lacking and that less is known about the disparities affecting minority groups other than African Americans (Hispanics, Asian Americans, Pacific Islanders, Native Americans, and Alaskan Natives). For instance, only in the mid-1980s did the Medicare database begin to collect data on patient groups outside the standard categories of "white," "black," and "other." Federal, private, and state-supported data-collection efforts are scattered and unsystematic, and many health care systems and hospitals still do not collect data on the race, ethnicity, or primary language of enrollees or patients. A survey by the Institute for Diversity in Health Management and the Health Research and Educational Trust in 2015 found that 98% of 1083 U.S. hospitals collected information on race, 95% collected data on ethnicity, and 94% collected data on primary language. However, only 45% collected data on race, 40% collected data on ethnicity, and 38% collected data on primary language to benchmark gaps in care. A survey by America's Health Insurance Plans Foundation in 2008 and 2010 showed that the proportion of enrollees in plans that collected race/ethnicity data of some type increased from 75 to 79%; however, the total percentage of plan enrollees whose race/ethnicity and language are recorded is still much lower than these figures.

COLLECTING, REPORTING, AND TRACKING OF SDOH DATA In 2014, the IOM Committee on Recommended Social and Behavioral Domains and Measures for Electronic Health Records recommended the routine collection, in the electronic health record, of a parsimonious panel of clinically significant SDOH measures that may be obtained by self-report in advance of or during the health care encounter and, when used together, provide a psychosocial vital sign. The IOM-recommended questionnaire includes 25 items addressing the following domains: race and ethnicity, education, financial resource strain, stress, depression, physical activity, tobacco use, alcohol use, social connection or isolation, intimate partner violence, residential address, and geocoded census tract median income. Implementation studies have demonstrated that collection of these data takes about 5 minutes, and both patients and providers saw this data collection as appropriate and important. Given that data access and monitoring is an essential component to disparities elimination, we highlight several important sources of up-to-date racial/ethnic disparities monitoring initiatives that are available to the general public and are updated regularly. We highlight only three examples of national data sources.

- Since 2003, the Agency for Healthcare Research and Quality has led the yearly compilation of *The National Healthcare Quality and Disparities Report*, which reports trends for measures related to access to health care, affordable care, care coordination, healthy living, patient safety, and the quality of care across acute and chronic disease management by race/ethnicity, income, and other SDOH (*https://www.ahrq.gov/research/findings/nhqrdr/index.html*).
- Since 2011, the Geospatial Research, Analysis, and Services Program (GRASP) created and maintains the Centers for Disease Control and Prevention Social Vulnerability Index. This database maps, for all U.S. Census tracts, 15 social factors (grouped in four SDOH categories: socioeconomic status, housing composition and disability, minority status and language, and housing and transportation) and is updated every 2 years (*https://www.atsdr.cdc.gov/placeandhealth/svi/index.html*).
- Launched in 2018, the Health Opportunity and Equity (HOPE) Initiative benchmarks and tracks 27 indicators by race, ethnicity, and socioeconomic status. The indicators measure social and economic factors, community and safety, physical environment, access to health care, and health outcomes for the United States (*https://www.nationalcollaborative.org/our-programs/hope-initiative-project/*).

INCREASE INSURANCE COVERAGE AND ACCESS Lack of access to high-quality health care is an important driver of racial/ethnic disparities. Signed into law in 2010, the Affordable Care Act (ACA) fundamentally transformed health insurance by decreasing the uninsured population from 16.3% in 2010 (~49.9 million) to 8.8.% in 2016 (~28.1 million). This represents the largest expansion of health insurance since the creation of Medicare and Medicaid in 1965. Prior to the ACA, non-Hispanic blacks were 70% and Hispanics nearly three times more likely to be uninsured than non-Hispanic whites. Of note, Medicaid expansion accounted for an estimated 60% of the ACA's effect through a combination of expanded eligibility and increased enrollment of previously eligible but unenrolled people. This is important given the higher number of racial/ethnic minorities who obtain insurance through Medicaid. Many studies have demonstrated that increased insurance coverage has also translated to greater improvement for blacks and Hispanics in access to care, more access to a usual source of care, and improved health outcomes.

ENCOURAGEMENT OF THE USE OF EVIDENCE-BASED GUIDELINES AND QUALITY IMPROVEMENT *Unequal Treatment* highlights the subjectivity of clinical decision-making as a potential cause of racial and

ethnic disparities in health care by describing how clinicians—despite the existence of well-delineated practice guidelines—may offer (consciously or unconsciously) different diagnostic and therapeutic options to different patients on the basis of their race or ethnicity. Therefore, the widespread adoption and implementation of evidence-based guidelines is a key recommendation in eliminating disparities. For instance, evidence-based guidelines are now available for the management of diabetes, HIV/AIDS, cardiovascular diseases, cancer screening and management, and asthma—all areas where significant disparities exist. As part of ongoing quality-improvement efforts, particular attention should be paid to the implementation of evidence-based guidelines for all patients, regardless of their race and ethnicity.

SUPPORT FOR THE USE OF LANGUAGE INTERPRETATION SERVICES IN THE CLINICAL SETTING As described previously, a lack of efficient and effective interpreter services in a health care system can lead to patient dissatisfaction, to poor comprehension and adherence, and thus to ineffective/lower-quality care for patients with limited English proficiency. *Unequal Treatment*'s recommendation to support the use of interpretation services has clear implications for delivery of quality health care by improving doctors' ability to communicate effectively with these patients.

INCREASES IN THE PROPORTION OF UNDERREPRESENTED MINORITIES IN THE HEALTH CARE WORKFORCE Data for 2018 from the Association of American Medical Colleges indicate that of active physicians, 56.2% identified as white, 5.8% identified as Hispanic, 5.0% identified as black or African American, and 0.3% identified as Native American or Alaskan Natives. Furthermore, U.S. national data show that only 3.6% of full-time faculty are black or African American, and 5.5% are Hispanic, Latino, or of Spanish origin (alone or in combination with another race/ethnicity), compared to 63.9% who identified as white. Longitudinal data demonstrate that minority faculty are more likely to be at or below the rank of assistant professor, while whites composed the highest proportion of full professors. Similarly, several studies have found that both Hispanic and black faculty were promoted at lower rates than their white counterparts. Despite representing ~30% of the U.S. population (a number projected to almost double by 2050), minority students are still underrepresented in medical schools. In 2018, matriculates to U.S. medical schools were 6.2% Latino, 7.1% African American, 0.1% Native Hawaiian or Other Pacific Islander, and 0.2% Native American or Alaskan Native. These percentages have decreased or remained nearly the same since 2007. It will be difficult to develop a diverse physician workforce that can meet the needs of an increasingly diverse population without dramatic changes in the racial and ethnic composition of medical student bodies. Long-term investment in pipeline programs and the nearly universal adoption of holistic admissions (a process by which schools consider each applicant individually to determine how they might contribute to the learning environment and the workforce instead of relying just on test scores and grades) have produced modest results. Institutional change in medical schools, focused on creating nurturing, inclusive, and equity-focused environments that dismantle the structural racism that has created the opportunity gap faced by many minority students, is needed to address this important workforce challenge.

Provider Interventions • **INTEGRATION OF CROSS-CULTURAL EDUCATION INTO THE TRAINING OF ALL HEALTH CARE PROFESSIONALS** The goal of cross-cultural education is to improve providers' ability to understand, communicate with, and care for patients from diverse backgrounds. Such education focuses on enhancing awareness of sociocultural influences on health beliefs and behaviors and on building skills to facilitate understanding and management of these factors in the medical encounter. Cross-cultural education includes curricula on health care disparities, use of interpreters, and effective communication and negotiation across cultures. These curricula can be incorporated into health professions training in medical schools, residency programs, nursing schools, and other health professions programs, and can be offered as a component of continuing education. Despite the importance of this area of education and the attention it has attracted from medical education accreditation bodies, a national survey of senior resident physicians by Weissman and colleagues found that up to 28% felt unprepared to deal with cross-cultural issues, including caring for patients who have religious beliefs that may affect treatment, patients who use complementary medicine, patients who have health beliefs at odds with Western medicine, patients who mistrust the health care system, and new immigrants. In a study at one medical school, 70% of fourth-year students felt inadequately prepared to care for patients with limited English proficiency. Efforts to incorporate cross-cultural education into medical education will contribute to improving communication and to providing a better quality of care for all patients.

INCORPORATION OF TEACHING ON THE IMPACT OF RACE, ETHNICITY, AND CULTURE ON CLINICAL DECISION-MAKING *Unequal Treatment* and more recent studies found that stereotyping by health care providers can lead to disparate treatment based on a patient's race or ethnicity. The Liaison Committee on Medical Education, which accredits medical schools, issued a directive that medical education should include instruction on how a patient's race, ethnicity, and culture might unconsciously impact communication and clinical decision-making.

Patient Interventions Difficulty navigating the health care system and obtaining access to care can be a hindrance to all populations, particularly to minorities. Similarly, lack of empowerment or involvement in the medical encounter by minorities can be a barrier to care. Patients need to be educated on how to navigate the health care system and how best to access care. Interventions should be used to increase patients' participation in treatment decisions.

General Recommendations • **INCREASE AWARENESS OF RACIAL/ETHNIC DISPARITIES IN HEALTH CARE** Efforts to raise awareness of racial/ethnic health care disparities have done little for the general public but have been fairly successful among physicians, according to a Kaiser Family Foundation report. In 2006, nearly 6 in 10 people surveyed believed that blacks received the same quality of care as whites, and 5 in 10 believed that Latinos received the same quality of care as whites. These estimates are similar to findings in a 1999 survey. Despite this lack of awareness, most people believed that all Americans deserve quality care, regardless of their background. In contrast, the level of awareness among physicians has risen sharply. In 2002, the majority (69%) of physicians said that the health care system "rarely or never" treated people unfairly on the basis of their racial/ethnic background. In 2005, less than one-quarter (24%) of physicians disagreed with the statement that "minority patients generally receive lower-quality care than white patients." More recently, a survey by WebMD showed that 42% of 16,000 physicians admitted that their own personal biases impact their clinical decision-making, including on characteristics such as race and ethnicity. Increasing awareness of racial and ethnic health disparities, and their root causes, among health care professionals and the public is an important first step in addressing these disparities. The ultimate goals are to generate discourse and to mobilize action to address disparities at multiple levels, including health policymakers, health systems, and the community.

CONDUCT FURTHER RESEARCH TO IDENTIFY SOURCES OF DISPARITIES AND PROMISING INTERVENTIONS While the literature that formed the basis for the findings reported and recommendations made in *Unequal Treatment* provided significant evidence for racial and ethnic disparities, additional research is needed in several areas. First, most of the literature on disparities focuses on black-versus-white differences; much less is known about the experiences of other minority groups. Improving the ability to collect racial and ethnic patient data should facilitate this process. However, in instances where the necessary systems are not yet in place, racial and ethnic patient data may be collected prospectively in the setting of clinical or health services research to more fully elucidate disparities for other populations. Second, much of the literature on disparities to date has focused on defining areas in which these disparities exist, but less has been done to identify the multiple factors that contribute to the disparities or to test interventions to address these factors. There is clearly a need for research that identifies promising practices and solutions to disparities.

IMPLICATIONS FOR CLINICAL PRACTICE

Individual health care providers can do several things in the clinical encounter to address racial and ethnic disparities in health care.

Be Aware That Disparities Exist Increasing awareness of racial and ethnic disparities among health care professionals is an important first step in addressing disparities in health care. Only with greater awareness can care providers be attuned to their behavior in clinical practice and thus monitor that behavior and ensure that all patients receive the highest quality of care, regardless of race, ethnicity, or culture.

Practice Culturally Competent Care Previous efforts have been made to teach clinicians about the attitudes, values, beliefs, and behaviors of certain cultural groups—the key practice "dos and don'ts" in caring for "the Hispanic patient" or the "Asian patient," for example. In certain situations, learning about a particular local community or cultural group, with a goal of following the principles of community-oriented primary care, can be helpful; when broadly and uncritically applied, however, this approach can actually lead to stereotyping and oversimplification of culture, without respect for its complexity.

Cultural competence has thus evolved from merely learning information and making assumptions about patients on the basis of their backgrounds to focusing on the development of skills that follow the principles of patient-centered care. *Patient-centeredness* encompasses the qualities of compassion, empathy, and responsiveness to the needs, values, and expressed preferences of the individual patient. *Cultural competence* aims to take things a step further by expanding the repertoire of knowledge and skills classically defined as "patient-centered" to include those that are especially useful in cross-cultural interactions (and that, in fact, are vital in all clinical encounters). This repertoire includes effectively using interpreter services, eliciting the patient's understanding of his or her condition, assessing decision-making preferences and the role of family, determining the patient's views about biomedicine versus complementary and alternative medicine, recognizing sexual and gender issues, and building trust. For example, while it is important to understand all patients' beliefs about health, it may be particularly crucial to understand the health beliefs of patients who come from a different culture or have a different health care experience. With the individual patient as teacher, the physician can adjust his or her practice style to meet the patient's specific needs.

Avoid Stereotyping Several strategies can allow health care providers to counteract, both systemically and individually, the normal tendency to stereotype. For example, when racially/ethnically/culturally/socially diverse teams in which each member is given equal power are assembled and are tasked to achieve a common goal, a sense of camaraderie develops and prevents the development of stereotypes based on race/ethnicity, gender, culture, or class. Thus, health care providers should aim to gain experiences working with and learning from a diverse set of colleagues. In addition, simply being aware of the operation of social cognitive factors allows providers to actively check up on or monitor their behavior. Physicians can constantly reevaluate to ensure that they are offering the same things, in the same ways, to all patients. Understanding one's own susceptibility to stereotyping—and how disparities may result—is essential in providing equitable, high-quality care to all patients.

Work to Build Trust Patients' mistrust of the health care system and of health care providers impacts multiple facets of the medical encounter, with effects ranging from decreased patient satisfaction to delayed care. Although the historic legacy of discrimination can never be erased, several steps can be taken to build trust with patients and to address disparities. First, providers must be aware that mistrust exists and is more prevalent among minority populations, given the history of discrimination in the United States and other countries. Second, providers must reassure patients that they come first, that everything possible will be done to ensure that they always get the best care available, and that their caregivers will serve as their advocates. Third, interpersonal skills and communication techniques that demonstrate honesty, openness, compassion, and respect on the part of the health care provider are essential tools in dismantling mistrust. Finally, patients indicate that trust is built when there is shared, participatory decision-making and the provider makes a concerted effort to understand the patient's background. When the doctor–patient relationship is reframed as one of solidarity, the patient's sense of vulnerability can be transformed into one of trust. The successful elimination of disparities requires trust-building interventions and strengthening of this relationship.

CONCLUSION

The issue of racial and ethnic disparities in health care has gained national prominence, both with the release of the IOM report *Unequal Treatment* and with more recent articles that have confirmed their persistence and explored their root causes. Furthermore, another influential IOM report, *Crossing the Quality Chasm*, has highlighted the importance of equity—i.e., no variations in quality of care due to personal characteristics, including race and ethnicity—as a central principle of quality. Current efforts in health care reform and transformation, including a greater focus on value (high-quality care and cost-control), will sharpen the nation's focus on the care of populations who experience low-quality, costly care. Addressing disparities will become a major focus, and there will be many obvious opportunities for interventions to eliminate them. Greater attention to addressing the root causes of disparities will improve the care provided to all patients, not just those who belong to racial and ethnic minorities.

11 Ethical Issues in Clinical Medicine

Christine Grady, Bernard Lo

Physicians face novel ethical dilemmas that can be perplexing and emotionally draining. For example, telemedicine, artificial intelligence, handheld personal devices, and learning health care systems all hold the promise of more coordinated and comprehensive care, but also raise concerns about confidentiality, the doctor–patient relationship, and responsibility. This chapter presents approaches and principles that physicians can use to address important vexing ethical issues they

encounter in their work. Physicians make ethical judgments about clinical situations every day. They should prepare for lifelong learning about ethical issues so they can respond appropriately. Traditional professional codes and ethical principles provide instructive guidance for physicians but need to be interpreted and applied to each situation. When facing or struggling with a challenging ethical issue, physicians may need to reevaluate their basic convictions, tolerate uncertainty, and maintain their integrity while respecting the opinions of others. Physicians should articulate their concerns and reasoning, discuss and listen to the views of others involved in the case, and utilize available resources, including other health care team members, palliative care, social work, and spiritual care. Moreover, ethics consultation services or a hospital ethics committee can help to clarify issues and identify strategies for resolution, including improving communication and dealing with strong or conflicting emotions. Through these efforts, physicians can gain deeper insight into the ethical issues they face and usually reach mutually acceptable resolutions to complex problems.

APPROACHES TO ETHICAL PROBLEMS

Several approaches are useful for resolving ethical issues, including approaches based on ethical principles, virtue ethics, professional oaths, and personal values. These various sources of guidance may seem to conflict in a particular case, leaving the physician in a quandary. In a diverse society, different individuals may turn to different sources of moral guidance. In addition, general moral precepts often need to be interpreted and applied to a particular clinical situation.

ETHICAL PRINCIPLES

Ethical principles can serve as general guidelines to help physicians determine the right thing to do.

Respecting Patients Physicians should always treat patients with respect, which entails understanding patients' goals, providing information, communicating effectively, obtaining informed and voluntary consent, respecting informed refusals, and protecting confidentiality. Different clinical goals and approaches are often feasible, and interventions can result in both benefit and harm. Individuals differ in how they value health and medical care and how they weigh the benefits and risks of medical interventions. Generally, physicians should respect patients' values and informed choices. Treating patients with respect is especially important when patients are responding to experiences of, or fears about, disrespect and discrimination.

GOALS AND TREATMENT DECISIONS Physicians should provide relevant and accurate information for patients about diagnoses, current clinical circumstances, expected future course, prognosis, treatment options, and uncertainties, and discuss patients' goals of care. Physicians may be tempted to withhold a serious diagnosis, misrepresent it by using ambiguous terms, or limit discussions of prognosis or risks for fear that patients will become anxious or depressed. Providing honest information about clinical situations promotes patients' autonomy and trust as well as sound communication with patients and colleagues. When physicians have to share bad news with patients, they should adjust the pace of disclosure, offer empathy and hope, provide emotional support, and call on other resources such as spiritual care or social work to help patients cope. Some patients may choose not to receive such information or may ask surrogates to make decisions on their behalf, as is common with serious diagnoses in some traditional cultures.

SHARED DECISION-MAKING AND OBTAINING INFORMED CONSENT Physicians should engage their patients in shared decision-making about their health and their care, whenever appropriate. Physicians should discuss with patients the nature, risks, and benefits of proposed care; any alternative; and the likely consequences of each option. Physicians promote shared decision-making by informing and educating patients, answering their questions, checking that they understand key issues, making recommendations, and helping them to deliberate. Medical jargon, needlessly complicated explanations, or the provision of too much information at once may overwhelm patients. Increasingly, decision aids can assist patients in playing a more active role in decision-making, improving the accuracy of their perception of risk and benefit, and helping them feel better informed and clearer about their values. Informed consent is more than obtaining signatures on consent forms and involves disclosure of honest and understandable information to promote understanding and choice. Competent, informed patients may refuse recommended interventions and choose among reasonable alternatives. In an emergency, treatment can be given without informed consent if patients cannot give their own consent and delaying treatment while surrogates are contacted would jeopardize patients' lives or health. People are presumed to want such emergency care unless they have previously indicated otherwise.

Respect for patients does not entitle patients to insist on any care or treatment that they want. Physicians are not obligated to provide interventions that have no physiologic rationale, that have already failed, or that are contrary to evidence-based practice recommendations or good clinical judgment. Public policies and laws also dictate certain decisions—e.g., allocation of scarce medical resources during a public health crisis such as the COVID-19 pandemic, use of cadaveric organs for transplantation, and requests for physician aid in dying.

CARING FOR PATIENTS WHO LACK DECISION-MAKING CAPACITY Some patients are unable to make informed decisions because of unconsciousness, advanced dementia, delirium, or other medical conditions. Courts have the legal authority to determine that a patient is legally incompetent, but in practice, physicians usually determine when patients lack the capacity to make particular health care decisions and arrange for authorized surrogates to make decisions, without involving the courts. Patients with decision-making capacity can express a choice and appreciate their medical situation; the nature, risks, and benefits of proposed care; and the consequences of each alternative. Patient choices should be consistent with their values and not the result of delusions, hallucinations, or misinformation. Physicians should use available and validated assessment tools, resources such as psychiatry or ethics consultation, and clinical judgment to ascertain whether individuals have the capacity to make decisions for themselves. Patients should not be assumed to lack capacity if they disagree with recommendations or refuse treatment. Such decisions should be probed, however, to ensure the patient is not deciding based on misunderstandings and has the capacity to make an informed decision. When impairments are fluctuating or reversible, decisions should be postponed if possible until the patient recovers decision-making capacity.

When a patient lacks decision-making capacity, physicians seek an appropriate surrogate. Patients may designate a health care proxy through an advance directive or on a Physician Orders for Life-Sustaining Treatment form; such choices should be respected (see **Chap. 12**). For patients who lack decision-making capacity and have not previously designated a health care proxy, family members usually serve as surrogates. Statutes in most U.S. states delineate a prioritized list of relatives to make medical decisions. Patients' values, goals, and previously expressed preferences guide surrogate decisions. However, the patient's current best interests may sometimes justify overriding earlier preferences if an intervention is likely to provide significant benefit, previous statements do not fit the situation well, or the patient gave the surrogate leeway in decisions.

MAINTAINING CONFIDENTIALITY Maintaining confidentiality is essential to respecting patients' autonomy and privacy; it encourages patients to seek treatment and to discuss problems candidly. However, confidentiality may be overridden to prevent serious harm to third parties or the patient. Exceptions to confidentiality are justified when the risk to others is serious and probable, no less restrictive measures can avert risk, and the adverse effects of overriding confidentiality are minimized and deemed acceptable by society. For example, laws require physicians to report cases of tuberculosis, sexually transmitted infection, elder or child abuse, and domestic violence.

Beneficence or Acting in Patients' Best Interests The principle of *beneficence* requires physicians to act for the patient's benefit. Patients typically lack medical expertise, and illness may make them vulnerable. Patients rely on and trust physicians to treat them with

compassion and provide sound recommendations and treatments aimed to promote their well-being. Physicians encourage such trust and have a fiduciary duty to act in the best interests of patients, which should prevail over physicians' self-interest or the interests of third parties such as hospitals or insurers. A principle related to beneficence, "first do no harm," obliges physicians to prevent unnecessary harm by recommending interventions that maximize benefit and minimize harm and forbids physicians from providing known ineffective interventions or acting without due care. Although often cited, this precept alone provides limited guidance because many beneficial interventions also pose serious risks.

Physicians increasingly provide care within interdisciplinary teams and rely on consultation with or referral to specialists. Team members and consultants contribute different types of expertise to the provision of comprehensive, high-quality care for patients. Physicians should collaborate with and respect the contributions of the various interdisciplinary team members and should initiate and participate in regular communication and planning to avoid diffusion of responsibility and ensure accountability for quality patient care.

INFLUENCES ON PATIENTS' BEST INTERESTS Conflicts arise when patients' refusal or request of interventions thwarts their own goals for care, causes serious harm, or conflicts with their best medical interests. For example, simply accepting a young asthmatic adult's refusal of mechanical ventilation for reversible respiratory failure, in the name of respecting autonomy, is morally constricted. Physicians should elicit patients' expectations and concerns, correct their misunderstandings, and try to persuade them to accept beneficial therapies. If disagreements persist after such efforts, physicians should call on institutional resources for assistance, but patients' informed choices and views of their own best interests should prevail.

Drug prices and out-of-pocket expenses for patients have been escalating in many parts of the world and may compromise care that is in the patients' best interests. Physicians should recognize that patients, especially those with high copayments or inadequate insurance, may not be able to afford prescribed tests and interventions. Physicians should strive to prescribe medications that are affordable and acceptable to the patient. Knowing what kind of insurance, if any, the patient has and whether certain medications are likely to be covered may help in determining appropriate prescriptions. Available alternatives should be considered and discussed. Physicians should follow up with patients who don't fill prescriptions, don't take their medications, or skip doses to explore whether cost and affordability are obstacles. It may be reasonable for physicians to advocate for coverage of nonformulary products for sound reasons, such as when the formulary drugs are less effective or not tolerated or are too costly for the patient to pay for out of pocket. These should be shared decisions with the patient to the extent possible.

Organizational policies and workplace conditions may sometimes conflict with patients' best interests. Physicians' focus and dedication to the well-being and interests of patients may be negatively influenced by perceived or actual staffing inadequacies, unfair wages, infrastructural deficiencies or lack of equipment, work-hour limitations, corporate culture, and threats to personal security in the workplace. Physicians should work with institutional leaders to ensure that policies and practices support their ability to provide quality care focused on patients' best interests.

Patients' interests are served by improvements in overall quality of care and the increasing use of evidence-based practice guidelines and performance benchmarking. However, practice guideline recommendations may not serve the interests of each individual patient, especially when another plan of care may provide substantially greater benefits. In prioritizing their duty to act in the patient's best interests, physicians should be familiar with relevant practice guidelines, be able to recognize situations that might justify exceptions, and advocate for reasonable exceptions.

Acting Justly The principle of *justice* provides guidance to physicians about how to ethically treat patients and make decisions about allocating important resources, including their own time. *Justice* in a general sense means fairness: people should receive what they deserve. In addition, it is important to act consistently in cases that are similar in ethically relevant ways, in order to avoid arbitrary, biased, and unfair decisions. Justice forbids discrimination in health care based on race, religion, gender, sexual orientation, disability, age, or other personal characteristics **(Chap. 10)**.

ALLOCATION OF RESOURCES Justice also requires fair allocation of limited health care resources. Universal access to medically needed health care remains an unrealized moral aspiration in the United States and many countries around the world. Patients with no or inadequate health insurance often cannot afford health care and lack access to safety-net services. Even among insured patients, insurers may deny coverage for interventions recommended by their physician. In this situation, physicians should advocate for patients' affordable access to indicated care, try to help patients obtain needed care, and work with institutions and policies to promote wider access. Doctors might consider—or patients might request—the use of lies or deception to obtain such benefits, for example, signing a disability form for a patient who does not meet disability criteria. Although motivated by a desire to help the patient, such deception breaches basic ethical guidelines and undermines physicians' credibility and trustworthiness.

Allocation of health care resources is unavoidable when resources are limited. Allocation policies should be fair, transparent, accountable, responsive to the concerns of those affected, and proportionate to the situation, including the supply relative to the need. In the 2019–2020 SARS-CoV-2/COVID-19 pandemic, some epicenters anticipated or faced shortages of staff, protective equipment, hospital and critical care beds, and ventilators, even after increasing supplies and modifying usual clinical procedures. Many jurisdictions developed guidelines for implementing crisis standards of care to allocate limited interventions and services. Under crisis standards of care, some aspects of conventional care are not possible and interventions may not be provided to all who might benefit or wish to receive them. Crisis standards of care aim to promote the good of the community by saving the most lives in the short term, using evidence-based criteria.

When demand for medications or other interventions exceeds the supply, allocation should be fair, strive to avoid discrimination, and mitigate health disparities. First-come, first-served allocation is not fair, because it disadvantages patients who experience barriers to accessing care. To avoid discrimination, allocation decisions should not consider personal social characteristics such as race, gender, or disability, nor consider insurance status or wealth. Allocation policies also should aspire to reduce health care disparities. U.S. African-American, Latino-American, and Native-American patients suffered a disproportionate number of COVID-19 cases and deaths, likely due in part to being employed in jobs that cannot be done remotely or with physical distancing, crowded housing, lack of health benefits, and poor access to health care.

Fair and well-considered guidelines help mitigate any emotional and moral distress that clinicians may experience making difficult allocation decisions. Authorizing triage officers or committees to make allocation decisions according to policies determined with public input allows treating physicians and nurses to dedicate their efforts to their patients. Ad hoc resource allocation by physicians at the bedside may be inconsistent, unfair, and ineffective. At the bedside, physicians should act as patient advocates within constraints set by society, reasonable insurance policies, and evidence-based practice. Many allocation decisions are made at the level of public policy, with physician and public input. For example, the United Network for Organ Sharing (*www.unos.org*) provides criteria for allocating scarce organs.

VIRTUE ETHICS

Virtue ethics focuses on physicians' character and qualities, with the expectation that doctors will cultivate virtues such as compassion, trustworthiness, intellectual honesty, humility, and integrity. Proponents argue that, if such characteristics become ingrained, they help guide physicians in unforeseen situations. Moreover, following ethical precepts or principles without any of these virtues could lead to uncaring doctor–patient relationships.

PROFESSIONAL OATHS AND CODES

Professional oaths and codes are useful guides for physicians. Most physicians take oaths during their medical training, and many are members of professional societies that have professional codes. Physicians pledge to the public and to their patients that they will be guided by the principles and values in these oaths or codes and commit to the spirit of the ethical ideals and precepts represented in oaths and professional codes of ethics.

PERSONAL VALUES

Personal values, cultural traditions, and religious beliefs are important sources of personal morality that help physicians address ethical issues and cope with any moral distress they may experience in practice. While essential, personal morality alone is a limited ethical guide in clinical practice. Physicians have role-specific ethical obligations that go beyond their obligations as good people, including the duties to obtain informed consent and maintain confidentiality discussed earlier. Furthermore, in a culturally and religiously diverse world, physicians should expect that some patients and colleagues will have personal moral beliefs that differ from their own.

ETHICALLY COMPLEX PROFESSIONAL ISSUES FOR PHYSICIANS

CLAIMS OF CONSCIENCE

Some physicians, based on their personal values, have conscientious objections to providing, or referring patients for, certain treatments such as contraception or physician aid in dying. Although physicians should not be asked to violate deeply held moral beliefs or religious convictions, patients need medically appropriate, timely care and should always be treated with respect. Institutions such as clinics and hospitals have a collective ethical duty to provide care that patients need while making reasonable attempts to accommodate health care workers' conscientious objections—for example, when possible by arranging for another professional to provide the service in question. Patients seeking a relationship with a doctor or health care institution should be notified in advance of any conscientious objections to the provision of specific interventions. Since insurance often constrains patients' selection of physicians or health care facilities, switching providers can be burdensome. There are also important limits on claims of conscience. Health care workers may not insist that patients receive unwanted medical interventions. They also may not refuse to treat or discriminate against patients because of their race, ethnicity, disability, genetic information, or diagnosis. Such discrimination is illegal and violates physicians' duties to respect patients. Refusal to treat patients for other reasons such as sexual orientation, gender identity, or other personal characteristics is legally more controversial, yet ethically inappropriate because it falls short of helping patients in need and respecting them as persons.

PHYSICIAN AS GATEKEEPER

In some cases, patients may ask their physicians to facilitate access to services that the physician has ethical qualms about providing. For example, a patient might request a prescription for a cognitively enhancing medication to temporarily augment his cognitive abilities in order to take an exam or apply for employment. Patients may request more pain medication than the physician believes is warranted for the given situation or marijuana to facilitate sleep. Patients may ask their physician to sign a waiver to avoid vaccines for reasons that are not included in state exceptions (see **Chap. 3**). A physician may feel uncomfortable prescribing attention-deficit/hyperactivity disorder medications to a young child because she is not convinced that the possible benefit justifies the risks to the child despite the parent's request. In these circumstances, the physician should work with the patient or parent to understand the reasons for their requests, some of which might be legitimate. In addition to considering possible risks and benefits to the patient, the physician should consider how meeting the request might affect other patients, societal values, and public trust in the medical profession. If the physician determines that fulfilling the request requires deception, is unfair, jeopardizes her professional responsibilities, or is inconsistent with the patient's best medical interests, the physician should decline and explain the reasons to the patient.

MORAL DISTRESS

Health care providers, including residents, medical students, and experienced physicians, may experience moral distress when they feel that ethically appropriate action is hindered by institutional policies or culture, decision-making hierarchies, limited resources, or other reasons. Moral distress can lead to anger, anxiety, depression, frustration, fatigue, work dissatisfaction, and burnout. A physician's health and well-being can affect how he or she cares for patients. Discussing complex or unfamiliar clinical situations with colleagues and seeking assistance with difficult decisions can help alleviate moral distress, as can a healthy work environment characterized by open communication, mutual respect, and emphasis on the common goal of good patient care. In addition, physicians should take good care of their own well-being and be aware of the personal and system factors associated with stress, burnout, and depression. Health care organizations should provide a supportive work environment, counseling, and other support services when needed.

OCCUPATIONAL RISKS AND BURDENS

Physicians accept some physical risk in fulfilling their professional responsibilities, including exposure to infectious agents or toxic substances, violence in the workplace, and musculoskeletal injury. Nonetheless, most physicians, nurses, and other hospital staff willingly care for patients, despite personal risk and fear, grueling hours, and sometimes inadequate personal protective equipment or information. During the COVID-19 pandemic, many communities honored clinicians' dedication to professional ideals, and some medical students who were relieved from in-person patient care responsibilities volunteered to support front-line workers in other ways. The burdens of navigating professional and personal responsibilities fall more heavily on women health care providers. Health care institutions are responsible for reducing occupational risk and burden by providing proper information, training and supervision, protective equipment, infrastructure and workflow modifications, and emotional and psychological support to physicians. Clinical leaders need to acknowledge fears about personal safety and take steps to mitigate the impact of work on family responsibilities, moral distress, and burnout.

USE OF SOCIAL MEDIA AND PATIENT PORTALS

Increasingly, physicians use social and electronic media to share information and advice with patients and other providers. Social networking may be especially useful in reaching young or otherwise hard-to-access patients. Patients increasingly access their physicians' notes through patient portals, which aim to transparently share information, promote patient engagement, and increase adherence. Physicians should be professional and respectful and consider patient confidentiality, professional boundaries, and therapeutic relationships when posting to social media or writing notes for the portal. Overall, appropriate use of these platforms can enhance communication and transparency while avoiding misunderstandings or harmful consequences for patients, physicians, or their colleagues. Unprofessional or careless posts that express frustration or anger over work incidents, disparage patients or colleagues, use offensive or discriminatory language, or reveal inappropriate personal information about the physician can have negative consequences. Physicians should separate professional from personal websites and accounts and follow institutional and professional society guidelines when communicating with patients.

CONFLICTS OF INTEREST

Acting in patients' best interests may sometimes conflict with a physician's self-interest or the interests of third parties such as insurers or hospitals. From an ethical viewpoint, patients' interests are paramount. Transparency, appropriate disclosure, and management of conflicts of interest are essential to maintain the trust of colleagues and the public. Disclosure requirements vary for different purposes, and software has

been developed to assist physicians in complying with specific requirements. Importantly, not all conflicts are financial. Physicians sometimes face conflicts of commitment between their patient's interests and their own personal interests, professional goals, responsibilities, and aspirations. As mentioned earlier, physicians should prioritize patients' interests while recognizing possible conflicts and using disclosure, discussion with the chief of service, and management of the conflict or recusal when appropriate.

In addition to individual physicians, medical institutions may have conflicts of interest arising from patent rights, industry-funded research programs, and donations from individuals and companies. Institutions need to be transparent about the presence and amount of such relationships and make clear the steps taken to prevent such relationships from having an impact on clinical or financial decisions. If there is good evidence that a donor acted in ways that breached ethical or legal standards, the institution should take steps not to benefit from the donation or honor the donor.

FINANCIAL INCENTIVES

Physicians have financial incentives to improve the quality or efficiency of care that might lead some to avoid patients who are older, are chronically ill, or have more complicated problems, or to focus on benchmarked outcomes even when not in the best interests of individual patients. In contrast, fee-for-service payments might encourage physicians to order more interventions than necessary or to refer patients to laboratory, imaging, or surgical facilities in which they have a financial stake. Regardless of financial incentives, physicians should recommend available care that is in the patient's best interests—no more and no less.

RELATIONSHIPS WITH PHARMACEUTICAL COMPANIES

Financial relationships between physicians and industry are increasingly scrutinized. Many academic medical centers have banned drug-company gifts, including branded pens and notepads and meals to physicians, to reduce inappropriate risk of undue influence or subconscious feelings of reciprocity and to decrease possible influences on public trust or the costs of health care.

The federal Open Payments website provides public information on the payments and amounts that drug and device companies give to individual physicians by name. The challenge is to distinguish payments for scientific consulting and research contracts—which should be encouraged as consistent with professional and academic missions—from those for promotional speaking and consulting whose goal is to increase sales of company products.

LEARNING CLINICAL SKILLS

Medical students', residents', and physicians' interests in learning, which fosters the long-term goal of benefiting future patients, may sometimes conflict with the short-term goal of providing optimal care to current patients. When trainees are learning procedures on patients, they lack the proficiency of experienced physicians, and patients may experience inconvenience, discomfort, longer procedures, or increased risk. Increasingly, institutions are developing clinical skills laboratories for simulation-based medical education and requiring students to demonstrate proficiency before carrying out procedures such as venipuncture and intravenous lines in patients. Furthermore, teaching hospitals are establishing proceduralist services in which procedure-specialist faculty members directly supervise interns for procedures such as lumbar puncture and thoracentesis and certify their proficiency. Medical students may need to defer learning such invasive procedures until internship. Seeking patients' consent for trainee participation in their care is always important and is particularly important for intimate examinations, such as pelvic, rectal, breast, and testicular examinations, and for invasive procedures. Patients should be told who is providing care and how trainees are supervised. Failing to introduce students or not telling patients that trainees will be performing procedures undermines trust, may lead to more elaborate deception, and makes it difficult for patients to make informed choices about their care. Most patients, when informed, allow trainees to play an active role in their care.

RESPONSE TO MEDICAL ERRORS

Errors are inevitable in clinical medicine, and some errors cause harm to patients. Most errors are caused by lapses of attention or flaws in the system of delivering health care; only a small number result from blameworthy individual behavior. Many health care institutions have adopted a just culture system, which encourages open and honest reporting of errors as essential to quality learning and shifts the focus from individual blame to system design for improvement in quality and safety (Chap. 8). This approach is more likely than a punitive approach to improve patient safety. However, professional discipline is appropriate for cases of gross incompetence, reckless behavior, physician impairment, and boundary violations. Physicians and students may fear that disclosing errors will damage their careers. Physicians and health care institutions show respect for patients by disclosing and explaining errors, offering an apology, offering appropriate compensation for harm done, and using errors as opportunities to improve the quality of care.

PHYSICIAN IMPAIRMENT

Physicians may hesitate to intervene when colleagues impaired by alcohol, drugs, or psychiatric or medical illness place patients at risk. However, society relies on physicians to regulate themselves. Colleagues of an impaired physician should take steps to protect patients and help their impaired colleague, starting with reporting their concerns to their clinical supervisor or director.

ETHICAL ISSUES IN CLINICAL RESEARCH

Clinical research is essential to translate scientific discoveries into beneficial interventions for patients. However, clinical research raises ethical concerns because participants face inconvenience and risks in research designed to advance scientific knowledge and not specifically to benefit them. Ethical guidelines require researchers to rigorously design and conduct research, minimize risk to participants, and obtain informed and voluntary consent from participants and approval from an institutional review board (IRB). IRBs determine that risks to participants are acceptable and have been minimized and recommend appropriate additional protections when research includes vulnerable participants.

Physicians may be clinical research investigators themselves or may be in a position to refer or recommend clinical trial participation to their patients. Physician-investigators are likely to feel some inherent tension between conducting research and providing health care. Awareness of this tension, familiarity with research ethics, collaboration with research and clinical team members, and utilizing research ethics consultation can help to mitigate tensions. Before starting clinical research, investigators should complete training in the ethics of clinical research, which is widely available.

Physicians also should be critical consumers of clinical research results and keep up with research advances that change standards of practice. Precision medicine initiatives aim to individualize clinical care by combining clinical information from electronic health records, genomic sequencing, and data from personal mobile devices. Furthermore, physicians and health care institutions are analyzing data routinely collected and available in electronic health records, leftover clinical specimens, and administrative data. Such studies encompass traditional discovery research as well as quality improvement, comparative effectiveness research, and learning health care systems. Efforts to improve the quality of care in real-world clinical settings are important but also raise new issues about informed consent, privacy, and risk.

EMERGING TECHNOLOGIES

Scientific advances in genome sequencing, gene editing (e.g., with CRISPR-Cas9), machine learning, artificial intelligence, computer–brain interfaces, and other technologies offer great promise for research and clinical care with the ultimate goal of improving the prediction, prevention, and treatment of disease. Groundbreaking innovations that have strong scientific plausibility need to be evaluated in rigorous clinical studies for efficacy and safety.

Physicians should keep up to date on the status of novel and often complex technologies as research evolves, data emerge, and technologies are incorporated into clinical practice. They can help their patients understand research findings and the evidence for clinical use, correct any misunderstandings, facilitate shared decision-making, and advocate for fair access to such therapies. Further, physicians should engage in professional and public discussion related to allocation of resources and fair access to expensive new therapies and emerging technologies and their impact on overall health care affordability.

Certain cell-based therapies, such as peripheral blood stem cell transplantation **(Chap. 114)** and chimeric antigen receptor (CAR)-T cell therapy **(Chap. 69)**, are approved for use in several serious hematologic cancers, and gene therapies have been approved as safe and effective for clinical use in certain serious inherited diseases and cancers. Patients may request these and other complex, highly technical, and expensive therapies for unproven indications. Yet, claims of cures through unproven stem cell or gene-based "therapies" pose significant health and financial risks to patients without evidence of benefit. Physicians should help patients distinguish approved therapies from unproven claims and refer interested patients to well-designed clinical trials.

Medical applications of CRISPR-Cas9 are promising, and their safety and efficacy for particular clinical conditions are being carefully evaluated in clinical trials. Applications of CRISPR genome editing in somatic cells to modify or correct problematic genes could lay the foundation for treating a variety of serious diseases, including blood disorders, HIV, cancer, and hereditary blindness. Germline gene editing in blastocysts or embryos raises many ethical questions and is currently not permitted in the United States in clinical trials or clinical practice.

In artificial intelligence (AI), computers carry out tasks typically done by humans. Machine learning (ML) is a type of AI that automatically learns and improves its performance without explicit programming. Clinical algorithms using AI and ML can make diagnoses from radiology images, retinal scans, or skin photographs and identify patients at increased risk for surgical complications, critical care, or hospital readmission. However, such algorithms can also pose risks. Bias may occur if an algorithm was derived or validated from a data set in which groups who suffer from health disparities or poor health outcomes are underrepresented or if the algorithm predicts outcomes that are not clinically meaningful. To address these ethical concerns, researchers should assess AI algorithms in well-designed randomized clinical trials with clinical endpoints. Institutions should integrate validated and unbiased algorithms into clinical workflow without unduly burdening physicians and nurses and should check effectiveness and safety in their particular settings and patient populations.

Physicians should stay informed of emerging evidence about such technologies and the ethical challenges that accompany their use and always keep their patients' best interests and preferences at the forefront.

GLOBAL CONSIDERATIONS

INTERNATIONAL RESEARCH

Clinical research is often conducted across multiple sites and across national borders. Societal, legal, and cultural norms and perspectives about research may vary, and there are many ethical challenges. Physician-investigators involved in international research should be familiar with international guidelines, such as the Declaration of Helsinki, the Council for International Organizations of Medical Sciences (CIOMS) guidelines, and the International Council on Harmonisation Good Clinical Practice guidelines, as well as national and local laws where research is taking place. Partnering with local researchers and communities is essential not only to demonstrate respect but also to facilitate successful clinical research.

INTERNATIONAL CLINICAL EXPERIENCES

Many physicians and trainees gain valuable experience providing patient care in international settings through international training opportunities or volunteering for humanitarian or other international clinical work. Such arrangements, however, raise ethical challenges—for example, as a result of differences in beliefs about health and illness, expectations regarding health care and physicians' roles, standards of clinical practice, resource limitations, and norms for disclosure of serious diagnoses. Additional dilemmas arise if visiting physicians and trainees take on responsibilities beyond their expertise or if donated drugs and equipment are not appropriate to local needs. Visiting physicians and trainees should prepare well for these experiences, receive training and mentoring, learn about cultural and clinical practices in the host community, respect local customs and values, collaborate closely with local professionals and staff, and be explicit and humble about their own skills, knowledge, and limits. Leaders of global health field experiences should ensure that participating physicians receive training on ethical and cultural issues, as well as mentoring, backup, and debriefing upon return home.

CONCLUSION

Ethical issues are common in clinical medicine and occur in circumstances that may be foreseeable, novel, or unexpected. Physicians address these ethical issues by being prepared, informed, and thoughtful and using appropriate available resources.

12 Palliative and End-of-Life Care

Ezekiel J. Emanuel

EPIDEMIOLOGY

CAUSES OF DEATH

In 2019, 2,854,838 individuals died in the United States **(Table 12-1)**. Approximately 74% of these deaths occurred in those aged ≥65 years. The epidemiology of death has changed significantly since 1900 and even since 1980. In 1900, heart disease caused ~8% of all deaths, and cancer accounted for <4% of all deaths. In 1980, heart disease accounted for 38.2% of all deaths, cancer 20.9%, and cerebrovascular disease 8.6% of all deaths. By 2019, there had been a dramatic drop in deaths from cardiovascular and cerebrovascular diseases. In 2019, 23.1% of all deaths were from cardiovascular disease and just 5.3% from cerebrovascular disease. Deaths attributable to cancer, however, had increased slightly to 21.0%. The proportions of deaths due to chronic lower respiratory disease, diabetes, Alzheimer's, and suicide have increased. Interestingly, in 2019, HIV/AIDS accounted for <0.18% of all U.S. deaths. While unlikely to continue being a leading cause of death in the future, COVID-19 was also the cause for >600,000 deaths in 2020–2021, and the official figure is almost certainly an undercount of the actual death toll.

TABLE 12-1 Ten Leading Causes of Death in the United States and Britain

CAUSE OF DEATH	UNITED STATES (2019)		ENGLAND AND WALES (2019)	
	NUMBER OF DEATHS, ALL AGES (%)	NUMBER OF DEATHS, PEOPLE ≥65 YEARS OF AGE	NUMBER OF DEATHS, ALL AGES (%)	NUMBER OF DEATHS, PEOPLE ≥65 YEARS OF AGE
All deaths	2,854,838	2,117,332	530,841	449,047
Heart disease[a]	659,041 (23.1)	531,583 (25.1)	87,095 (16.4)	74,967 (16.7)
Malignant neoplasms	599,601 (21.0)	435,462 (20.6)	147,419 (27.8)	118,982 (26.5)
Chronic lower respiratory diseases	156,979 (5.5)	133,246 (6.3)	31,221 (5.9)	28,235 (6.3)
Accidents	173,040 (6.1)	60,527 (2.9)	15,141 (2.9)	8999 (2.0)
Cerebrovascular diseases	150,005 (5.3)	129,193 (6.1)	29,816 (5.6)	27,210 (6.0)
Alzheimer's disease	121,499 (4.3)	120,090 (5.7)	20,400 (3.8)	20,279 (4.5)
Diabetes mellitus	87,647 (3.1)	62,397 (2.9)	6528 (1.2)	5552 (1.2)
Influenza and pneumonia	49,783 (1.7)	40,399 (1.9)	26,398 (5.0)	24,269 (5.4)
Nephritis, nephritic syndrome, nephrosis	51,565 (1.8)	42,230 (2.0)	3575 (0.7)	3323 (0.7)
Intentional self-harm	47,511 (1.7)	—	4832 (0.9)	751 (0.2)

[a]Calculated using International Classification of Diseases codes I00–I09, I11, I13, I20–I51.

This change in the epidemiology of death is also reflected in the costs of illness. In the United States, ~84% of all health care spending goes to patients with chronic illnesses, and 12% of total personal health care spending—slightly less than $400 billion in 2015—goes to the 0.83% of the population in the last year of their lives.

In upper-middle- and upper-income countries, an estimated 70% of all deaths are preceded by a disease or condition, making it reasonable to plan for dying in the foreseeable future. Cancer has served as the paradigm for terminal care, but it is not the only type of illness with a recognizable and predictable terminal phase. Since heart failure, chronic obstructive pulmonary disease (COPD), chronic liver failure, dementia, and many other conditions have recognizable terminal phases, a systematic approach to end-of-life care should be part of all medical specialties. Many patients with chronic illness–related symptoms and suffering also can benefit from palliative care regardless of prognosis. Ideally, palliative care should be considered part of comprehensive care for all chronically ill patients. Strong evidence demonstrates that palliative care can be improved by coordination between caregivers, doctors, and patients for advance care planning, as well as dedicated teams of physicians, nurses, and other providers.

SITE OF DEATH

Where patients die varies by country. In Belgium and Canada, for instance, over half of all cancer patients still die in the hospital. The past few decades have seen a steady shift, both in the United States and other countries like the Netherlands, out of the hospital, as patients and their families list their own homes as the preferred site of death. In the early 1980s, ~70% of American cancer patients died in the hospital. Today, that percentage is ~25% **(Fig. 12-1)**. A recent report shows that since 2000, there has been a shift in the United States from inpatient to home deaths, especially for patients with cancer, COPD, and dementia. For instance, among Medicare beneficiaries, 30.1% of deaths due to cancer in 2000 occurred in acute care hospitals; by 2009, this figure had dropped to 22.1%; by 2015, it was 19.8%.

Paradoxically, while deaths in acute care hospitals have declined in the United States since 2000, both hospitalizations in the last 90 days of life and—even more troublingly—admission to the intensive care unit (ICU) in the last 30 days have actually increased. Over 40% of cancer patients in the United States are admitted to the ICU in their last 6 months of life, and >25% of cancer patients are admitted to the hospital in the last 30 days.

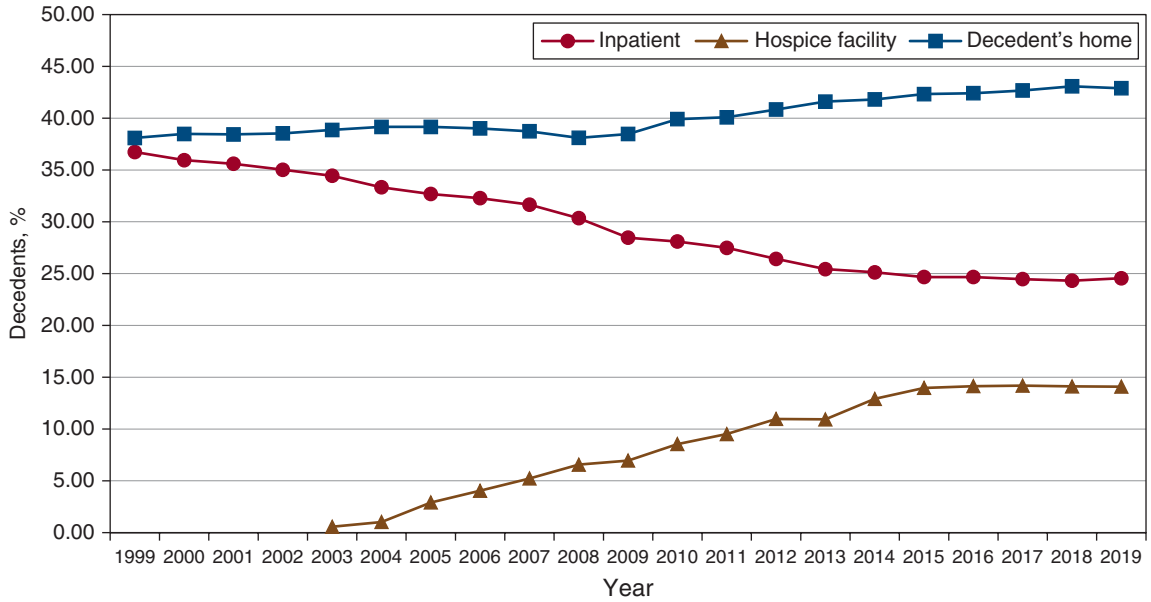

FIGURE 12-1 Graph showing trends in cancer decedents' site of death 1999–2019. *(Source: Centers for Disease Control and Prevention, National Center for Health Statistics. Underlying Cause of Death 1999-2019 on CDC WONDER Online Database. http://wonder.cdc.gov.)*

The shift in deaths out of the hospital has been accompanied by an increase in the use of hospice in the United States. In 2000, 21.6% of Medicare decedents used hospice at the time of death; by 2009, 42.2% were using hospice; and by 2018, 50.7% of Medicare decedents were enrolled in hospice at the time of death. Among cancer patients, ~60% were using hospice at the time of death. Hospice is also increasingly being used by noncancer patients. Today, cancer patients constitute ~20% of hospice users. But since 2014, the proportion of patients with other diagnoses using hospice has grown substantially, including those with circulatory/heart disease (17.4% in 2018 vs 13.8% in 2014), stroke (9.5% vs 6.2%), and respiratory disease (11.0% vs 9.4%). Of 2018 Medicare hospice decedents, 51.5% died at home, 17.4% in a nursing facility, 12.8% in a hospice inpatient facility, and 12.3% in assisted living.

Unfortunately, significant racial disparities exist in end-of-life care and the use of hospice, especially for noncancer deaths. Racial and ethnic minorities are less likely to receive hospice services than white decedents and are more likely to receive invasive or aggressive care in end-of-life treatment. Of people who died of head and neck cancers between 1999 and 2017, African Americans and Asians/Pacific Islanders were less likely to die at home or in hospice. Among Medicare beneficiaries who had a pancreatectomy for pancreatic cancer and lived at least 30 days, racial and ethnic minority patients remained 22% less likely than white patients to initiate hospice before death.

In 2008, for the first time, the American Board of Medical Specialties (ABMS) offered certification in hospice and palliative medicine. With the shortening of hospital stays, many serious conditions are now being treated at home or on an outpatient basis. Consequently, providing optimal palliative and end-of-life care requires ensuring that appropriate services are available in a variety of settings, including noninstitutional settings.

HOSPICE AND THE PALLIATIVE CARE FRAMEWORK

Central to this type of care is an interdisciplinary team approach that typically encompasses pain and symptom management, spiritual and psychological care for the patient, and support for family caregivers during the patient's illness and the bereavement period.

One of the more important changes in this field is beginning palliative care many months before death in order to focus on symptom relief and then switching to hospice in the patient's last few months. This approach avoids leaving hospice until the very end by introducing palliative care earlier, thereby allowing patients and families time to accommodate and transition. Phasing palliative care into end-of-life care means that patients will often receive palliative interventions long before they are formally diagnosed as terminally ill, or likely to die within 6 months.

Fundamental to ensuring quality palliative and end-of-life care is a focus on four broad domains: (1) physical symptoms; (2) psychological symptoms; (3) social needs that include interpersonal relationships, caregiving, and economic concerns; and (4) existential or spiritual needs.

ASSESSMENT AND CARE PLANNING

Comprehensive Assessment Standardized methods for conducting a comprehensive assessment focus on evaluating the patient's condition in all four domains affected by the illness: physical, psychological, social, and spiritual.

A comprehensive assessment should follow a modified version of the traditional medical history and physical examination and should emphasize both physical and mental symptoms. Questions should aim to elucidate symptoms, discern sources of suffering, and gauge how much those symptoms interfere with the patient's quality of life. Standardized and repeated assessments to evaluate the effectiveness of interventions are critical. Thus, clinicians should use shorter, validated instruments, such as (1) the revised Edmonton Symptom Assessment Scale; (2) Condensed Memorial Symptom Assessment Scale (MSAS); (3) MD Anderson Brief Symptom Inventory; (4) Rotterdam Symptom Checklist; (5) Symptom Distress Scale; (6) Patient-Reported Outcomes Measurement Information System; and (7) Interactive Symptom Assessment and Collection (ISAAC) tool.

MENTAL HEALTH With respect to mental health, many practices use the Patient Health Questionnaire-9 (PHQ-9) to screen for depression and the Generalized Anxiety Disorder-7 (GAD-7) to screen for anxiety. Using such tools ensures that the assessment is comprehensive and does not focus excessively on only pain.

INVASIVE TESTS Invasive tests are best avoided in end-of-life care, and even minimally invasive tests should be evaluated carefully for their benefit-to-burden ratio for the patient. Aspects of the physical examination that are uncomfortable and unlikely to yield useful information that change patient management should be omitted.

SOCIAL NEEDS Health care providers should also assess the status of important relationships, financial burdens, caregiving needs, and access to medical care. Relevant questions include the following: *How often is there someone to feel close to? How has this illness been for your family? How has it affected your relationships? How much help do you need with things like getting meals and getting around? How much trouble do you have getting the medical care you need?*

EXISTENTIAL NEEDS To determine a patient's existential needs, providers should assess distress, the patient's sense of emotional and existential well-being, and whether the patient believes he or she has found purpose or meaning. Helpful assessment questions can include the following: *How much are you able to find meaning since your illness began? What things are most important to you at this stage?*

PERCEPTION OF CARE In addition, it can be helpful to ask how the patient perceives his or her care: *How much do you feel your doctors and nurses respect you? How clear is the information from us about what to expect regarding your illness? How much do you feel that the medical care you are getting fits with your goals?* If concern is detected in any of these areas, deeper evaluative questions are warranted.

Communication Particularly when an illness is life-threatening, there exists the potential for many emotionally charged and potentially conflict-creating moments—collectively called "bad news" situations—in which empathic and effective communication skills are essential. Those moments include the sharing of a terminal diagnosis with the patient and/or family, the discussion of the patient's prognosis and any treatment failures, the consideration of deemphasizing efforts to cure and prolong life while focusing more on symptom management and palliation, advance care planning, and the patient's actual death. Although these conversations can be difficult, research indicates that end-of-life discussions can lead to earlier hospice referrals, rather than overly aggressive treatment, ultimately benefiting quality of life for patients and improving the bereavement process for families.

Just as surgeons prepare for major operations and investigators rehearse a presentation of research results, physicians and health care providers caring for patients with significant or advanced illnesses should develop a standardized approach for sharing important information and planning interventions. In addition, physicians must be aware that families often care not only about how prepared the physician was to deliver bad news, but also the setting in which it was delivered. For instance, one study found that 27% of families making critical decisions for patients in an ICU desired better and more private physical space to communicate with physicians.

One structured seven-step procedure for communicating bad news goes by the acronym P-SPIKES: (1) ***p***repare for the discussion, (2) ***s***et up a suitable environment, (3) begin the discussion by finding out what the ***p***atient and/or family understand, (4) determine how they will comprehend new ***i***nformation best and how much they want to know, (5) provide needed new ***k***nowledge accordingly, (6) allow for ***e***motional responses, and (7) ***s***hare plans for the next steps in care **(Table 12-2)**.

Continuous Goal Assessment Major barriers to providing high-quality palliative and end-of-life care include the difficulty in determining an accurate prognosis and the emotional resistance of patients and their families to accepting the implications of a poor prognosis. A practical solution to these barriers is to integrate palliative care interventions or home visits from a palliative care visiting nurse months before the estimated final 6 months of life. Under this

TABLE 12-2 Elements of Communicating Bad News—The P-SPIKES Approach

ACRONYM	STEPS	AIM OF THE INTERACTION	PREPARATIONS, QUESTIONS, OR PHRASES
P	Preparation	Mentally prepare for the interaction with the patient and/or family.	Review what information needs to be communicated. Plan how you will provide emotional support. Rehearse key steps and phrases in the interaction.
S	Setting of the interaction	Ensure the appropriate setting for a serious and potentially emotionally charged discussion.	Ensure that patient, family, and appropriate social supports are present. Devote sufficient time. Ensure privacy and prevent interruptions by people or beeper. Bring a box of tissues.
P	Patient's perception and preparation	Begin the discussion by establishing the baseline and whether the patient and family can grasp the information. Ease tension by having the patient and family contribute.	Start with open-ended questions to encourage participation. Possible questions to use: *What do you understand about your illness?* *When you first had symptom X, what did you think it might be?* *What did Dr. X tell you when he or she sent you here?* *What do you think is going to happen?*
I	Invitation and information needs	Discover what information needs the patient and/or family have and what limits they want regarding the bad information.	Possible questions to use: *If this condition turns out to be something serious, do you want to know?* *Would you like me to tell you all the details of your condition? If not, who would you like me to talk to?*
K	Knowledge of the condition	Provide the bad news or other information to the patient and/or family sensitively.	Do not just dump the information on the patient and family. Check for patient and family understanding. Possible phrases to use: *I feel badly to have to tell you this, but…* *Unfortunately, the tests showed…* *I'm afraid the news is not good…*
E	Empathy and exploration	Identify the cause of the emotions—e.g., poor prognosis. Empathize with the patient's and/or family's feelings. Explore by asking open-ended questions.	Strong feelings in reaction to bad news are normal. Acknowledge what the patient and family are feeling. Remind them such feelings are normal, even if frightening. Give them time to respond. Remind the patient and family you won't abandon them. Possible phrases to use: *I imagine this is very hard for you to hear.* *You look very upset. Tell me how you are feeling.* *I wish the news were different.* *We'll do whatever we can to help you.*
S	Summary and planning	Delineate for the patient and the family the next steps, including additional tests or interventions.	It is the unknown and uncertain that can increase anxiety. Recommend a schedule with goals and landmarks. Provide your rationale for the patient and/or family to accept (or reject). If the patient and/or family are not ready to discuss the next steps, schedule a follow-up visit.

approach, palliative care no longer conveys the message of failure, having no more treatments, or "giving up hope." The transition from palliative to end-of-life care or hospice also feels less hasty and unexpected to the family. Fundamental to integrating palliative care with curative therapy is the inclusion of a continuous goal assessment as part of the routine patient reassessments that occur at most patient-physician encounters.

Goals for care are numerous, ranging from curing a specific disease, to prolonging life, to relieving a particular symptom, to adapting to a progressive disability without disrupting the family, to finding peace of mind or personal meaning, to dying in a manner that leaves loved ones with positive memories. Discerning a patient's goals for care can be approached through a seven-step protocol: (1) ensure that medical and other information is as complete as reasonably possible and is understood by all relevant parties (see above); (2) explore what the patient and/or family is hoping for, while also identifying relevant and realistic goals; (3) share all the options with the patient and family; (4) respond with empathy as they adjust to changing expectations; (5) make a plan that emphasizes what can be done to achieve the realistic goals; (6) follow through with the plan; and (7) periodically review the plan and consider at every encounter whether the goals of care should be revised with the patient and/or family. Each of these steps need not be followed in rote order, but together they provide a helpful framework for interactions with patients and their families regarding their goals for care. Such interactions can be especially challenging if a patient or family member has difficulty letting go of an unrealistic goal. In such cases, the provider should help them refocus on more realistic goals and should also suggest that while it is fine to hope for the best, it is still prudent to plan for other outcomes as well.

Advance Care Planning • PRACTICES Advance care planning is the process of planning for future medical care in case the patient becomes incapable of making medical decisions. A 2010 study of adults aged ≥60 who died between 2000 and 2006 found that while 42% of adults were required to make treatment decisions in their final days of life, 70% lacked decision-making capacity. Among those lacking decision-making capacity, approximately one-third did not have advance planning directives. Ideally, such planning would occur before a health care crisis or the terminal phase of an illness. Unfortunately, diverse barriers prevent this. Approximately 80% of Americans endorse advance care planning and living wills. However, according to a 2013 Pew survey, only 35% of adults have written down their end-of-life wishes. Other studies report that even fewer Americans—with some estimates as low as 26% of adults—have filled out advance care directives. A review of studies suggests that the percentage of Americans who had written advance directives did not change between 2011 and 2016 and remains slightly over one-third of Americans. Larger numbers of adults, between 50 and 70%, claim to have talked with someone

about their treatment wishes. Americans aged 65 and older are more likely to complete an advance directive compared to younger adults (46% vs 32%).

Effective advance care planning should follow six key steps: (1) introducing the topic, (2) structuring a discussion, (3) reviewing plans that have been discussed by the patient and family, (4) documenting the plans, (5) updating them periodically, and (6) implementing the advance care directives **(Table 12-3)**. Two of the main barriers to advance care planning are problems in raising the topic and difficulty in structuring a succinct discussion. Raising the topic can be done efficiently as a routine matter, noting that it is recommended for all patients, analogous to purchasing insurance or estate planning. Many of the most difficult cases have involved unexpected, acute episodes of brain damage in young individuals.

Structuring a focused discussion is an important communication skill. To do so, a provider must first identify the health care proxy and recommend his or her involvement in the advance care planning process. Next, a worksheet must be selected that has been demonstrated to produce reliable and valid expressions of patient preferences, and the patient and proxy must be oriented to it. Such worksheets exist for both general and disease-specific situations. The provider should then discuss with the patient and proxy one example scenario to demonstrate how to think about the issues. It is often helpful to begin with a scenario in which the patient is likely to have settled preferences for care, such as being in a persistent vegetative state. Once the patient's preferences for interventions in this scenario are determined, the provider should suggest that the patient and proxy discuss and complete the worksheet for each other. If appropriate, the patient and proxy should consider involving other family members in the discussion. During a subsequent return visit, the provider should go over the patient's preferences, checking and resolving any inconsistencies. After having the patient and proxy sign the document, the provider should place the document in the patient's medical chart and make sure that copies are provided to relevant family members and care sites. Since patients' preferences can change, these documents must be reviewed periodically.

TYPES OF DOCUMENTS Advance care planning documents are of two broad types. The first includes living wills, also known as instructional directives; these are advisory documents that describe the types of decisions that should direct a patient's care. Some are more specific, delineating different scenarios and interventions for the patient to choose from. Among these, some are for general use and others are designed for use by patients with a specific type of disease, such as cancer, renal failure, or HIV. Less specific directives can be general statements, such as not wanting life-sustaining interventions, or forms that describe the values that should guide specific discussions about terminal care. The second type of advance directive allows the designation of a health care proxy (sometimes also referred to as a durable attorney for health care), an individual selected by the patient to make decisions. The choice is not either/or; a combined directive that includes a living

TABLE 12-3 Steps in Advance Care Planning

STEP	GOALS TO BE ACHIEVED AND MEASURES TO COVER	USEFUL PHRASES OR POINTS TO MAKE
Introduce advance care planning	Ask the patient what he or she knows about advance care planning and if he or she has already completed an advance care directive.	*I'd like to talk with you about something I try to discuss with all my patients. It's called advance care planning. In fact, I feel that this is such an important topic that I have done this myself. Are you familiar with advance care planning or living wills?*
	Indicate that you as a physician have completed advance care planning.	*Have you thought about the type of care you would want if you ever became too sick to speak for yourself? That is the purpose of advance care planning.*
	Indicate that you try to perform advance care planning with all patients regardless of prognosis.	*There is no change in health that we have not discussed. I am bringing this up now because it is sensible for everyone, no matter how well or ill, old or young.*
	Explain the goals of the process as empowering the patient and ensuring that you and the proxy understand the patient's preferences.	*Have many copies of advance care directives available, including in the waiting room, for patients and families.*
	Provide the patient relevant literature, including the advance care directive that you prefer to use.	*Know resources for state-specific forms (available at www.nhpco.org).*
	Recommend the patient identify a proxy decision-maker who should attend the next meeting.	
Have a structured discussion of scenarios with the patient	Affirm that the goal of the process is to follow the patient's wishes if the patient loses decision-making capacity.	*Use a structured worksheet with typical scenarios.*
	Elicit the patient's overall goals related to health care. Elicit the patient's preferences for specific interventions in a few salient and common scenarios. Help the patient define the threshold for withdrawing and withholding interventions. Define the patient's preference for the role of the proxy.	*Begin the discussion with persistent vegetative state and consider other scenarios, such as recovery from an acute event with serious disability; then ask the patient about his or her preferences regarding specific interventions, such as ventilators, artificial nutrition, and CPR; finally, proceeding to less invasive interventions, such as blood transfusions and antibiotics.*
Review the patient's preferences	After the patient has made choices of interventions, review them to ensure they are consistent and the proxy is aware of them.	
Document the patient's preferences	Formally complete the advance care directive and have a witness sign it.	
	Provide a copy for the patient and the proxy.	
	Insert a copy into the patient's medical record and summarize it in a progress note.	
Update the directive	Periodically, and with major changes in health status, review the directive with the patient and make any modifications.	
Apply the directive	The directive goes into effect only when the patient becomes unable to make medical decisions for himself or herself.	
	Reread the directive to be sure about its content.	
	Discuss your proposed actions based on the directive with the proxy.	

Abbreviation: CPR, cardiopulmonary resuscitation.

will and designates a proxy is often used, and the directive should indicate clearly whether the specified patient preferences or the proxy's choice takes precedence if they conflict. Some states have begun to put into practice a "Physician Orders for Life-Sustaining Treatment (POLST)" directive, which builds on communication between providers and patients by including guidance for end-of-life care in a color-coordinated form that follows the patient across treatment settings. The procedures for completing advance care planning documents vary according to state law.

A potentially misleading distinction relates to statutory, as opposed to advisory, documents. Statutory documents are drafted to fulfill relevant state laws. Advisory documents are drafted to reflect the patient's wishes. Both are legal, the former under state law and the latter under common or constitutional law.

LEGAL ASPECTS As of 2021, 48 states and the District of Columbia had enacted living will legislation. Massachusetts and Michigan are the two states without living will legislation. Indiana has a life-prolonging procedures declaration. States differ in the requirements for advanced directives, including whether they need to be witnessed and, if so, by how many witnesses and whether they need to be notarized. Importantly, in 25 states, the laws state that the living will is not valid if a woman is pregnant. All states except Alaska have enacted durable power of attorney for health care laws that permit patients to designate a proxy decision-maker with authority to terminate life-sustaining treatments. Only in Alaska does the law prohibit proxies from terminating life-sustaining treatments for pregnant women.

The U.S. Supreme Court has ruled that patients have a constitutional right to decide any issues related to refusing or terminating medical interventions, including life-sustaining interventions, and that mentally incompetent patients can exercise this right by providing "clear and convincing evidence" of their preferences. Since advance care directives permit patients to provide such evidence, commentators agree that they are constitutionally protected. Most commentators believe that a state is required to honor any clear advance care directive, regardless of whether it is written on an "official" form. Many states have enacted laws for the explicit purpose of honoring out-of-state directives. If a patient is not using a statutory form, it may be advisable to attach a statutory form to the advance care directive being used. State-specific forms are readily available free of charge for health care providers, patients, and families through the website of the National Hospice and Palliative Care Organization (*http://www.nhpco.org*).

REIMBURSEMENT As of January 1, 2016, the Centers for Medicare and Medicaid Services amended the physician fee schedule to reimburse discussions of advance care planning under Current Procedural Terminology codes 99497 and 99498. The session must be voluntary and include an explanation of advance care planning but need not include a completed advance care document. There can be multiple bills for the discussion if it extends over several encounters. A study found that patients who engaged in a billed advance care planning encounter were more likely to be enrolled in hospice and less likely to receive intensive therapies, despite being more likely to be hospitalized in the ICU. However, a billing incentive in and of itself may not increase advance care planning discussions by clinicians. In 2016, just 1.6% of Medicare Advantage patients had a discussion of advance care planning that was billed. Factors beyond reimbursement, such as clinicians' lack of comfort and skill in carrying out advance care planning discussions and lack of time, appear to impede discussions of advance care planning.

INTERVENTIONS

PHYSICAL SYMPTOMS AND THEIR MANAGEMENT

Great emphasis has been placed on addressing dying patients' pain. In order to emphasize its importance, pain assessment has frequently been included as the fifth vital sign. Heightened consideration of pain has been advocated by large health care systems such as the Veterans' Administration and accrediting bodies such as The Joint Commission. Although this embrace of pain has been symbolically important, available data suggest that making pain the fifth vital sign does not lead to improved pain management practices. In light of the opioid crisis in the United States, the emphasis on pain management has begun to be reexamined. For instance, in 2017 draft standards, The Joint Commission recommends nonpharmacologic pain treatment as well as identification of psychosocial risk factors for addiction. Importantly, good palliative care requires much more than good pain management. The frequency of symptoms varies by disease and other factors. The most common physical and psychological symptoms among all terminally ill patients include pain, fatigue, insomnia, anorexia, dyspnea, depression, anxiety, nausea, and vomiting. In the last days of life, terminal delirium is also common. Assessments of patients with advanced cancer have shown that patients experienced an average of 11.5 different physical and psychological symptoms **(Table 12-4)**.

TABLE 12-4 Common Physical and Psychological Symptoms of Terminally Ill Patients

PHYSICAL SYMPTOMS	PSYCHOLOGICAL SYMPTOMS
Pain	Anxiety
Fatigue and weakness	Depression
Dyspnea	Hopelessness
Insomnia	Meaninglessness
Dry mouth	Irritability
Anorexia	Impaired concentration
Nausea and vomiting	Confusion
Constipation	Delirium
Cough	Loss of libido
Swelling of arms or legs	
Itching	
Diarrhea	
Dysphagia	
Dizziness	
Fecal and urinary incontinence	
Numbness/tingling in hands/feet	

In the vast majority of cases, evaluations to determine the etiology of these symptoms should be limited to the history and physical examination. In some cases, radiologic or other diagnostic examinations will provide sufficient benefit in directing optimal palliative care to warrant the risks, potential discomfort, and inconvenience, especially to a seriously ill patient. Only a few of the common symptoms that present difficult management issues will be addressed in this chapter. **Additional information on the management of other symptoms, such as nausea and vomiting, insomnia, and diarrhea, can be found in Chaps. 45, 31, and 46, respectively. Information on the management of patients with cancer is provided in Chap. 69.**

Pain • **FREQUENCY** The frequency of pain among terminally ill patients varies significantly. Cancer (~85%), congestive heart failure (CHF; ~75%), and AIDS have been associated with a higher prevalence of pain compared to other advanced illnesses, such as COPD (~45%), chronic kidney disease (~40%), and dementia (~40%). One meta-analysis of adults with advanced or terminal illness found pain prevalence of 30–94% in patients with cancer, compared to 21–77% for COPD, 14–78% for CHF, 11–83% for end-stage renal disease, 14–63% for dementia, and 30–98% for AIDS.

ETIOLOGY There are two types of pain: nociceptive and neuropathic. Nociceptive pain is further divided into somatic or visceral pain. *Somatic pain* is the result of direct mechanical or chemical stimulation of nociceptors and normal neural signaling to the brain. It tends to be localized, aching, throbbing, and cramping. The classic example is bone metastases. *Visceral pain* is caused by nociceptors in gastrointestinal (GI), respiratory, and other organ systems. It is a deep or colicky type of pain classically associated with pancreatitis, myocardial infarction, or tumor invasion of viscera. *Neuropathic pain* arises from

disordered nerve signals. It is described by patients as burning, electrical, or shock-like pain. Classic examples are post-stroke pain, tumor invasion of the brachial plexus, and herpetic neuralgia.

ASSESSMENT Pain is a subjective experience. Depending on the patient's circumstances, perspective, and physiologic condition, the same physical lesion or disease state can produce different levels of reported pain and need for pain relief. Systematic assessment includes eliciting the following: (1) type: throbbing, cramping, burning, etc.; (2) periodicity: continuous, with or without exacerbations, or incident; (3) location; (4) intensity; (5) modifying factors; (6) effects of treatments; (7) functional impact; and (8) impact on patient. Several validated pain assessment measures may be used, including the Visual Analogue Scale (VAS), the Brief Pain Inventory (BPI), or the Numerical Pain Rating Scale (NRS-11). Other scales have been developed for neuropathic pain, such as the Neuropathic Pain Scale and the DN4 Questionnaire. Frequent reassessments on a consistent scale are essential to assess the impact of and need to readjust interventions.

INTERVENTIONS Interventions for pain must be tailored to each individual, with the goal of preempting chronic pain and relieving breakthrough pain. At the end of life, there is rarely reason to doubt a patient's report of pain. With the opioid crisis in the United States, there is more emphasis on making opioids one component of multimodal analgesia. Nevertheless, at the end of life, pain medications, especially opioids, remain the cornerstone of management **(Fig. 12-2)**. If they are failing and nonpharmacologic interventions—including radiotherapy and anesthetic or neurosurgical procedures such as peripheral nerve blocks or epidural medications—are required, a pain consultation is appropriate.

Pharmacologic interventions still largely follow the World Health Organization three-step, "analgesic ladder" approach, which involves nonopioid analgesics, "mild" opioids, and "strong" opioids, with or without adjuvants **(Chap. 13)**. Nonopioid analgesics, especially nonsteroidal anti-inflammatory drugs (NSAIDs), are the initial treatments for mild pain. They work primarily by inhibiting peripheral prostaglandins and reducing inflammation but may also have central nervous system (CNS) effects. Additionally, NSAIDs have a ceiling effect. Ibuprofen, up to 2400 mg/d qid, has a minimal risk of causing bleeding and renal impairment and is a good initial choice. In patients with a history of severe GI or other bleeding, however, ibuprofen should be avoided. In patients with a history of mild gastritis or gastroesophageal reflux disease (GERD), acid-lowering therapy, such as a proton pump inhibitor, should be used. Acetaminophen is an alternative in patients with a history of GI bleeding and can be used safely at up to 4 g/d qid. In patients with liver dysfunction due to metastases or other causes and in patients with heavy alcohol use, doses should be reduced.

If nonopioid analgesics are insufficient, opioids should be introduced. Opioids primarily work by interacting with μ opioid receptors to activate pain-inhibitory neurons in the CNS, although they also interact variably with δ and κ receptors. Receptor agonists, such as morphine, codeine, and fentanyl, produce analgesia by activating pain-inhibitory neurons in the CNS. Partial agonists, such as buprenorphine, have a ceiling effect for analgesia and a lower potential for abuse. They are useful for postacute pain but should not be used for chronic pain in end-of-life care. Pure antagonists, such as naloxone and methylnaltrexone, are used for reversal of opioid effects.

Traditionally, "weak" opioids such as codeine were used first. If they failed to relieve pain after dose escalation, "strong" opioids like morphine were used in doses of 5–10 mg every 4 h. However, this breakdown between "weak" and "strong" opioids is no longer commonly accepted, with smaller doses of "stronger" opioids frequently being preferred over similar or larger doses of "weaker" opioids, and different pain syndromes having different preferred therapies. Regardless, nonopioid analgesics should be combined with opioids, as they potentiate the effect of opioids.

Importantly, the goal is to prevent patients from experiencing pain. Consequently, for continuous pain, opioids should be administered on a regular, around-the-clock basis consistent with their duration of analgesia, and the next dose should occur before the effect of the previous dose wears off. They should not be provided only when the patient

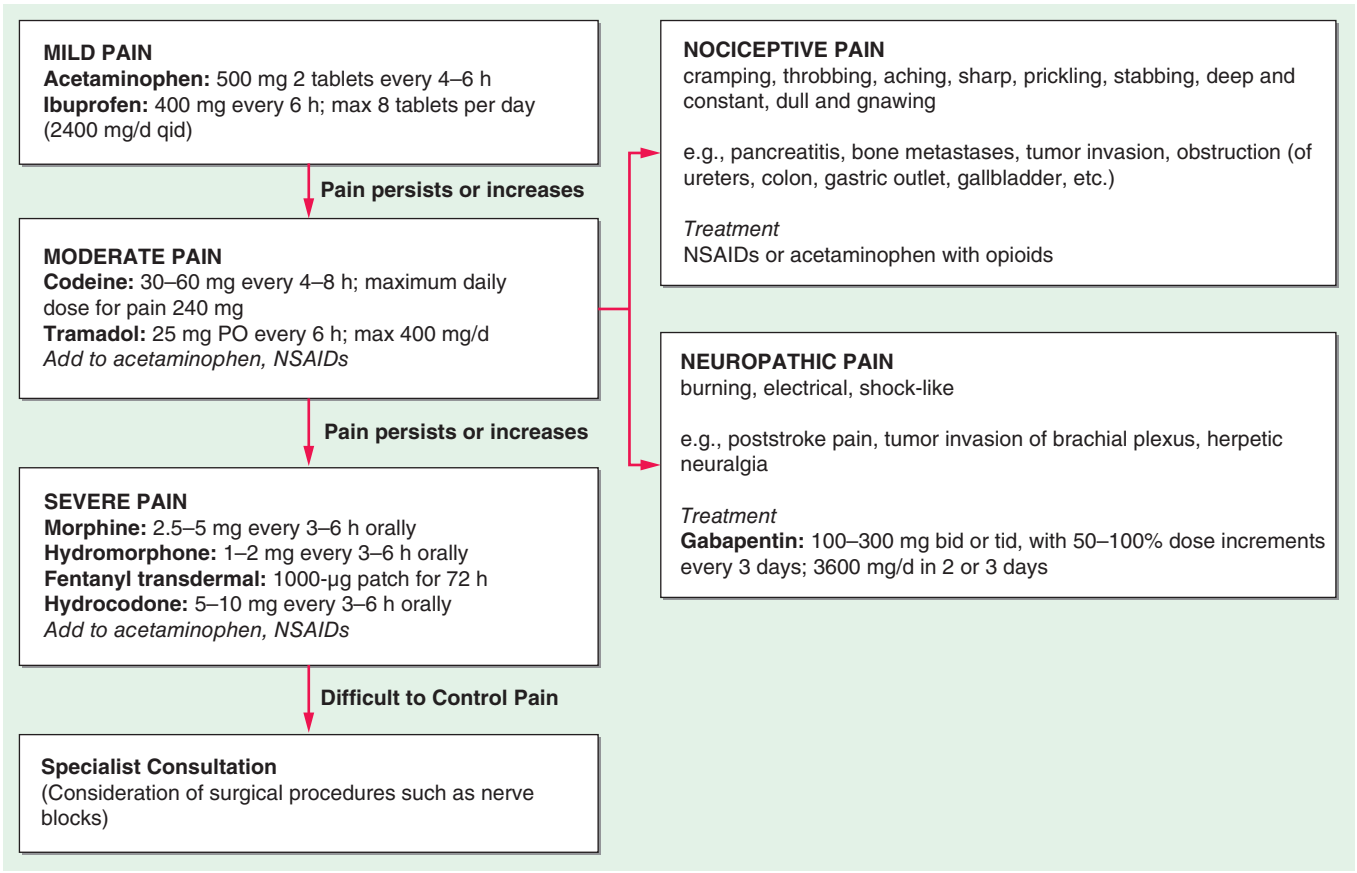

FIGURE 12-2 Terminal pain management flow chart. NSAIDs, nonsteroidal anti-inflammatory drugs.

experiences pain. Patients should also be provided rescue medication, such as liquid morphine, for breakthrough pain, generally at 20% of the baseline dose. Patients should be informed that using the rescue medication does not obviate the need to take the next standard dose of pain medication. If the patient's pain remains uncontrolled after 24 h and recurs before the next dose, requiring the patient to utilize the rescue medication, the daily opioid dose can be increased by the total dose of rescue medications used by the patient, or by 50% of the standing opioid daily dose for moderate pain and 100% for severe pain.

It is inappropriate to start with extended-release preparations. Instead, an initial focus on using short-acting preparations to determine how much is required in the first 24–48 h will allow clinicians to determine opioid needs. Once pain relief is obtained using short-acting preparations, the switch should be made to extended-release preparations. Even with a stable extended-release preparation regimen, the patient may experience incident pain, such as during movement or dressing changes. Short-acting preparations should be taken before such predictable episodes. Although less common, patients may have "end-of-dose failure" with long-acting opioids, meaning that they develop pain after 8 h in the case of an every-12-h medication. In these cases, a trial of giving an every-12-h medication every 8 h is appropriate.

Due to differences in opioid receptors, cross-tolerance among opioids is incomplete, and patients may experience different side effects with different opioids. Therefore, if a patient is not experiencing pain relief or is experiencing too many side effects, a change to another opioid preparation is appropriate. When switching, one should begin with 50–75% of the published equianalgesic dose of the new opioid.

Unlike NSAIDs, opioids have no ceiling effect; therefore, there is no maximum dose, no matter how many milligrams the patient is receiving. The appropriate dose is the dose needed to achieve pain relief. This is an important point for clinicians to explain to patients and families. Addiction or excessive respiratory depression is extremely unlikely in the terminally ill; fear of these side effects should neither prevent escalating opioid medications when the patient is experiencing insufficient pain relief nor justify using opioid antagonists.

Opioid side effects should be anticipated and treated preemptively. Nearly all patients experience constipation that can be debilitating (see below). Failure to prevent constipation often results in noncompliance with opioid therapy. The preferred treatment is prevention. Cathartics (senna 2 tbsp qHS), stool softeners (docusate 100 mg PO qd), and/or laxatives (laxtulose 30 mL qd) are considered first-line treatment. For refractory cases, opioid antagonists or other therapies, such as lubiprostone, should be considered.

Methylnaltrexone is the best-studied opioid antagonist for use in refractory opioid-induced constipation. It reverses opioid-induced constipation by blocking peripheral opioid receptors, but not central receptors, for analgesia. In placebo-controlled trials, it has been shown to cause laxation within 24 h of administration. As with the use of opioids, about a third of patients using methylnaltrexone experience nausea and vomiting, but unlike with opioid usage, tolerance usually develops within a week. Therefore, when one is beginning opioids, an antiemetic such as metoclopramide or a serotonin antagonist is often prescribed prophylactically and stopped after 1 week. Olanzapine has also been shown to have antinausea properties and can be effective in countering delirium or anxiety, with the advantage of some weight gain.

Drowsiness, a common side effect of opioids, also usually abates within a week. For refractory or severe cases, pharmacologic therapy should be considered. The best-studied agents are the psychostimulants dextroamphetamine, methylphenidate, and modafinil, although evidence regarding their efficacy is weak. Modafinil has the advantage of once-a-day dosing compared to methyphenidate's twice daily dosing.

Seriously ill patients who require chronic pain relief rarely become addicted. Suspicion of addiction should not be a reason to withhold pain medications from terminally ill patients. Nonetheless, patients and families may withhold prescribed opioids for fear of addiction or dependence. Physicians and health care providers should reassure patients and families that the patient will not become addicted to opioids if they are used as prescribed for pain relief; this fear should not prevent the patient from taking the medications around the clock. However, diversion of drugs for use by other family members or illicit sale may occur. It may be necessary to advise the patient and caregiver about secure storage of opioids. Contract writing with the patient and family can help. If that fails, transfer to a safe facility may be necessary.

Tolerance describes the need to increase medication dosage for the same pain relief without a concurrent change in disease. In the case of patients with advanced disease, the need for increasing opioid dosage for pain relief usually is caused by disease progression rather than tolerance. Physical dependence is indicated by symptoms resulting from the abrupt withdrawal of opioids and should not be confused with addiction.

In recent years, the potential dangers of opioid drugs have become increasingly apparent. To help mitigate the risk of these powerful drugs, several strategies should be used to reduce the risk of aberrant drug use. To start, all patients should be assessed for their individual levels of risk. While there are multiple surveys available, including the Opioid Risk Tool, none have gained widespread use or validation. In general, however, it is important to screen for prior substance abuse and major psychiatric disorders.

For patients deemed to be high risk, a multidisciplinary effort should be pursued to reduce the risk of adverse consequences, such as addiction and diversion. Prescribing strategies include selecting opioids with longer durations of action and lower street values, such as methadone, and prescribing smaller quantities with more frequent follow-up. Monitoring options include periodic urine screening and referral to pain specialists. In some cases, it may also be reasonable to consider not offering short-acting opioids for breakthrough pain. In no situation, however, should adequate pain relief be withheld due to risk.

Adjuvant analgesic medications are nonopioids that potentiate the analgesic effects of opioids. They are especially important in the management of neuropathic pain. Gabapentin, an anticonvulsant initially studied in the setting of herpetic neuralgia, is now the first-line treatment for neuropathic pain resulting from a variety of causes. It is begun at 100–300 mg bid or tid, with 50–100% dose increments every 3 days. Usually 900–3600 mg/d in two or three doses is effective. The combination of gabapentin and nortriptyline may be more effective than gabapentin alone. Two potential side effects of gabapentin to be aware of are confusion and drowsiness, especially in the elderly. Other effective adjuvant medications include pregabalin, which has the same mechanism of action as gabapentin but is absorbed more efficiently from the GI tract. Lamotrigine is a novel agent whose mechanism of action is unknown but has been shown to be effective. It is recommended to begin at 25–50 mg/d, increasing to 100 mg/d. Carbamazepine, a first-generation agent, has been proven effective in randomized trials for neuropathic pain. Other potentially effective anticonvulsant adjuvants include topiramate (25–50 mg qd or bid, rising to 100–300 mg/d) and oxcarbazepine (75–300 mg bid, rising to 1200 mg bid).

Glucocorticoids, preferably dexamethasone given once a day, can be useful in reducing inflammation that causes pain, while also elevating mood, energy, and appetite. Its main side effects include confusion, sleep difficulties, and fluid retention. Glucocorticoids are especially effective for bone pain and abdominal pain from distention of the GI tract or liver. Other drugs, including clonidine and baclofen, can be effective in providing pain relief. These drugs are adjuvants and generally should be used in conjunction with—not instead of—opioids. Methadone, carefully dosed because of its unpredictable half-life in many patients, has activity at the *N*-methyl-D-aspartamate (NMDA) receptor and is useful for complex pain syndromes and neuropathic pain. It is generally reserved for cases in which first-line opioids (morphine, oxycodone, hydromorphone) are either ineffective or unavailable.

Radiation therapy can treat bone pain from single metastatic lesions. Bone pain from multiple metastases can be amenable to radiopharmaceuticals such as strontium-89 and samarium-153. Bisphosphonates, such as pamidronate (90 mg every 4 weeks) and calcitonin (200 IU intranasally once or twice a day), also provide relief from bone pain but have multiday onsets of action.

Constipation • **FREQUENCY** Constipation is reported in up to 70–100% of patients requiring palliative care.

ETIOLOGY Although hypercalcemia and other factors can cause constipation, it is most frequently a predictable consequence of the use of opioids for pain and dyspnea relief and of the anticholinergic effects of tricyclic antidepressants, as well as due to the inactivity and poor diets common among seriously ill patients. If left untreated, constipation can cause substantial pain and vomiting and also is associated with confusion and delirium. Whenever opioids and other medications known to cause constipation are used, preemptive treatment for constipation should be instituted.

ASSESSMENT Assessing constipation can be difficult because people describe it differently. Four commonly used assessment scales are the Bristol Stool Form Scale, the Constipation Assessment Scale, the Constipation Visual Analogue Scale, and the Eton Scale Risk Assessment for Constipation. The Bowel Function Index can be used to quantify opioid-induced constipation. The physician should establish the patient's previous bowel habits, as well as any changes in subjective and objective qualities such as bloating or decreased frequency. Abdominal and rectal examinations should be performed to exclude impaction or an acute abdomen. Radiographic assessments beyond a simple flat plate of the abdomen in cases in which obstruction is suspected are rarely necessary.

INTERVENTION Any measure to address constipation during end-of-life care should include interventions to reestablish comfortable bowel habits and to relieve pain or discomfort. Although physical activity, adequate hydration, and dietary treatments with fiber can be helpful, each is limited in its effectiveness for most seriously ill patients, and fiber may exacerbate problems in the setting of dehydration or if impaired motility is the etiology. Fiber is contraindicated in the presence of opioid use. Stimulant and osmotic laxatives, stool softeners, fluids, and enemas are the mainstays of therapy **(Table 12-5)**. To prevent constipation from opioids and other medications, a combination of a laxative and a stool softener (such as senna and docusate) should be used. If after several days of treatment a bowel movement has not occurred, a rectal examination to remove impacted stool and place a suppository is necessary. For patients with impending bowel obstruction or gastric stasis, octreotide to reduce secretions can be helpful. For patients in whom the suspected mechanism is dysmotility, metoclopramide can be helpful.

TABLE 12-5 Medications for the Management of Constipation

INTERVENTION	DOSE	COMMENT
Stimulant laxatives		These agents directly stimulate peristalsis and may reduce colonic absorption of water.
Prune juice	120–240 mL/d	Work in 6–12 h.
Senna (Senokot)	2–8 tablets PO bid	
Bisacodyl	5–15 mg/d PO, PR	
Osmotic laxatives		These agents are not absorbed. They attract and retain water in the gastrointestinal tract.
Lactulose	15–30 mL PO q4–8h	Lactulose may cause flatulence and bloating.
Magnesium hydroxide (Milk of Magnesia)	15–30 mL/d PO	Lactulose works in 1 day, magnesium products in 6 h.
Magnesium citrate	125–250 mL/d PO	
Stool softeners		These agents work by increasing water secretion and as detergents, increasing water penetration into the stool.
Sodium docusate (Colace)	300–600 mg/d PO	Work in 1–3 days.
Calcium docusate	300–600 mg/d PO	
Suppositories and enemas		
Bisacodyl	10–15 PR qd	
Sodium phosphate enema	PR qd	Fixed dose, 4.5 oz, Fleet's.

Nausea • **FREQUENCY** Up to 70% of patients with advanced cancer have nausea, defined as the subjective sensation of wanting to vomit.

ETIOLOGY Nausea and vomiting are both caused by stimulation at one of four sites: the GI tract, the vestibular system, the chemoreceptor trigger zone (CTZ), and the cerebral cortex. Medical treatments for nausea are aimed at receptors at each of these sites: the GI tract contains mechanoreceptors, chemoreceptors, and 5-hydroxytryptamine type 3 (5-HT_3) receptors; the vestibular system probably contains histamine and acetylcholine receptors; and the CTZ contains chemoreceptors, dopamine type 2 receptors, and 5-HT3 receptors. An example of nausea that most likely is mediated by the cortex is anticipatory nausea before a dose of chemotherapy or other noxious stimuli.

Specific causes of nausea include metabolic changes (liver failure, uremia from renal failure, hypercalcemia), bowel obstruction, constipation, infection, GERD, vestibular disease, brain metastases, medications (including antibiotics, NSAIDs, proton pump inhibitors, opioids, and chemotherapy), and radiation therapy. Anxiety can also contribute to nausea.

INTERVENTION Medical treatment of nausea is directed at the anatomic and receptor-mediated cause revealed by a careful history and physical examination. When no specific cause of nausea is identified, many advocate beginning treatment with metoclopramide; a serotonin type 3 (5-HT_3) receptor antagonist such as ondansetron, granisetron, palonosetron, dolasetron, tropisetron, or ramosetron; or a dopamine antagonist such as chlorpromazine, haloperidol, or prochlorperazine. When decreased motility is suspected, metoclopramide can be an effective treatment. When inflammation of the GI tract is suspected, glucocorticoids, such as dexamethasone, are an appropriate treatment. For nausea that follows chemotherapy and radiation therapy, one of the 5-HT_3 receptor antagonists or neurokinin-1 antagonists, such as aprepitant or fosaprepitant, is recommended. Clinicians should attempt prevention of postchemotherapy nausea, rather than simply providing treatment after the fact. Current clinical guidelines recommend tailoring the strength of treatments to the specific emetic risk posed by a specific chemotherapy drug. When a vestibular cause (such as "motion sickness" or labyrinthitis) is suspected, antihistamines, such as meclizine (whose primary side effect is drowsiness), or anticholinergics, such as scopolamine, can be effective. In anticipatory nausea, patients can benefit from nonpharmacologic interventions, such as biofeedback and hypnosis. The most common pharmacologic intervention for anticipatory nausea is a benzodiazepine, such as lorazepam. As with antihistamines, drowsiness and confusion are the main side effects.

The use of medical marijuana or oral cannabinoids for palliative treatment of nausea is controversial, as there are no controlled trials showing its effectiveness for patients at the end of life. A 2015 meta-analysis showed "low-quality evidence suggesting that cannabinoids were associated with improvements in nausea and vomiting due to chemotherapy," and such treatments are not as good as 5-HT_3 receptor antagonists and can sometimes even cause cannabis hyperemesis syndrome. Older patients, who compose the vast majority of dying patients, seem to tolerate cannabinoids poorly.

Dyspnea • **FREQUENCY** Dyspnea is the subjective experience of being short of breath. Over 50%, and as many as 75%, of dying patients, especially those with lung cancer, metastases to the lung, CHF, and COPD, experience dyspnea at some point near the end of life. Dyspnea is among the most distressing of physical symptoms and can be even more distressing than pain.

ASSESSMENT As with pain, dyspnea is a subjective experience that may not correlate with objective measures of PO_2, PCO_2, or respiratory rate. Consequently, measurements of oxygen saturation through pulse oximetry or blood gases are rarely helpful in guiding therapy. Despite the limitations of existing assessment methods, physicians should regularly assess and document patients' experience of dyspnea

and its intensity. Guidelines recommend visual analogue dyspnea scales to assess the severity of symptoms and the effects of treatment. Potentially reversible or treatable causes of dyspnea include infection, pleural effusions, pulmonary emboli, pulmonary edema, asthma, and tumor encroachment on the airway. However, the risk-versus-benefit ratio of the diagnostic and therapeutic interventions for patients with little time left to live must be considered carefully before undertaking diagnostic steps. Frequently, the specific etiology cannot be identified, and dyspnea is the consequence of progression of the underlying disease that cannot be treated. The anxiety caused by dyspnea and the choking sensation can significantly exacerbate the underlying dyspnea in a negatively reinforcing cycle.

INTERVENTIONS When reversible or treatable etiologies are diagnosed, they should be treated as long as the side effects of treatment, such as repeated drainage of effusions or anticoagulants, are less burdensome than the dyspnea itself. More aggressive treatments such as stenting a bronchial lesion may be warranted if it is clear that the dyspnea is due to tumor invasion at that site and if the patient and family understand the risks of such a procedure.

Usually, treatment will be symptomatic **(Table 12-6)**. Supplemental oxygen does not appear to be effective. "A systematic review of the literature failed to demonstrate a consistent beneficial effect of oxygen inhalation over air inhalation for study participants with dyspnea due to end-stage cancer or cardiac failure." Therefore, oxygen may be no more than an expensive placebo. Low-dose opioids reduce the sensitivity of the central respiratory center and relieve the sensation of dyspnea. If patients are not receiving opioids, weak opioids can be initiated; if patients are already receiving opioids, morphine or other stronger opioids should be used. Controlled trials do not support the use of nebulized opioids for dyspnea at the end of life. Phenothiazines and chlorpromazine may be helpful when combined with opioids. Benzodiazepines can be helpful in treating dyspnea, but only if anxiety is present. Benzodiazepines should not be used as first-line therapy or if there is no anxiety. If the patient has a history of COPD or asthma, inhaled bronchodilators and glucocorticoids may be helpful. If the patient has pulmonary edema due to heart failure, diuresis with a medication such as furosemide is indicated. Excess secretions can be transdermally or intravenously dried with scopolamine. More general interventions that medical staff can perform include sitting the patient upright, removing smoke or other irritants like perfume, ensuring a supply of fresh air with sufficient humidity, and minimizing other factors that can increase anxiety.

TABLE 12-6 Medications for the Management of Dyspnea

INTERVENTION	DOSE	COMMENTS
Weak opioids		For patients with mild dyspnea
Codeine (or codeine with 325 mg acetaminophen)	30 mg PO q4h	For opioid-naïve patients
Hydrocodone	5 mg PO q4h	
Strong opioids		For opioid-naïve patients with moderate to severe dyspnea
Morphine	5–10 mg PO q4h	For patients already taking opioids for pain or other symptoms
	30–50% of baseline opioid dose q4h	
Oxycodone	5–10 mg PO q4h	
Hydromorphone	1–2 mg PO q4h	
Anxiolytics		Give a dose every hour until the patient is relaxed; then provide a dose for maintenance
Lorazepam	0.5–2.0 mg PO/SL/IV qh then q4–6h	
Clonazepam	0.25–2.0 mg PO q12h	
Midazolam	0.5 mg IV q15min	

Fatigue • FREQUENCY Fatigue is one of the most commonly reported symptoms not only of cancer treatment but also of the palliative care of multiple sclerosis, COPD, heart failure, and HIV. More than 90% of terminally ill patients experience fatigue and/or weakness. Fatigue is frequently cited as one of the most distressing symptoms in these patients.

ETIOLOGY The multiple causes of fatigue in the terminally ill can be categorized as resulting from the underlying disease; from disease-induced factors such as tumor necrosis factor and other cytokines; and from secondary factors such as dehydration, anemia, infection, hypothyroidism, and drug side effects. In addition to low caloric intake, loss of muscle mass and changes in muscle enzymes may play an important role in fatigue during terminal illness. The importance of changes in the CNS, especially the reticular activating system, have been hypothesized based on reports of fatigue in patients receiving cranial radiation, experiencing depression, or having chronic pain in the absence of cachexia or other physiologic changes. Finally, depression and other causes of psychological distress can contribute to fatigue.

ASSESSMENT Like pain and dyspnea, fatigue is subjective, as it represents a patient's sense of tiredness and decreased capacity for physical work. Objective changes, even in body mass, may be absent. Consequently, assessment must rely on patient self-reporting. Scales used to measure fatigue, such as the Edmonton Functional Assessment Tool, the Fatigue Self-Report Scales, and the Rhoten Fatigue Scale, are usually appropriate for research but not clinical purposes. In clinical practice, a simple performance assessment such as the Karnofsky performance status or the Eastern Cooperative Oncology Group (ECOG)'s question "How much of the day does the patient spend in bed?" may be the best measure. In the ECOG 0–4 performance status assessment, 0 = normal activity; 1 = symptomatic without being bedridden; 2 = requiring some, but <50%, bed time; 3 = bedbound more than half the day; and 4 = bedbound all the time. Such a scale allows for assessment over time and correlates with overall disease severity and prognosis. A 2008 review by the European Association of Palliative Care also described several longer assessment tools that contained 9–20 items, including the Piper Fatigue Inventory, the Multidimensional Fatigue Inventory, and the Brief Fatigue Inventory (BFI).

INTERVENTIONS Reversible causes of fatigue, such as anemia and infection, should be treated. However, at the end of life, it must be realistically acknowledged that fatigue will not be "cured." The goal is to ameliorate fatigue and help patients and families adjust expectations. Behavioral interventions should be utilized to avoid blaming the patient for inactivity and to educate both the family and the patient that the underlying disease causes physiologic changes that produce low energy levels. Understanding that the problem is physiologic and not psychological can help alter expectations regarding the patient's level of physical activity. Practically, this may mean reducing routine activities such as housework, cooking, and social events outside the house and making it acceptable to receive guests while lying on a couch. At the same time, the implementation of exercise regimens and physical therapy can raise endorphins, reduce muscle wasting, and decrease the risk of depression. In addition, ensuring good hydration without worsening edema may help reduce fatigue. Discontinuing medications that worsen fatigue may help, including cardiac medications, benzodiazepines, certain antidepressants, or opioids if the patient's pain is well-controlled. As end-of-life care proceeds into its final stages, fatigue may protect patients from further suffering, and continued treatment could be detrimental.

Only a few pharmacologic interventions target fatigue and weakness. Randomized controlled trials suggest glucocorticoids can increase energy and enhance mood. Dexamethasone (8 mg/d) is preferred for its once-a-day dosing and minimal mineralocorticoid activity. Benefit, if any, is usually seen within the first month. For fatigue related to anorexia, megestrol (480–800 mg) can be helpful. Psychostimulants such as dextroamphetamine (5–10 mg PO) and methylphenidate (2.5–5 mg PO) may enhance energy levels, although controlled trials have not shown these drugs to be effective for fatigue induced by mild

to moderate cancer. Doses should be given in the morning and at noon to minimize the risk of counterproductive insomnia. Modafinil and armodafinil, developed for narcolepsy, have shown promise in the treatment of fatigue and have the advantage of once-daily dosing. Their precise role in fatigue at the end of life has not been documented but may be worth trying if other interventions are not beneficial. Anecdotal evidence suggests that L-carnitine may improve fatigue, depression, and sleep disruption.

PALLIATIVE SEDATION

Palliative sedation is used in distressing situations that cannot be addressed in other ways. When patients experience severe symptoms, such as pain or dyspnea, that cannot be relieved by conventional interventions or experience acute catastrophic symptoms, such as uncontrolled seizures, then palliative sedation should be considered as an intervention of last resort. It can be abused if done to hasten death (which it usually does not), when done at the request of the family rather than according to the patient's wishes, or when there are other interventions that could still be tried. The use of palliative sedation in cases of extreme existential or spiritual distress remains controversial. Typically, palliative sedation should be introduced only after the patient and family have been assured that all other interventions have been tried and after the patient and their loved ones have been able to "say goodbye."

Palliative sedation can be achieved by significantly increasing opioid doses until patients become unconscious and then putting them on a continuous infusion. Another commonly used medication for palliative sedation is midazolam at 1–5 mg IV every 5–15 min to calm the patient, followed by a continuous IV or subcutaneous infusion of 1 mg/h. In hospital settings, a continuous propofol infusion of 5 μg/kg per min can be used. There are also other, less commonly used medications for palliative sedation that include levomepromazine, chlorpromazine, and phenobarbital.

PSYCHOLOGICAL SYMPTOMS AND THEIR MANAGEMENT

Depression • **FREQUENCY AND IMPACT** Depression at the end of life presents an apparently paradoxical situation. Many people believe that depression is normal among seriously ill patients because they are dying. People frequently say, "Wouldn't you be depressed?" Although sadness, anxiety, anger, and irritability are normal responses to a serious condition, they are typically of modest intensity and transient. Persistent sadness and anxiety and the physically disabling symptoms that they can lead to are abnormal and suggestive of major depression. The precise number of terminally ill patients who are depressed is uncertain, primarily due to a lack of consistent diagnostic criteria and screening. Careful follow-up of patients suggests that while as many as 75% of terminally ill patients experience depressive symptoms, ~25% of terminally ill patients have major depression. Depression at the end of life is concerning because it can decrease the quality of life, interfere with closure in relationships and other separation work, obstruct adherence to medical interventions, and amplify the suffering associated with pain and other symptoms.

ETIOLOGY Previous history of depression, family history of depression or bipolar disorder, and prior suicide attempts are associated with increased risk for depression among terminally ill patients. Other symptoms, such as pain and fatigue, are associated with higher rates of depression; uncontrolled pain can exacerbate depression, and depression can cause patients to be more distressed by pain. Many medications used in the terminal stages, including glucocorticoids, and some anticancer agents, such as tamoxifen, interleukin 2, interferon α, and vincristine, also are associated with depression. Some terminal conditions, such as pancreatic cancer, certain strokes, and heart failure, have been reported to be associated with higher rates of depression, although this is controversial. Finally, depression may be attributable to grief over the loss of a role or function, social isolation, or loneliness.

ASSESSMENT Unfortunately, many studies suggest that most depressed patients at the end of life are not diagnosed, or if they are diagnosed, they are not properly treated. Diagnosing depression among seriously ill patients is complicated, as many of the vegetative symptoms in the *DSM-V* (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) criteria for clinical depression—insomnia, anorexia and weight loss, fatigue, decreased libido, and difficulty concentrating—are associated with the process of dying itself. The assessment of depression in seriously ill patients therefore should focus on the dysphoric mood, helplessness, hopelessness, and lack of interest, enjoyment, and concentration in normal activities. It is now recommended that patients near the end of life should be screened with either the PHQ-9 or the PHQ-2, which asks "Over the past 2 weeks, how often have you been bothered by any of the following problems? (1) Little interest or pleasure in doing things and (2) feeling down, depressed or hopeless." The answer categories are as follows: not at all, several days, more than half the days, nearly every day. Other possible diagnostic tools include the short form of the Beck Depression Index or a visual analogue scale.

Certain conditions may be confused with depression. Endocrinopathies, such as hypothyroidism and Cushing's syndrome, electrolyte abnormalities, such as hypercalcemia, and akathisia, especially from dopamine-blocking antiemetics such as metoclopramide and prochlorperazine, can mimic depression and should be excluded.

INTERVENTIONS Undertreatment of depressed, terminally ill patients is common. Physicians must treat any physical symptom, such as pain, that may be causing or exacerbating depression. Fostering adaptation to the many losses that the patient is experiencing can also be helpful. Unfortunately, there are few randomized trials to guide such interventions. Thus, treatment typically follows the treatment used for non–terminally ill depressed patients.

In the absence of randomized controlled trials, nonpharmacologic interventions, including group or individual psychological counseling, and behavioral therapies such as relaxation and imagery can be helpful, especially in combination with drug therapy.

Pharmacologic interventions remain at the core of therapy. The same medications are used to treat depression in terminally ill as in non–terminally ill patients. Psychostimulants may be preferred for patients with a poor prognosis or for those with fatigue or opioid-induced somnolence. Psychostimulants are comparatively fast-acting, working within a few days instead of the weeks required for selective serotonin reuptake inhibitors (SSRIs). Dextroamphetamine or methylphenidate should be started at 2.5–5.0 mg in the morning and at noon, the same starting doses used for treating fatigue. The doses can eventually be escalated up to 15 mg bid. Modafinil is started at 100 mg qd and can be increased to 200 mg if there is no effect at the lower dose. Pemoline is a nonamphetamine psychostimulant with minimal abuse potential. It is also effective as an antidepressant beginning at 18.75 mg in the morning and at noon. Because it can be absorbed through the buccal mucosa, it is preferred for patients with intestinal obstruction or dysphagia. If it is used for prolonged periods, liver function must be monitored. The psychostimulants can also be combined with more traditional antidepressants while waiting for the antidepressants to become effective, then tapered down after a few weeks if necessary. Psychostimulants have side effects, particularly initial anxiety, insomnia, and very rarely paranoia, which may necessitate lowering the dose or discontinuing treatment.

Mirtazapine, an antagonist at the postsynaptic serotonin receptors, is a promising psychostimulant. It should be started at 7.5 mg before bed and titrated up no more than once every 1–2 weeks to a maximal dose of 45 mg/d. It has sedating, antiemetic, and anxiolytic properties, with few drug interactions. Its side effect of weight gain may be beneficial for seriously ill patients; it is available in orally disintegrating tablets.

For patients with a prognosis of several months or longer, SSRIs, including fluoxetine, sertraline, paroxetine, escitalopram, and citalopram, and serotonin-noradrenaline reuptake inhibitors, such as venlafaxine and duloxetine, are the preferred treatments, due to their efficacy and comparatively few side effects. Because low doses of these medications may be effective for seriously ill patients, one should use half the usual starting dose as for healthy adults. The starting dose for

fluoxetine is 10 mg once a day. In most cases, once-a-day dosing is possible. The choice of which SSRI to use should be driven by (1) the patient's past success or failure with the specific medication and (2) the most favorable side effect profile for that specific agent. For instance, for a patient in whom fatigue is a major symptom, a more activating SSRI (fluoxetine) would be appropriate. For a patient in whom anxiety and sleeplessness are major symptoms, a more sedating SSRI (paroxetine) would be appropriate. Importantly, it can take up to 4 weeks for these drugs to have an effect.

Atypical antidepressants are recommended only in select circumstances, usually with the assistance of a specialty consultation. Trazodone can be an effective antidepressant but is sedating and can cause orthostatic hypotension and, occasionally, priapism. Therefore, it should be used before bed and only when a sedating effect is desired and is often used for patients with insomnia at a dose starting at 25 mg. Bupropion can also be used. In addition to its antidepressant effects, bupropion is energizing, making it useful for depressed patients who experience fatigue. However, it can cause seizures, preventing its use for patients with a risk of CNS neoplasms or terminal delirium. Finally, alprazolam, a benzodiazepine, starting at 0.25–1.0 mg tid, can be effective in seriously ill patients who have a combination of anxiety and depression. Although it is potent and works quickly, it has many drug interactions and may cause delirium, especially among very ill patients, because of its strong binding to the benzodiazepine–γ-aminobutyric acid (GABA) receptor complex.

Unless used as adjuvants for the treatment of pain, tricyclic antidepressants are not recommended. While they can be effective, their therapeutic window and serious side effects typically limit their utility. Similarly, monoamine oxidase (MAO) inhibitors are not recommended because of their side effects and dangerous drug interactions.

Delirium **(See Chap. 27)** • **FREQUENCY** In the weeks or months before death, delirium is uncommon, although it may be significantly underdiagnosed. However, delirium becomes relatively common in the days and hours immediately before death. Up to 85% of patients dying from cancer may experience terminal delirium.

ETIOLOGY Delirium is a global cerebral dysfunction characterized by alterations in cognition and consciousness. It is frequently preceded by anxiety, changes in sleep patterns (especially reversal of day and night), and decreased attention. In contrast to dementia, delirium has an acute onset, is characterized by fluctuating consciousness and inattention, and is reversible, although reversibility may be more theoretical than real for patients near death. Delirium may occur in a patient with dementia; indeed, patients with dementia are more vulnerable to delirium.

Causes of delirium include metabolic encephalopathy arising from liver or renal failure, hypoxemia, or infection; electrolyte imbalances such as hypercalcemia; paraneoplastic syndromes; dehydration; and primary brain tumors, brain metastases, or leptomeningeal spread of tumor. Among dying patients, delirium is commonly caused by side effects of treatments, including radiation for brain metastases and medications, such as opioids, glucocorticoids, anticholinergic drugs, antihistamines, antiemetics, benzodiazepines, and chemotherapeutic agents. The etiology may be multifactorial; e.g., dehydration may exacerbate opioid-induced delirium.

ASSESSMENT Delirium should be recognized in any terminally ill patient exhibiting new onset of disorientation, impaired cognition, somnolence, fluctuating levels of consciousness, or delusions with or without agitation. Delirium must be distinguished from acute anxiety, depression, and dementia. The central distinguishing feature is altered consciousness, which usually is not noted in anxiety, depression, or dementia. Although "hyperactive" delirium, characterized by overt confusion and agitation, is probably more common, patients should also be assessed for "hypoactive" delirium, which is characterized by sleep-wake reversal and decreased alertness.

In some cases, use of formal assessment tools such as the Mini-Mental Status Examination (which does not distinguish delirium from dementia) and the Delirium Rating Scale (which does distinguish delirium from dementia) may be helpful in distinguishing delirium from other processes. The patient's list of medications must be evaluated carefully. Nonetheless, a reversible etiologic factor for delirium is found in fewer than half of all terminally ill patients. Given that most terminally ill patients experiencing delirium are very close to death and often at home, extensive diagnostic evaluations such as lumbar punctures and neuroradiologic examinations are inappropriate.

INTERVENTIONS One of the most important objectives of terminal care is to provide terminally ill patients the lucidity to say goodbye to the people they love. Delirium, especially when in combination with agitation during the final days, is distressing to family and caregivers. A strong determinant of bereavement difficulties is witnessing a difficult death. Thus, terminal delirium should be treated aggressively.

At the first sign of delirium, such as day-night reversal with slight changes in mentation, the physician should let the family members know that it is time to be sure that everything they want to say has been said. The family should be informed that delirium is common just before death.

If medications are suspected of being a cause of the delirium, unnecessary agents should be discontinued. Other potentially reversible causes, such as constipation, urinary retention, and metabolic abnormalities, should be treated. Supportive measures aimed at providing a familiar environment should be instituted, including restricting visits only to individuals with whom the patient is familiar and eliminating new experiences; orienting the patient, if possible, by providing a clock and calendar; and gently correcting the patient's hallucinations or cognitive mistakes.

Pharmacologic management focuses on the use of neuroleptics and, in extreme cases, anesthetics **(Table 12-7)**. Haloperidol remains the first-line therapy. Usually, patients can be controlled with a low dose (1–3 mg/d), given every 6 h, although some may require as much as 20 mg/d. Haloperidol can be administered PO, SC, or IV. IM injections should not be used, except when this is the only way to address a patient's delirium. Olanzapine, an atypical neuroleptic, has shown significant effectiveness in completely resolving delirium in cancer patients. It also has other beneficial effects for terminally ill patients, including antinausea, antianxiety, and weight gain. Olanzapine is useful for patients with longer anticipated life expectancies because it is less likely to cause dysphoria and has a lower risk of dystonic reactions. Additionally, because olanzapine is metabolized through multiple pathways, it can be used in patients with hepatic and renal dysfunction. Olanzapine has the disadvantage that it is only available orally and takes a week to reach steady state. The usual dose is 2.5–5 mg PO bid. Chlorpromazine (10–25 mg every 4–6 h) can be useful if sedation is desired and can be administered IV or PR in addition to PO. Dystonic reactions resulting from dopamine blockade are a side effect of neuroleptics, although they are reported to be rare when these drugs are used to treat terminal delirium. If patients develop dystonic reactions, benztropine should be administered. Neuroleptics may be

TABLE 12-7 Medications for the Management of Delirium

INTERVENTIONS	DOSE
Neuroleptics	
Haloperidol	0.5–5 mg q2–12h, PO/IV/SC/IM
Thioridazine	10–75 mg q4–8h, PO
Chlorpromazine	12.5–50 mg q4–12h, PO/IV/IM
Atypical neuroleptics	
Olanzapine	2.5–5 mg qd or bid, PO
Risperidone	1–3 mg q12h, PO
Anxiolytics	
Lorazepam	0.5–2 mg q1–4h, PO/IV/IM
Midazolam	1–5 mg/h continuous infusion, IV/SC
Anesthetics	
Propofol	0.3–2.0 mg/h continuous infusion, IV

combined with lorazepam to reduce agitation when the delirium is the result of alcohol or sedative withdrawal.

If no response to first-line therapy is observed, a specialty consultation should be obtained with a goal to change to a different medication. If the patient fails to improve after a second neuroleptic, sedation with either an anesthetic such as propofol or continuous-infusion midazolam may be necessary. By some estimates, as many as 25% of patients at the very end of life who experience delirium, especially restless delirium with myoclonus or convulsions, may require sedation.

Physical restraints should be used with great reluctance and only when patients' violence is threatening to themselves or others. If restraints are used, their appropriateness should be frequently reevaluated.

Insomnia • **FREQUENCY** Sleep disorders, defined as difficulty initiating sleep or maintaining sleep, sleep difficulty at least 3 nights a week, or sleep difficulty that causes impairment of daytime functioning, occurs in 19–63% of patients with advanced cancer. Some 30–74% of patients with other end-stage conditions, including AIDS, heart disease, COPD, and renal disease, experience insomnia.

ETIOLOGY Patients with cancer may experience changes in sleep efficiency, such as an increase in stage I sleep. Insomnia may also coexist with both physical illnesses, like thyroid disease, and psychological illnesses, like depression and anxiety. Medications, including antidepressants, psychostimulants, glucocorticoids, and β agonists, are significant contributors to sleep disorders, as are caffeine and alcohol. Multiple over-the-counter medications contain caffeine and antihistamines, which can contribute to sleep disorders.

ASSESSMENT Assessments should include specific questions concerning sleep onset, sleep maintenance, and early-morning wakening, as these will provide clues to both the causative agents and management of insomnia. Patients should be asked about previous sleep problems, screened for depression and anxiety, and asked about symptoms of thyroid disease. Caffeine and alcohol are prominent causes of sleep problems, and a careful history of the use of these substances should be obtained. Both excessive use and withdrawal from alcohol can be causes of sleep problems.

INTERVENTIONS The mainstays of any intervention include improvement of sleep hygiene (encouragement of regular time for sleep, decreased nighttime distractions, elimination of caffeine and other stimulants and alcohol), interventions to treat anxiety and depression, and treatment for the insomnia itself. For patients with depression who have insomnia and anxiety, a sedating antidepressant such as mirtazapine can be helpful. In the elderly, trazodone, beginning at 25 mg at nighttime, is an effective sleep aid at doses lower than those that cause its antidepressant effect. Zolpidem may have a decreased incidence of delirium in patients compared with traditional benzodiazepines, but this has not been clearly established. When benzodiazepines are prescribed, short-acting ones (such as lorazepam) are favored over longer-acting ones (such as diazepam). Patients who receive these medications should be observed for signs of increased confusion and delirium.

SOCIAL NEEDS AND THEIR MANAGEMENT

Financial Burdens • **FREQUENCY** Dying can impose substantial economic strains on patients and families, potentially causing distress. This is known as financial toxicity. In the United States, which has the least comprehensive health insurance systems among wealthy countries, a quarter of families coping with end-stage cancer report that care was a major financial burden and a third used up most of their savings. Among Medicare beneficiaries, average out-of-pocket costs were >$8000. Between 10% and 30% of families are forced to sell assets, use savings, or take out a mortgage to pay for the patient's health care costs.

The patient is likely to reduce hours worked and eventually stop working altogether. In 20% of cases, a family member of the terminally ill patient also must stop working to provide care. The major underlying causes of economic burden are related to poor physical functioning and care needs, such as the need for housekeeping, nursing, and personal care. More debilitated patients and poor patients experience greater economic burdens.

INTERVENTION The economic burden of end-of-life care should not be ignored as a private matter. It has been associated with a number of adverse health outcomes, including preferring comfort care over life-prolonging care, as well as consideration of euthanasia or physician-assisted suicide (PAS). Economic burdens increase the psychological distress of the families and caregivers of terminally ill patients, and poverty is associated with many adverse health outcomes. Importantly, studies have found that "patients with advanced cancer who reported having end-of-life conversations with physicians had significantly lower health care costs in their final week of life. Higher costs were associated with worse quality of death." Assistance from a social worker, early on if possible, to ensure access to all available benefits may be helpful. Many patients, families, and health care providers are unaware of options for long-term care insurance, respite care, the Family Medical Leave Act (FMLA), and other sources of assistance. Some of these options (such as respite care) may be part of a formal hospice program, but others (such as the FMLA) do not require enrollment in a hospice program.

Relationships • **FREQUENCY** Settling personal issues and closing the narrative of lived relationships are universal needs. When asked if sudden death or death after an illness is preferable, respondents often initially select the former, but soon change to the latter as they reflect on the importance of saying goodbye. Bereaved family members who have not had the chance to say goodbye often have a more difficult grief process.

INTERVENTIONS Care of seriously ill patients requires efforts to facilitate the types of encounters and time spent with family and friends that are necessary to meet those needs. Family and close friends may need to be accommodated in hospitals and other facilities with unrestricted visiting hours, which may include sleeping near the patient, even in otherwise regimented institutional settings. Physicians and other health care providers may be able to facilitate and resolve strained interactions between the patient and other family members. Assistance for patients and family members who are unsure about how to create or help preserve memories, whether by providing materials such as a scrapbook or memory box or by offering them suggestions and informational resources, can be deeply appreciated. Taking photographs and creating videos can be especially helpful to terminally ill patients who have younger children or grandchildren.

Family Caregivers • **FREQUENCY** Caring for seriously ill patients places a heavy burden on families. Families are frequently required to provide transportation and homemaking, as well as other services. Typically, paid professionals, such as home health nurses and hospice workers, supplement family care; only about a quarter of all caregiving consists of exclusively paid professional assistance. Over the past 40 years, there has been a significant decline in the United States of deaths occurring in hospitals, with a simultaneous increase in deaths in other facilities and at home. Over a third of deaths occur in patients' homes. This increase in out-of-hospital deaths increases reliance on families for end-of-life care. Increasingly, family members are being called upon to provide physical care (such as moving and bathing patients) and medical care (such as assessing symptoms and giving medications) in addition to emotional care and support.

Three-quarters of family caregivers of terminally ill patients are women—wives, daughters, sisters, and even daughters-in-law. Since many are widowed, women tend to be able to rely less on family for caregiving assistance and may need more paid assistance. About 20% of terminally ill patients report substantial unmet needs for nursing and personal care. The impact of caregiving on family caregivers is substantial: both bereaved and current caregivers have a higher mortality rate than that of non-caregiving controls.

INTERVENTIONS It is imperative to inquire about unmet needs and to try to ensure that those needs are met either through the family or by paid professional services when possible. Community assistance through houses of worship or other community groups often can be mobilized by telephone calls from the medical team to someone the patient or family identifies. Sources of support specifically for family

caregivers should be identified through local sources or nationally through groups such as the National Family Caregivers Association (*www.nfcacares.org*), the American Cancer Society (*www.cancer.org*), and the Alzheimer's Association (*www.alz.org*).

EXISTENTIAL NEEDS AND THEIR MANAGEMENT

Frequency Religion and spirituality are often important to dying patients. Nearly 70% of patients report becoming more religious or spiritual when they became terminally ill, and many find comfort in religious or spiritual practices such as prayer. However, ~20% of terminally ill patients become less religious, frequently feeling cheated or betrayed by becoming terminally ill. For other patients, the need is for existential meaning and purpose that is distinct from, and may even be antithetical to, religion or spirituality. When asked, patients and family caregivers frequently report wanting their professional caregivers to be more attentive to religion and spirituality.

Assessment Health care providers are often hesitant about involving themselves in the religious, spiritual, and existential experiences of their patients because it may seem private or not relevant to the current illness. But physicians and other members of the care team should be able at least to detect spiritual and existential needs. Screening questions have been developed for a physician's spiritual history taking. Spiritual distress can amplify other types of suffering and even masquerade as intractable physical pain, anxiety, or depression. The screening questions in the comprehensive assessment are usually sufficient. Deeper evaluation and intervention are rarely appropriate for the physician unless no other member of a care team is available or suitable. Pastoral care providers may be helpful, whether from the medical institution or from the patient's own community.

Interventions Precisely how religious practices, spirituality, and existential explorations can be facilitated and improve end-of-life care is not well established. What is clear is that for physicians, one main intervention is to inquire about the role and importance of spirituality and religion in a patient's life. This will help a patient feel heard and help physicians identify specific needs. In one study, only 36% of respondents indicated that a clergy member would be comforting. Nevertheless, the increase in religious and spiritual interest among a substantial fraction of dying patients suggests inquiring of individual patients how this need can be addressed. Some evidence supports specific methods of addressing existential needs in patients, ranging from establishing a supportive group environment for terminal patients to individual treatments emphasizing a patient's dignity and sources of meaning.

MANAGING THE LAST STAGES

PALLIATIVE CARE SERVICES: HOW AND WHERE

Determining the best approach to providing palliative care to patients will depend on patient preferences, the availability of caregivers and specialized services in close proximity, institutional resources, and reimbursement. Hospice is a leading, but not the only, model of palliative care services. In the United States, slightly more than a third—35.7%—of hospice care is provided in private residential homes with 14.5% of hospice care in nursing homes. In the United States, Medicare pays for hospice services under Part A, the hospital insurance part of reimbursement. Two physicians must certify that the patient has a prognosis of ≤6 months if the disease runs its usual course. Prognoses are probabilistic by their nature; patients are not required to die within 6 months but rather to have a condition from which half the individuals with it would not be alive within 6 months. Patients sign a hospice enrollment form that states their intent to forgo curative services related to their terminal illness but can still receive medical services for other comorbid conditions. Patients also can withdraw enrollment and reenroll later; the hospice Medicare benefit can be revoked later to secure traditional Medicare benefits. Payments to the hospice are per diem (or capitated), not fee-for-service. Payments are intended to cover physician services for the medical direction of the care team; regular home care visits by registered nurses and licensed practical nurses; home health aide and homemaker services; chaplain services; social work services; bereavement counseling; and medical equipment, supplies, and medications. No specific therapy is excluded, and the goal is for each therapy to be considered for its symptomatic (as opposed to disease-modifying) effect. Additional clinical care, including services of the primary physician, is covered by Medicare Part B even while the hospice Medicare benefit is in place.

The Affordable Care Act directs the secretary of Health and Human Services to gather data on Medicare hospice reimbursement with the goal of reforming payment rates to account for resource use over an entire episode of care. The legislation also requires additional evaluations and reviews of eligibility for hospice care by hospice physicians or nurses. The Center for Medicare and Medicaid Innovation (CMMI) sponsors and carries out demonstration projects to test models and evaluate the potential of new methods. In 2016, CMMI started a 5-year test of concurrent hospice and palliative care services with curative treatment for terminally ill patients who have a life expectancy of ≤6 months. A 4-year test initiated in 2021 will examine the inclusion of hospice in Medicare Advantage covering 8% of the market and include important health plans.

By 2018, the average length of enrollment in a hospice for Medicare beneficiaries was 90 days. However, the median length of stay was just 18 days, suggesting most patients are in hospice for a short time. Such short stays create barriers to establishing high-quality palliative services in patients' homes and also place financial strains on hospice providers since the initial assessments are resource intensive. Physicians should initiate early referrals to the hospice to allow more time for patients to receive palliative care.

In the United States, hospice care has been the main method for securing palliative services for terminally ill patients. However, leading physicians have increasingly emphasized the need to introduce palliative care much earlier in patients' illness, and efforts are being made to develop palliative care services that can be provided before the last 6 months of life and across a variety of settings. Studies of terminally ill patients indicate that those who received in-home palliative care delivered by an interdisciplinary team compared to usual care were more satisfied, more likely to die at home, and had fewer visits to the emergency room and lower per-day costs. More companies and home health agencies are now offering nonhospice palliative care services in patients' homes in an effort to increase quality of life and forestall emergency room visits and hospitalizations. Similarly, palliative care services are increasingly available via consultation, rather than being available only in hospital, day care, outpatient, and nursing home settings. Palliative care consultations for nonhospice patients can be billed as for other consultations under Medicare Part B. It is argued that using palliative care earlier in patients' illness allows patients and family members to become more acculturated to avoiding life-sustaining treatments, facilitating a smoother transition to hospice care closer to death.

WITHDRAWING AND WITHHOLDING LIFE-SUSTAINING TREATMENT

Legal Aspects For centuries, it has been deemed ethical to withhold or withdraw life-sustaining interventions. The current legal consensus in the United States and most wealthy countries is that patients have a moral as well as legal right to refuse medical interventions. American courts also have held that incompetent patients have a right to refuse medical interventions. For patients who are incompetent and terminally ill and who have not completed an advance care directive, next of kin can exercise that right, although this may be restricted in some states, depending on how clear and convincing the evidence is of the patient's preferences. Courts have limited families' ability to terminate life-sustaining treatments in patients who are conscious and incompetent but not terminally ill. In theory, patients' right to refuse medical therapy can be limited by four countervailing interests: (1) preservation of life, (2) prevention of suicide, (3) protection of third parties such as children, and (4) preservation of the integrity of the

medical profession. In practice, these interests almost never override the right of competent patients and incompetent patients who have left explicit wishes or advance care directives.

For incompetent patients who either appointed a proxy without specific indications of their wishes or never completed an advance care directive, three criteria have been suggested to guide the decision to terminate medical interventions. First, some commentators suggest that ordinary care should be administered but extraordinary care could be terminated. Because the ordinary/extraordinary distinction is too vague, courts and commentators widely agree that it should not be used to justify decisions about stopping treatment. Second, many courts have advocated the use of the substituted-judgment criterion, which holds that the proxy decision-makers should try to imagine what the incompetent patient would do if he or she were competent. However, multiple studies indicate that many proxies, even close family members, cannot accurately predict what the patient would have wanted. Therefore, substituted judgment becomes more of a guessing game than a way of fulfilling the patient's wishes. Finally, the best-interests criterion holds that proxies should evaluate treatments by balancing their benefits and risks and select those treatments where the benefits maximally outweigh the burdens of treatment. Clinicians have a clear and crucial role in this by carefully and dispassionately explaining the known benefits and burdens of specific treatments. Yet even when that information is as clear as possible, different individuals can have very different views of what is in the patient's best interests, and families may have disagreements or even overt conflicts. This criterion has been criticized because there is no single way to determine the balance between benefits and burdens; it depends on a patient's personal values. For instance, for some people, being alive even if mentally incapacitated is a benefit, whereas for others, it may be the worst possible existence. As a matter of practice, physicians rely on family members to make decisions that they feel are best and object only if those decisions seem to demand treatments that the physicians consider not beneficial.

Practices Withholding and withdrawing acutely life-sustaining medical interventions from terminally ill patients are now standard practice. More than 90% of American patients die without cardiopulmonary resuscitation (CPR), and just as many forgo other potentially life-sustaining interventions. For instance, in ICUs in the period of 1987–1988, CPR was performed 49% of the time, but it was performed only 10% of the time in 1992–1993 and on just 1.8% of admissions from 2001 to 2008. On average, 3.8 interventions, such as vasopressors and transfusions, were stopped for each dying ICU patient. However, up to 19% of decedents in hospitals received interventions such as extubation, ventilation, and surgery in the 48 h preceding death. There is wide variation in practices among hospitals and ICUs, suggesting an important element of physician preferences rather than consistent adherence to professional society recommendations.

Mechanical ventilation may be the most challenging intervention to withdraw. The two approaches are *terminal extubation*, which is the removal of the endotracheal tube, and *terminal weaning*, which is the gradual reduction of the fraction of inspired oxygen (FIO_2) or ventilator rate. One-third of ICU physicians prefer to use the terminal weaning technique, and 13% extubate; the majority of physicians utilize both techniques. The American Thoracic Society's 2008 clinical policy guidelines note that there is no single correct process of ventilator withdrawal and that physicians use and should be proficient in both methods but that the chosen approach should carefully balance benefits and burdens as well as patient and caregiver preferences. Some recommend terminal weaning because patients do not develop upper airway obstruction and the distress caused by secretions or stridor; however, terminal weaning can prolong the dying process and not allow a patient's family to be with the patient unencumbered by an endotracheal tube. To ensure comfort for conscious or semiconscious patients before withdrawal of the ventilator, neuromuscular blocking agents should be terminated and sedatives and analgesics administered. Removing the neuromuscular blocking agents permits patients to show discomfort, facilitating the titration of sedatives and analgesics; it also permits interactions between patients and their families. A common practice is to inject a bolus of midazolam (2–4 mg) or lorazepam (2–4 mg) before withdrawal, followed by a bolus of 5–10 mg of morphine and continuous infusion of morphine (50% of the bolus dose per hour) during weaning. In patients who have significant upper airway secretions, IV scopolamine at a rate of 100 μg/h can be administered. Additional boluses of morphine or increases in the infusion rate should be administered for respiratory distress or signs of pain. Higher doses will be needed for patients already receiving sedatives and opioids.

The median time to death after stopping of the ventilator is 1 h. However, up to 10% of patients unexpectedly survive for 1 day or more after mechanical ventilation is stopped. Women and older patients tend to survive longer after extubation. Families need to be reassured about both the continuations of treatments for common symptoms, such as dyspnea and agitation, after withdrawal of ventilatory support and the uncertainty of length of survival after withdrawal of ventilatory support.

FUTILE CARE

Beginning in the late 1980s, some commentators argued that physicians could terminate futile treatments demanded by the families of terminally ill patients. Although no objective definition or standard of futility exists, several categories have been proposed. Physiologic futility means that an intervention will have no physiologic effect. Some have defined qualitative futility as applying to procedures that "fail to end a patient's total dependence on intensive medical care." Quantitative futility occurs "when physicians conclude (through personal experience, experiences shared with colleagues, or consideration of reported empiric data) that in the last 100 cases, a medical treatment has been useless." The term conceals subjective value judgments about when a treatment is "not beneficial." Deciding whether a treatment that obtains an additional 6 weeks of life or a 1% survival advantage confers benefit depends on patients' preferences and goals. Furthermore, physicians' predictions of when treatments are futile deviate markedly from the quantitative definition. When residents thought CPR was quantitatively futile, more than one in five patients had a >10% chance of survival to hospital discharge. Most studies that purport to guide determinations of futility are based on insufficient data and therefore cannot provide statistical confidence for clinical decision-making. Quantitative futility rarely applies in ICU settings.

Many commentators reject using futility as a criterion for withdrawing care, preferring instead to consider futility situations as ones that represent conflict that calls for careful negotiation between families and health care providers. The American Medical Association and other professional societies have developed process-based approaches to resolving cases clinicians feel are futile. These process-based measures mainly suggest involving consultants and/or ethics committees when there are seemingly irresolvable differences. Some hospitals have enacted "unilateral do-not-resuscitate" policies to allow clinicians to provide a do-not-resuscitate order in cases in which consensus cannot be reached with families and medical opinion is that resuscitation would be futile if attempted. This type of a policy is not a replacement for careful and patient communication and negotiation but recognizes that agreement cannot always be reached.

In 1999, Texas enacted the so-called Futile Care Act. Other states, such as Virginia, Maryland, and California, have also enacted such laws that provide physicians a "safe harbor" from liability if they refuse a patient's or family's request for life-sustaining interventions. For instance, in Texas, when a disagreement about terminating interventions between the medical team and the family has not been resolved by an ethics consultation, the physician is tasked with trying to facilitate transfer of the patient to an institution willing to provide treatment. If this fails after 10 days, the hospital and physician may unilaterally withdraw treatments determined to be futile. The family may appeal to a state court. Early data suggest that the law increases futility consultations for the ethics committee and that, although most families concur with withdrawal, ~10–15% of families refuse to withdraw treatment. As of 2007, there had been 974 ethics committee consultations on medical futility cases and 65 in which committees ruled against families and gave notice that treatment would be terminated. In 2007,

a survey of Texas hospitals showed that 30% of hospitals had used the futility law in 213 adult cases and 42 pediatric cases. Treatment was withdrawn for 27 of those patients, and the remainder were transferred to other facilities or died while awaiting transfer.

EUTHANASIA AND PHYSICIAN-ASSISTED SUICIDE

Euthanasia and PAS are defined in Table 12-8. Terminating life-sustaining care and providing opioid medications to manage symptoms such as pain or dyspnea have long been considered ethical by the medical profession and legal by courts and should not be conflated with euthanasia or PAS.

Legal Aspects Euthanasia and PAS are legal in the Netherlands, Belgium, Luxembourg, Colombia, Canada, Spain, Western Australia, and New Zealand. Euthanasia was legalized in the Northern Territory of Australia in 1996, but that legislation was repealed 9 months later in 1997. Under certain conditions, a layperson in Switzerland or Germany can legally elect assisted suicide. In the United States, PAS is legal in Washington, D.C., and 10 states: Oregon, Washington State, Montana, Vermont, California, Colorado, Hawaii, Maine, New Jersey, and New Mexico. No state in the United States has legalized euthanasia. In the United States, multiple criteria must be met for PAS: the patient must have a terminal condition of <6 months and must be determined eligible through a process that includes a 15-day waiting period. In 2009, the state supreme court of Montana ruled that state law permits PAS for terminally ill patients. Many other countries, such as Portugal, are actively debating the legalization of euthanasia and/or PAS.

Practices Fewer than 10–20% of terminally ill patients actually consider euthanasia and/or PAS for themselves. Use of euthanasia and PAS is increasing but remains relatively rare. In all countries, even the Netherlands and Belgium where these practices have been tolerated and legal for many years, <5% of death occur by euthanasia or PAS. As of the most recent data, 4.7% of all deaths were by euthanasia or PAS in the Netherlands (2015) and 4.6% in Belgium (2013). Just 0.50% of all deaths in Oregon in 2019 (188 of 37,397 deaths) and 0.36% of all deaths in Washington State in 2018 (203 of 56,913 deaths) were reported to be by PAS, although these may be underestimates since the cause of some deaths of patients who received medications could not be verified.

In Belgium, the Netherlands, Oregon, and Washington, >70% of patients utilizing these interventions are dying of cancer; <10% of deaths by euthanasia or PAS involve patients with AIDS or amyotrophic lateral sclerosis. While the numbers are small, in the Netherlands, the numbers of euthanasia or PAS cases in patients with psychiatric disorders, dementia, and the accumulation of health issues are increasing.

TABLE 12-8 Definitions of Physician-Assisted Suicide and Euthanasia

TERM	DEFINITION	LEGAL STATUS
Voluntary active euthanasia	Intentionally administering medications or other interventions to cause the patient's death with the patient's informed consent	Netherlands, Belgium, Luxembourg, Canada, Colombia, Spain, Western Australia, New Zealand
Involuntary active euthanasia	Intentionally administering medications or other interventions to cause the patient's death when the patient was competent to consent but did not—e.g., the patient may not have been asked	Nowhere
Passive euthanasia	Withholding or withdrawing life-sustaining medical treatments from a patient to let him or her die (terminating life-sustaining treatments)	Everywhere
Physician-assisted suicide	A physician provides medications or other interventions to a patient with the understanding that the patient can use them to commit suicide	Netherlands, Belgium, Luxembourg, Canada, Colombia, Germany, Switzerland, Oregon, Washington, Montana, Vermont, California, Colorado, District of Columbia, Hawaii, Maine, New Jersey, New Mexico

Pain is not the primary motivator for patients' requests for or interest in euthanasia and/or PAS. Among the first patients to receive PAS in Oregon, only 1 of the 15 patients had inadequate pain control, compared with 15 of the 43 patients in a control group who experienced inadequate pain relief. About 33% of patients in Oregon seeking PAS currently cite pain or fear of pain as their main reason for doing so. Conversely, depression and hopelessness are strongly associated with patient interest in euthanasia and PAS. Concerns about loss of dignity or autonomy or being a burden on family members appear to be more important factors motivating a desire for euthanasia or PAS. Losing autonomy (87% Oregon [OR], 85% Washington [WA]), not being able to enjoy activities (90% OR, 84% WA), and fear of losing dignity (72% OR, 69% WA) are the most-cited end-of-life concerns in both states. A high percentage of patients seeking PAS note being a burden on family (59% OR, 51% WA). A study from the Netherlands showed that depressed terminally ill cancer patients were four times more likely to request euthanasia and confirmed that uncontrolled pain was not associated with greater interest in euthanasia.

Euthanasia and PAS are no guarantee of a painless, quick death. Data from the Netherlands indicate that in as many as 20% of euthanasia and PAS cases technical and other problems arose, including patients waking from coma, not becoming comatose, regurgitating medications, and experiencing a prolonged time to death. Data from Oregon between 1998 and 2017 and Washington between 2009 and 2017 indicate that of patients who received PAS prescriptions, 81% died at home and prescribers were present in 9.7% of cases. The time between drug intake and coma ranged from 1 min to 11 h, and the time from drug intake to death ranged from 1 min to 104 h. The median time from ingestion to coma was 5 min and from ingestion to death was 25 min. In Oregon between 1998 and 2015, 53% of patients had no complications, 44% of patients had no data on complications, and 2.4% of patients had regurgitation after taking the prescribed medicine as the only complication. In addition, six patients awakened. In Washington State between 2014 and 2015, 1.4% of patients had regurgitation, one patient had a seizure, and the reported range of time to death extended to 30 h. In the Netherlands, problems were significantly more common in PAS, sometimes requiring the physician to intervene and provide euthanasia.

Regardless of whether they practice in a setting where euthanasia is legal or not, many physicians over the course of their careers will receive a patient request for euthanasia or PAS. In the United States, 18% of physicians have received a request for PAS and 11% have received a request for euthanasia. Three percent complied with a request for PAS, while 5% complied with a request for euthanasia. In the Netherlands, where the practices are legal, 77% of physicians have received a request for PAS or euthanasia and 60% have performed these interventions.

Competency in dealing with such a request is crucial. Although challenging, the request can also provide a chance to address intense suffering. After receiving a request for euthanasia and/or PAS, health care providers should carefully clarify the request with empathic, open-ended questions to help elucidate the underlying cause for the request, such as, "What makes you want to consider this option?" Endorsing either moral opposition or moral support for the act tends to be counterproductive, giving an impression of being judgmental or of endorsing the idea that the patient's life is worthless. Health care providers must reassure the patient of continued care and commitment. The patient should be educated about alternative, less laden options, such as symptom management and withdrawing any unwanted treatments, and the reality of euthanasia and/or PAS, since the patient may have misconceptions about their effectiveness as well as the legal implications of the choice. Depression, hopelessness, and other symptoms of psychological distress, as well as physical suffering and economic burdens, are likely factors motivating the request, and such factors should be assessed and treated aggressively. After these interventions and clarification of options, most patients proceed with another approach,

declining life-sustaining interventions, possibly including refusal of nutrition and hydration.

CARE DURING THE LAST HOURS

Most laypersons have limited experiences with the actual dying process and death. They frequently do not know what to expect of the final hours and afterward. The family and other caregivers must be prepared, especially if the plan is for the patient to die at home.

Patients in the last days of life typically experience extreme weakness and fatigue and become bedbound; this can lead to pressure sores. The issue of turning patients who are near the end of life, however, must be balanced against the potential discomfort that movement may cause. Patients stop eating and drinking with drying of mucosal membranes and dysphagia. Careful attention to oral swabbing, lubricants for lips, and use of artificial tears can provide a form of care to substitute for attempts at feeding the patient. With loss of the gag reflex and dysphagia, patients may also experience accumulation of oral secretions, producing noises during respiration sometimes called "the death rattle." Scopolamine can reduce the secretions. Patients also experience changes in respiration with periods of apnea or Cheyne-Stokes breathing. Decreased intravascular volume and cardiac output cause tachycardia, hypotension, peripheral coolness, and livedo reticularis (skin mottling). Patients can have urinary and, less frequently, fecal incontinence. Changes in consciousness and neurologic function generally lead to two different paths to death.

Each of these terminal changes can cause patients and families distress, requiring reassurance and targeted interventions **(Table 12-9)**. Informing families that these changes might occur and providing them with an information sheet can help preempt problems and minimize distress. Understanding that patients stop eating because they are dying, not dying because they have stopped eating, can reduce family and caregiver anxiety. Similarly, informing the family and caregivers that the "death rattle" may occur and that it is not indicative of suffocation, choking, or pain can reduce their worry from the breathing sounds.

Families and caregivers may also feel guilty about stopping treatments, fearing that they are "killing" the patient. This may lead to demands for interventions, such as feeding tubes, that may be ineffective. In such cases, the physician should remind the family and caregivers about the inevitability of events and the palliative goals.

TABLE 12-9 Managing Changes in the Patient's Condition during the Final Days and Hours

CHANGES IN THE PATIENT'S CONDITION	POTENTIAL COMPLICATION	FAMILY'S POSSIBLE REACTION AND CONCERN	ADVICE AND INTERVENTION
Profound fatigue	Bedbound with development of pressure ulcers that are prone to infection, malodor, and pain, and joint pain	Patient is lazy and giving up.	Reassure family and caregivers that terminal fatigue will not respond to interventions and should not be resisted. Use an air mattress if necessary.
Anorexia	None	Patient is giving up; patient will suffer from hunger and will starve to death.	Reassure family and caregivers that the patient is not eating because he or she is dying; not eating at the end of life does not cause suffering or death. Forced feeding, whether oral, parenteral, or enteral, does not reduce symptoms or prolong life.
Dehydration	Dry mucosal membranes (see below)	Patient will suffer from thirst and die of dehydration.	Reassure family and caregivers that dehydration at the end of life does not cause suffering because patients lose consciousness before any symptom distress. Intravenous hydration can worsen symptoms of dyspnea by pulmonary edema and peripheral edema as well as prolong the dying process.
Dysphagia	Inability to swallow oral medications needed for palliative care		Do not force oral intake. Discontinue unnecessary medications that may have been continued, including antibiotics, diuretics, antidepressants, and laxatives. If swallowing pills is difficult, convert essential medications (analgesics, antiemetics, anxiolytics, and psychotropics) to oral solutions, buccal, sublingual, or rectal administration.
"Death rattle"—noisy breathing		Patient is choking and suffocating.	Reassure the family and caregivers that this is caused by secretions in the oropharynx and the patient is not choking. Reduce secretions with scopolamine (0.2–0.4 mg SC q4h or 1–3 patches q3d). Reposition patient to permit drainage of secretions. Do not suction. Suction can cause patient and family discomfort and is usually ineffective.
Apnea, Cheyne-Stokes respirations, dyspnea		Patient is suffocating.	Reassure family and caregivers that unconscious patients do not experience suffocation or air hunger. Apneic episodes are frequently a premorbid change. Opioids or anxiolytics may be used for dyspnea. Oxygen is unlikely to relieve dyspneic symptoms and may prolong the dying process.
Urinary or fecal incontinence	Skin breakdown if days until death Potential transmission of infectious agents to caregivers	Patient is dirty, malodorous, and physically repellent.	Remind family and caregivers to use universal precautions. Frequent changes of bedclothes and bedding. Use diapers, urinary catheter, or rectal tube if diarrhea or high urine output.
Agitation or delirium	Day/night reversal Hurt self or caregivers	Patient is in horrible pain and going to have a horrible death.	Reassure family and caregivers that agitation and delirium do not necessarily connote physical pain. Depending on the prognosis and goals of treatment, consider evaluating for causes of delirium and modifying medications. Manage symptoms with haloperidol, chlorpromazine, diazepam, or midazolam.
Dry mucosal membranes	Cracked lips, mouth sores, and candidiasis can also cause pain. Odor	Patient may be malodorous, physically repellent.	Use baking soda mouthwash or saliva preparation q15–30 min. Use topical nystatin for candidiasis. Coat lips and nasal mucosa with petroleum jelly q60–90 min. Use ophthalmic lubricants q4h or artificial tears q30 min.

Interventions may prolong the dying process and cause discomfort. Physicians also should emphasize that withholding treatments is both legal and ethical and that the family members are not the cause of the patient's death. This reassurance may have to be provided multiple times.

Hearing and touch are said to be the last senses to stop functioning. Whether this is the case or not, families and caregivers can be encouraged to communicate with the dying patient. Encouraging them to talk directly to the patient, even if he or she is unconscious, and hold the patient's hand or demonstrate affection in other ways can be an effective way to channel their urge "to do something" for the patient.

When the plan is for the patient to die at home, the physician must inform the family and caregivers how to determine that the patient has died. The cardinal signs are cessation of cardiac function and respiration; the pupils become fixed; the body becomes cool; muscles relax; and incontinence may occur. Remind the family and caregivers that the eyes may remain open even after the patient has died.

The physician should establish a plan for who the family or caregivers will contact when the patient is dying or has died. Without a plan, family members may panic and call 911, unleashing a cascade of unwanted events, from arrival of emergency personnel and resuscitation to hospital admission. The family and caregivers should be instructed to contact the hospice (if one is involved), the covering physician, or the on-call member of the palliative care team. They should also be told that the medical examiner need not be called unless the state requires it for all deaths. Unless foul play is suspected, the health care team need not contact the medical examiner either.

Just after the patient dies, even the best-prepared family may experience shock and loss and be emotionally distraught. They need time to assimilate the event and be comforted. Health care providers are likely to find it meaningful to write a bereavement card or letter to the family. The purpose is to communicate about the patient, perhaps emphasizing the patient's virtues and the honor it was to care for the patient, and to express concern for the family's hardship. Some physicians attend the funerals of their patients. Although this is beyond any medical obligation, the presence of the physician can be a source of support to the grieving family and provides an opportunity for closure for the physician.

Death of a spouse is a strong predictor of poor health, and even mortality, for the surviving spouse. It may be important to alert the spouse's physician about the death so that he or she is aware of symptoms that might require professional attention.

Section 1 Pain

13 Pain: Pathophysiology and Management

James P. Rathmell, Howard L. Fields

The province of medicine is to preserve and restore health and to relieve suffering. Understanding pain is essential to both of these goals. Because pain is universally understood as a signal of disease, it is the most common symptom that brings a patient to a physician's attention. The function of the pain sensory system is to protect the body and maintain homeostasis. It does this by detecting, localizing, and identifying potential or actual tissue-damaging processes. Because different diseases produce characteristic patterns of tissue damage, the quality, time course, and location of a patient's pain lend important diagnostic clues. It is the physician's responsibility to assess each patient promptly for any remediable cause underlying the pain and to provide rapid and effective pain relief whenever possible.

THE PAIN SENSORY SYSTEM

Pain is an unpleasant sensation localized to a part of the body. It is often described in terms of a penetrating or tissue-destructive process (e.g., stabbing, burning, twisting, tearing, squeezing) and/or of a bodily or emotional reaction (e.g., terrifying, nauseating, sickening). Furthermore, any pain of moderate or higher intensity is accompanied by anxiety and the urge to escape or terminate the feeling. These properties illustrate the duality of pain: it is both sensation and emotion. When it is acute, pain is characteristically associated with behavioral arousal and a stress response consisting of increased blood pressure, heart rate, pupil diameter, and plasma cortisol levels. In addition, local muscle contraction (e.g., limb flexion, abdominal wall rigidity) is often present.

PERIPHERAL MECHANISMS

The Primary Afferent Nociceptor A peripheral nerve consists of the axons of three different types of neurons: primary sensory afferents, motor neurons, and sympathetic postganglionic neurons (Fig. 13-1). The cell bodies of primary sensory afferents are located in the dorsal root ganglia within the vertebral foramina. The primary afferent axon has two branches: one projects centrally into the spinal cord and the other projects peripherally to innervate tissues. Primary afferents are classified by their diameter, degree of myelination, and conduction velocity. The largest diameter afferent fibers, A-beta (Aβ), respond maximally to light touch and/or moving stimuli; they are present primarily in nerves that innervate the skin. In normal individuals, the activity of these fibers does not produce pain. There are two other classes of primary afferent nerve fibers: the small diameter myelinated A-delta (Aδ) and the unmyelinated (C) axons (Fig. 13-1). These fibers are present in nerves to the skin and to deep somatic and visceral structures. Some tissues, such as the cornea, are innervated only by Aδ and C fiber afferents. Most Aδ and C fiber afferents respond maximally to intense (painful) stimuli and produce the subjective experience of pain when they are activated; this defines them as *primary afferent nociceptors* (*pain receptors*). The ability to detect painful stimuli is completely abolished when conduction in Aδ and C fiber axons is blocked.

Individual primary afferent nociceptors can respond to several different types of noxious stimuli. For example, most nociceptors respond to heat; intense cold; intense mechanical distortion, such as a pinch; changes in pH, particularly an acidic environment; and application of chemical irritants including adenosine triphosphate (ATP), serotonin, bradykinin (BK), and histamine. The transient receptor potential cation channel subfamily V member 1 (TrpV1), also known as the vanilloid receptor, mediates perception of some noxious stimuli, especially heat sensations, by nociceptive neurons; it is activated by heat, acidic pH, endogenous mediators, and capsaicin, a component of hot chili peppers.

Sensitization When intense, repeated, or prolonged stimuli are applied to damaged or inflamed tissues, the threshold for activating primary afferent nociceptors is lowered, and the frequency of firing is higher for all stimulus intensities. Inflammatory mediators such as BK, nerve-growth factor, some prostaglandins (PGs), and leukotrienes contribute to this process, which is called *sensitization*. Sensitization occurs at the level of the peripheral nerve terminal (*peripheral sensitization*) as well as at the level of the dorsal horn of the spinal cord (*central sensitization*). Peripheral sensitization occurs in damaged or inflamed tissues, when inflammatory mediators activate intracellular signal transduction in nociceptors, prompting an increase in the production, transport, and membrane insertion of chemically gated and voltage-gated ion channels. These changes increase the excitability of nociceptor terminals and lower their threshold for activation by mechanical, thermal, and chemical stimuli. Central sensitization occurs when activity, generated by nociceptors during inflammation, enhances the excitability of nerve cells in the dorsal horn of the spinal cord. Following injury and resultant sensitization, normally innocuous stimuli can produce pain (termed *allodynia*). Sensitization is a clinically important process that contributes to tenderness, soreness, and *hyperalgesia* (increased pain intensity in response to the same noxious stimulus; e.g., pinprick causes severe pain). A striking example of sensitization is sunburned skin, in which severe pain can be produced by a gentle slap or a warm shower.

Sensitization is of particular importance for pain and tenderness in deep tissues. Viscera are normally relatively insensitive to noxious mechanical and thermal stimuli, although hollow viscera do generate

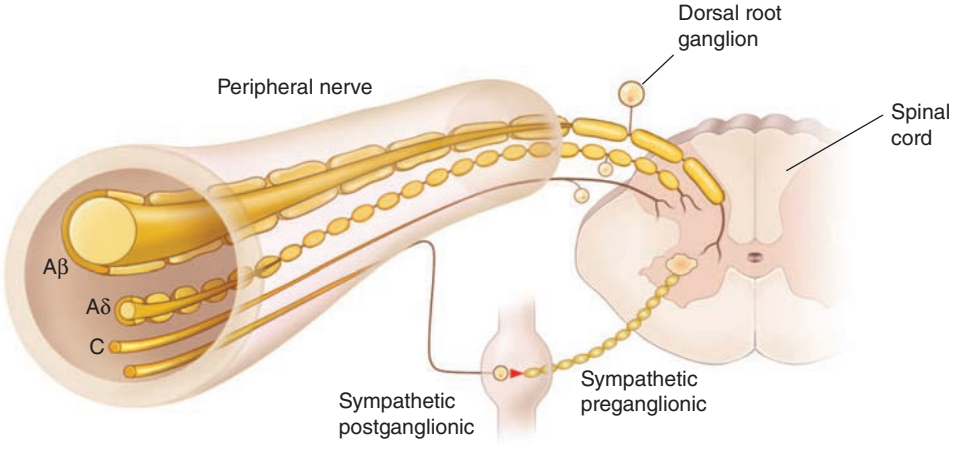

FIGURE 13-1 Components of a typical cutaneous nerve. There are two distinct functional categories of axons: primary afferents with cell bodies in the dorsal root ganglion and sympathetic postganglionic fibers with cell bodies in the sympathetic ganglion. Primary afferents include those with large-diameter myelinated (Aβ), small-diameter myelinated (Aδ), and unmyelinated (C) axons. All sympathetic postganglionic fibers are unmyelinated.

significant discomfort when distended. In contrast, when affected by a disease process with an inflammatory component, deep structures such as joints or hollow viscera characteristically become exquisitely sensitive to mechanical stimulation.

A large proportion of Aδ and C fiber afferents innervating viscera are completely insensitive in normal noninjured, noninflamed tissue. That is, they cannot be activated by known mechanical or thermal stimuli and are not spontaneously active. However, in the presence of inflammatory mediators, these afferents become sensitive to mechanical stimuli. Such afferents have been termed *silent nociceptors*, and their characteristic properties may explain how, under pathologic conditions, the relatively insensitive deep structures can become the source of severe and debilitating pain and tenderness. Low pH, PGs, leukotrienes, and other inflammatory mediators such as BK play a significant role in sensitization.

Nociceptor-Induced Inflammation Primary afferent nociceptors are not simply passive messengers of threats to tissue injury but also play an active role in tissue protection through a neuroeffector function. Most nociceptors contain polypeptide mediators, including substance P, calcitonin gene related peptide (CGRP), and cholecystokinin, that are released from their peripheral terminals when they are activated **(Fig. 13-2)**. Substance P is an 11-amino-acid peptide that is released in peripheral tissues from primary afferent nociceptors and has multiple biologic activities. It is a potent vasodilator, causes mast cell degranulation, is a chemoattractant for leukocytes, and increases the production and release of inflammatory mediators. Interestingly, depletion of substance P from joints reduces the severity of experimental arthritis.

CENTRAL MECHANISMS

The Spinal Cord and Referred Pain The axons of primary afferent nociceptors enter the spinal cord via the dorsal root. They terminate in the dorsal horn of the spinal gray matter **(Fig. 13-3)**. The terminals of primary afferent axons contact spinal neurons that transmit the pain signal to brain sites involved in pain perception. When primary afferents are activated by noxious stimuli, they release neurotransmitters from their terminals that excite the spinal cord neurons. The major neurotransmitter released is glutamate, which rapidly excites the second-order dorsal horn neurons. Primary afferent nociceptor terminals also release substance P and CGRP, which produce a slower and longer-lasting excitation of the dorsal horn neurons. The axon of each primary afferent contacts many spinal neurons, and each spinal neuron receives convergent inputs from many primary afferents.

The convergence of sensory inputs to a single spinal pain-transmission neuron is of great importance because it underlies the phenomenon of referred pain. All spinal neurons that receive input from the viscera and deep musculoskeletal structures also receive input from the skin. The convergence patterns are determined by the spinal segment of the dorsal root ganglion that supplies the afferent innervation of a structure. For example, the afferents that supply the central diaphragm are derived from the third and fourth cervical dorsal root ganglia. Primary afferents with cell bodies in these same ganglia supply the skin of the shoulder and lower neck. Thus, sensory inputs from both the shoulder skin and the central diaphragm converge on pain-transmission neurons in the third and fourth cervical spinal segments. *Because of this convergence and the fact that the spinal neurons are most often activated by inputs from the skin, activity evoked in spinal neurons by input from deep structures is often mislocalized by the patient to a bodily location that roughly corresponds with the region of skin innervated by the same spinal segment*. Thus, inflammation near the central diaphragm is often reported as shoulder discomfort. This spatial displacement of pain sensation from the site of the injury that produces it is known as *referred pain*.

Ascending Pathways for Pain A majority of spinal neurons contacted by primary afferent nociceptors send their axons to the contralateral thalamus. These axons form the contralateral spinothalamic tract, which lies in the anterolateral white matter of the spinal cord,

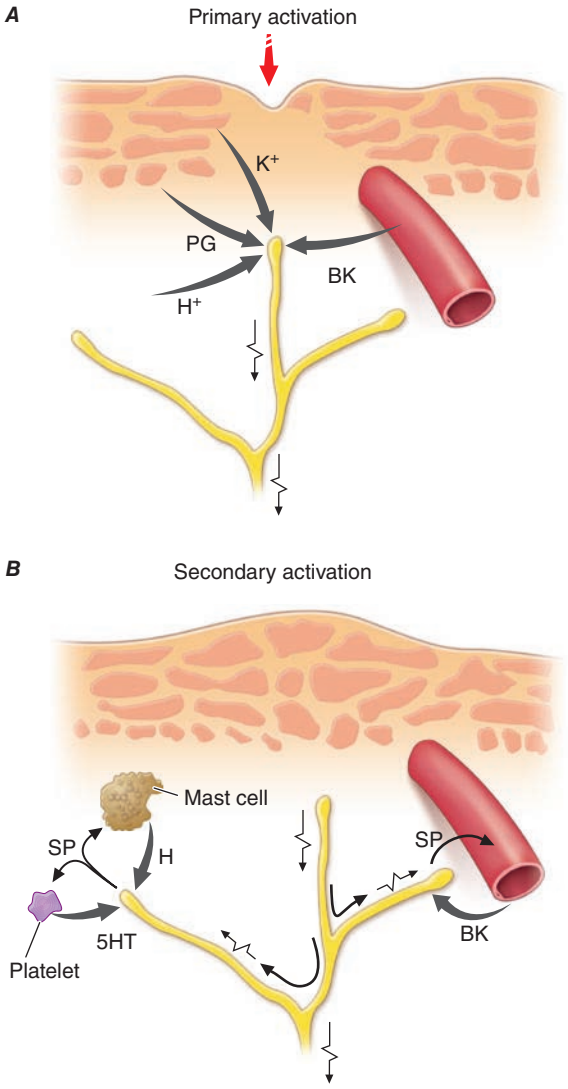

FIGURE 13-2 Events leading to activation, sensitization, and spread of sensitization of primary afferent nociceptor terminals. ***A***. Direct activation by intense pressure and consequent cell damage. Cell damage induces lower pH (H^+) and leads to release of potassium (K^+) and to synthesis of prostaglandins (PGs) and bradykinin (BK). PGs increase the sensitivity of the terminal to BK and other pain-producing substances. ***B***. Secondary activation. Impulses generated in the stimulated terminal propagate not only to the spinal cord but also into other terminal branches where they induce the release of peptides, including substance P (SP). Substance P causes vasodilation and neurogenic edema with further accumulation of BK. Substance P also causes the release of histamine (H) from mast cells and serotonin (5HT) from platelets.

the lateral edge of the medulla, and the lateral pons and midbrain. The spinothalamic pathway is crucial for pain sensation in humans. Interruption of this pathway produces permanent deficits in pain and temperature discrimination.

Spinothalamic tract axons ascend to several regions of the thalamus. There is tremendous divergence of the pain signal from these thalamic sites to several distinct areas of the cerebral cortex that subserve different aspects of the pain experience **(Fig. 13-4)**. One of the thalamic projections is to the somatosensory cortex. This projection mediates the sensory discriminative aspects of pain, i.e., its location, intensity, and quality. Other thalamic neurons project to cortical regions that are linked to emotional responses, such as the cingulate and insular cortex. These pathways to the frontal cortex subserve the affective or unpleasant emotional dimension of pain. This affective dimension of pain produces suffering and exerts potent control of behavior. Because of this dimension, fear is a constant companion of pain. As a consequence, injury or surgical lesions to areas of the frontal cortex activated by painful stimuli can diminish the emotional impact of pain while

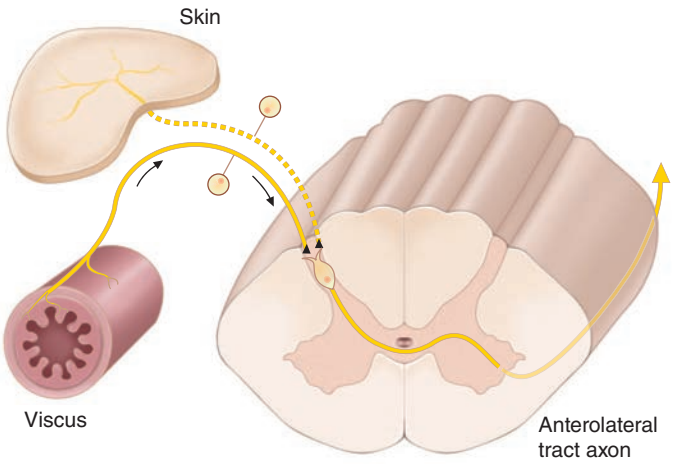

FIGURE 13-3 The convergence-projection hypothesis of referred pain. According to this hypothesis, visceral afferent nociceptors converge on the same pain-projection neurons as the afferents from the somatic structures in which the pain is perceived. The brain has no way of knowing the actual source of input and mistakenly "projects" the sensation to the somatic structure.

largely preserving the individual's ability to recognize noxious stimuli as painful.

PAIN MODULATION

The pain produced by injuries of similar magnitude is remarkably variable in different situations and in different individuals. For example, athletes have been known to sustain serious fractures with only minor pain, and Beecher's classic World War II survey revealed that many soldiers in battle were unbothered by injuries that would have produced agonizing pain in civilian patients. Furthermore, even the suggestion that a treatment will relieve pain can have a significant analgesic effect (the *placebo effect*). On the other hand, many patients find even minor injuries such as venipuncture frightening and unbearable, and the expectation of pain can induce pain even without a noxious stimulus. The suggestion that pain will worsen following administration of an inert substance can increase its perceived intensity (the *nocebo effect*).

The powerful effect of expectation and other psychological variables on the perceived intensity of pain is explained by brain circuits that modulate the activity of the pain-transmission pathways. One of these circuits has links to the hypothalamus, midbrain, and medulla, and it selectively controls spinal pain-transmission neurons through a descending pathway (Fig. 13-4).

Human brain-imaging studies have implicated this pain-modulating circuit in the pain-relieving effect of attention, suggestion, and opioid analgesic medications **(Fig. 13-5)**. Furthermore, each of the component structures of the pathway contains opioid receptors and is sensitive to the direct application of opioid drugs. In animals, lesions of this descending modulatory system reduce the analgesic effect of

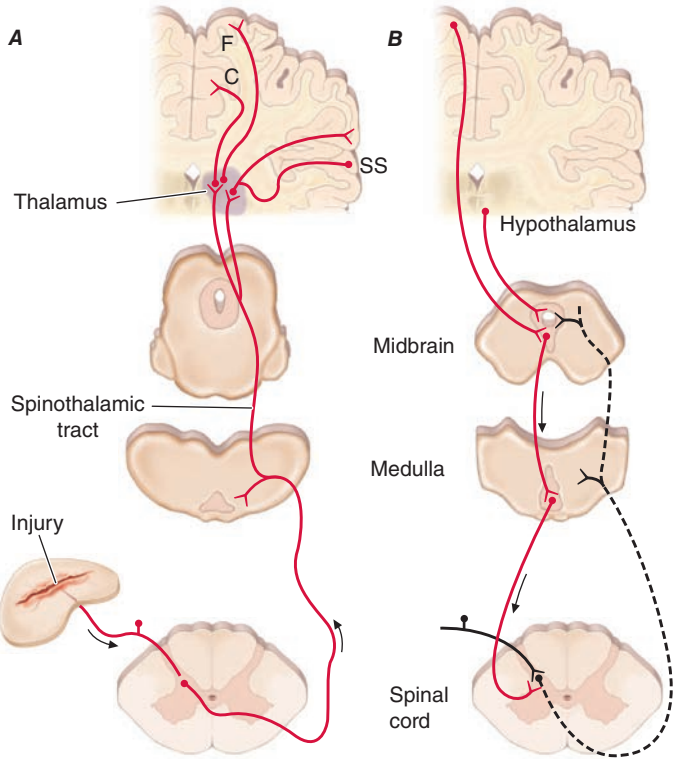

FIGURE 13-4 Pain-transmission and modulatory pathways. ***A***. Transmission system for nociceptive messages. Noxious stimuli activate the sensitive peripheral ending of the primary afferent nociceptor by the process of transduction. The message is then transmitted over the peripheral nerve to the spinal cord, where it synapses with cells of origin of the major ascending pain pathway, the spinothalamic tract. The message is relayed in the thalamus to the anterior cingulate (C), frontal insular (F), and somatosensory cortex (SS). ***B***. Pain-modulation network. Inputs from frontal cortex and hypothalamus activate cells in the midbrain that control spinal pain-transmission cells via cells in the medulla.

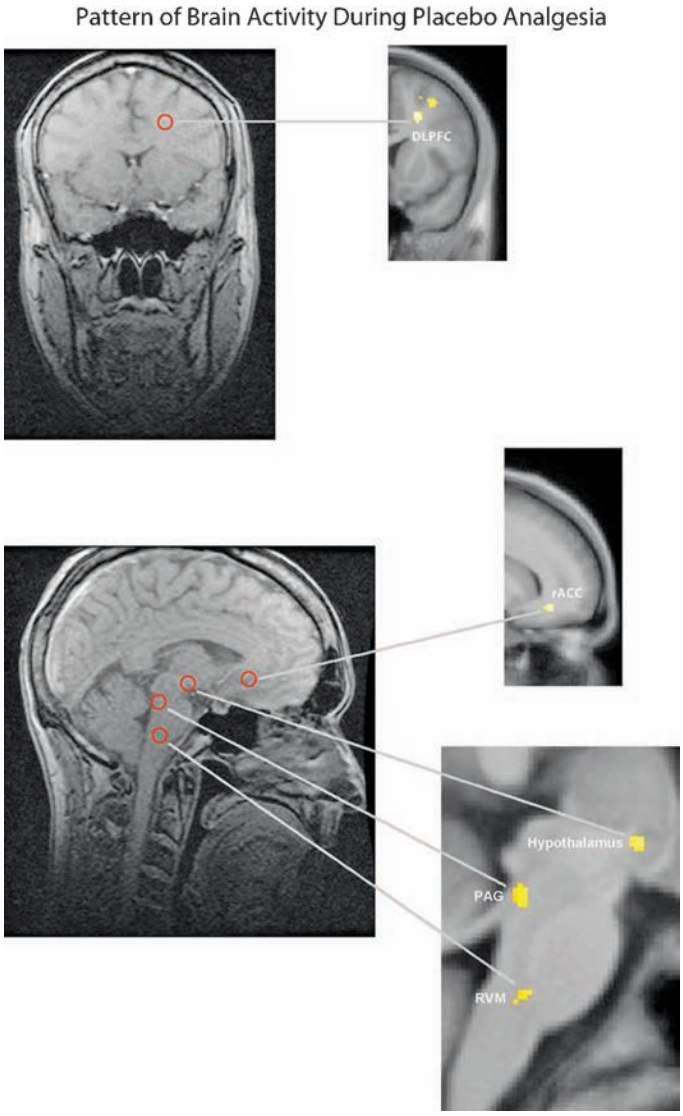

FIGURE 13-5 Functional magnetic resonance imaging (fMRI) demonstrates placebo-enhanced brain activity in anatomic regions correlating with the opioidergic descending pain control system. *Top panel:* Frontal fMRI image shows placebo-enhanced brain activity in the dorsal lateral prefrontal cortex (DLPFC). *Bottom panel:* Sagittal fMRI images show placebo-enhanced responses in the rostral anterior cingulate cortex (rACC), the rostral ventral medullae (RVM), the periaqueductal gray (PAG) area, and the hypothalamus. The placebo-enhanced activity in all areas was reduced by naloxone, demonstrating the link between the descending opioidergic system and the placebo analgesic response. *(F Eippert et al: Activation of the opioidergic descending pain control system underlies placebo analgesia. Neuron 63(4):533-543, 2009.)*

systemically administered opioids such as morphine. Along with the opioid receptor, the component nuclei of this pain-modulating circuit contain endogenous opioid peptides such as the enkephalins and β-endorphin.

The most reliable way to activate this endogenous opioid-mediated modulating system is by suggestion of pain relief or by intense emotion directed away from the pain-causing injury (e.g., during severe threat or an athletic competition). In fact, pain-relieving endogenous opioids are released following surgical procedures and in patients given a placebo for pain relief.

Pain-modulating circuits can enhance as well as suppress pain. Both pain-inhibiting and pain-facilitating neurons in the medulla project to and control spinal pain-transmission neurons. Because pain-transmission neurons can be activated by modulatory neurons, it is theoretically possible to generate a pain signal with no peripheral noxious stimulus. In fact, human functional imaging studies have demonstrated increased activity in this circuit during migraine headaches. A central circuit that facilitates pain could account for the finding that pain can be induced by suggestion or enhanced by expectation and provides a framework for understanding how psychological factors can contribute to chronic pain.

NEUROPATHIC PAIN

Lesions of the peripheral or central nociceptive pathways typically result in a loss or impairment of pain sensation. Paradoxically, damage to or dysfunction of these pathways can also produce pain. For example, damage to peripheral nerves, as occurs in diabetic neuropathy, or to primary afferents, as in herpes zoster infection, can result in pain that is referred to the body region innervated by the damaged nerves. Pain may also be produced by damage to the central nervous system (CNS), for example, in some patients following trauma or vascular injury to the spinal cord, brainstem, or thalamic areas that contain central nociceptive pathways. Such pains are termed *neuropathic* and are often severe and resistant to standard treatments for pain.

Neuropathic pain typically has an unusual burning, tingling, or electric shock-like quality and may occur spontaneously, without any stimulus, or be triggered by very light touch. These features are rare in other types of pain. On examination, a sensory deficit is characteristically co-extensive with the area of the patient's pain. *Hyperpathia*, a greatly exaggerated pain response to innocuous or mild nociceptive stimuli, especially when applied repeatedly, is also characteristic of neuropathic pain; patients often complain that the very lightest moving stimulus evokes exquisite pain (allodynia). In this regard, it is of clinical interest that a topical preparation of 5% lidocaine in patch form is effective for patients with postherpetic neuralgia who have prominent allodynia.

A variety of mechanisms contribute to neuropathic pain. As with sensitized primary afferent nociceptors, damaged primary afferents, including nociceptors, become highly sensitive to mechanical stimulation and may generate impulses in the absence of stimulation. Increased sensitivity and spontaneous activity are due, in part, to an increased density of sodium channels in the damaged nerve fiber. Damaged primary afferents may also develop sensitivity to norepinephrine. Interestingly, spinal cord pain-transmission neurons cut off from their normal input may also become spontaneously active. Thus, both central and peripheral nervous system hyperactivity contribute to neuropathic pain.

Sympathetically Maintained Pain Patients with peripheral nerve injury occasionally develop spontaneous pain in or beyond the region innervated by the nerve. This pain is often described as having a burning quality. The pain typically begins after a delay of hours to days or even weeks and is accompanied by swelling of the extremity, periarticular bone loss, and arthritic changes in the distal joints. Early in the course of the condition, the pain may be relieved by a local anesthetic block of the sympathetic innervation to the affected extremity. Damaged primary afferent nociceptors acquire adrenergic sensitivity and can be activated by stimulation of the sympathetic outflow. This constellation of spontaneous pain and signs of sympathetic dysfunction following injury has been termed *complex regional pain syndrome* (CRPS). When this occurs after an identifiable nerve injury, it is termed CRPS type II (also known as posttraumatic neuralgia or, if severe, *causalgia*). When a similar clinical picture appears without obvious nerve injury, it is termed CRPS type I (also known as *reflex sympathetic dystrophy*). CRPS can be produced by a variety of injuries, including fractures of bone, soft tissue trauma, myocardial infarction, and stroke. CRPS type I typically resolves with symptomatic treatment; however, when it persists, detailed examination often reveals evidence of peripheral nerve injury. Although the pathophysiology of CRPS is poorly understood, the pain and the signs of inflammation, when acute, can be rapidly relieved by blocking the sympathetic nervous system. This implies that sympathetic activity can activate undamaged nociceptors when inflammation is present. Signs of sympathetic hyperactivity should be sought in patients with posttraumatic pain and inflammation and no other obvious explanation.

TREATMENT

Acute Pain

The ideal treatment for any pain is to remove the cause; thus, while treatment can be initiated immediately, efforts to establish the underlying etiology should always proceed as treatment begins. Sometimes, treating the underlying condition does not immediately relieve pain. Furthermore, some conditions are so painful that rapid and effective analgesia is essential (e.g., the postoperative state, burns, trauma, cancer, or sickle cell crisis). Analgesic medications are a first line of treatment in these cases, and all practitioners should be familiar with their use.

ASPIRIN, ACETAMINOPHEN, AND NONSTEROIDAL ANTI-INFLAMMATORY AGENTS (NSAIDS)

These drugs are considered together because they are used for similar problems and may have a similar mechanism of action **(Table 13-1)**. All these compounds inhibit cyclooxygenase (COX), and except for acetaminophen, all have anti-inflammatory actions, especially at higher dosages. They are particularly effective for mild to moderate headache and for pain of musculoskeletal origin.

Because they are effective for these common types of pain and are available without prescription, COX inhibitors are by far the most commonly used analgesics. They are absorbed well from the gastrointestinal tract and, with occasional use, have only minimal side effects. With chronic use, gastric irritation is a common side effect of aspirin and NSAIDs and is the problem that most frequently limits the dose that can be given. Gastric irritation is most severe with aspirin, which may cause erosion and ulceration of the gastric mucosa leading to bleeding or perforation. Because aspirin irreversibly acetylates platelet COX and thereby interferes with coagulation of the blood, gastrointestinal bleeding is a particular risk. Older age and history of gastrointestinal disease increase the risks of aspirin and NSAIDs. In addition to the well-known gastrointestinal toxicity of NSAIDs, nephrotoxicity is a significant problem for patients using these drugs on a chronic basis. Patients at risk for renal insufficiency, particularly those with significant contraction of their intravascular volume as occurs with chronic diuretic use or acute hypovolemia, should avoid NSAIDs. NSAIDs can also increase blood pressure in some individuals. Long-term treatment with NSAIDs requires regular blood pressure monitoring and treatment if necessary. Although toxic to the liver when taken in high doses, acetaminophen rarely produces gastric irritation and does not interfere with platelet function.

The introduction of parenteral forms of NSAIDs, ketorolac and diclofenac, extends the usefulness of this class of compounds in the management of acute severe pain. Both agents are sufficiently potent and rapid in onset to supplant opioids as first-line treatment for many patients with acute severe headache and musculoskeletal pain.

There are two major classes of COX: COX-1 is constitutively expressed, and COX-2 is induced in the inflammatory state.

TABLE 13-1 Drugs for Relief of Pain

GENERIC NAME	DOSE, mg	INTERVAL	COMMENTS
Nonnarcotic Analgesics: Usual Doses and Intervals			
Acetylsalicylic acid	650 PO	q4h	Enteric-coated preparations available
Acetaminophen	650 PO	q4h	Side effects uncommon
Ibuprofen	400 PO	q4–6h	Available without prescription
Naproxen	250–500 PO	q12h	Naproxen is the common NSAID that poses the least cardiovascular risk, but it has a somewhat higher incidence of gastrointestinal bleeding
Fenoprofen	200 PO	q4–6h	Contraindicated in renal disease
Indomethacin	25–50 PO	q8h	Gastrointestinal side effects common
Ketorolac	15–60 IM/IV	q4–6h	Available for parenteral use
Celecoxib	100–200 PO	q12–24h	Useful for arthritis
Valdecoxib	10–20 PO	q12–24h	Removed from U.S. market in 2005

GENERIC NAME	PARENTERAL DOSE, mg	PO DOSE, mg	COMMENTS
Narcotic Analgesics: Usual Doses and Intervals			
Codeine	30–60 q4h	30–60 q4h	Nausea common
Oxycodone	—	5–10 q4–6h	Usually available with acetaminophen or aspirin
Oxycodone extended-release	—	10-40 q12h	Oral extended-release tablet; high potential for misuse
Morphine	5 q4h	30 q4h	
Morphine sustained release	—	15–60 bid to tid	Oral slow-release preparation
Hydromorphone	1–2 q4h	2–4 q4h	Shorter acting than morphine sulfate
Levorphanol	2 q6–8h	4 q6–8h	Longer acting than morphine sulfate; absorbed well PO
Methadone	5–10 q6–8h	5–20 q6–8h	Due to long half-life, respiratory depression and sedation may persist after analgesic effect subsides; therapy should not be initiated with >40 mg/d, and dose escalation should be made no more frequently than every 3 days
Meperidine	50–100 q3–4h	300 q4h	Poorly absorbed PO; normeperidine is a toxic metabolite; routine use of this agent is not recommended
Butorphanol	—	1–2 q4h	Intranasal spray
Fentanyl	25–100 µg/h	—	72-h transdermal patch
Buprenorphine	5–20 µg/h		7-day transdermal patch
Buprenorphine	0.3 q6–8h		Parenteral administration
Tramadol	—	50–100 q4–6h	Mixed opioid/adrenergic action

GENERIC NAME	UPTAKE BLOCKADE 5-HT	UPTAKE BLOCKADE NE	SEDATIVE POTENCY	ANTICHOLINERGIC POTENCY	ORTHOSTATIC HYPOTENSION	CARDIAC ARRHYTHMIA	AVERAGE DOSE, mg/d	RANGE, mg/d
Antidepressants[a]								
Doxepin	++	+	High	Moderate	Moderate	Less	200	75–400
Amitriptyline	++++	++	High	Highest	Moderate	Yes	150	25–300
Imipramine	++++	++	Moderate	Moderate	High	Yes	200	75–400
Nortriptyline	+++	++	Moderate	Moderate	Low	Yes	100	40–150
Desipramine	+++	++++	Low	Low	Low	Yes	150	50–300
Venlafaxine	+++	++	Low	None	None	No	150	75–400
Duloxetine	+++	+++	Low	None	None	No	40	30–60

GENERIC NAME	PO DOSE, mg	INTERVAL	COMMENTS
Anticonvulsants and Antiarrythmics[a]			
Carbamazepine	200–300	q6h	Rare aplastic anemia, GI irritation, hepatoitoxicity
Oxcarbamazepine	300	bid	Similar to carbamazepine
Gabapentin[b]	600–1200	q8h	Dizziness, GI irritation; useful in trigeminal neuralgia
Pregabalin	150–600	bid	Similar to gabapentin; dry mouth, edema

[a]Antidepressants, anticonvulsants, and antiarrhythmics have not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of pain. [b]Gabapentin in doses up to 1800 mg/d is FDA approved for postherpetic neuralgia.

Abbreviations: 5-HT, serotonin; NE, norepinephrine; NSAID, nonsteroidal anti-inflammatory agent.

COX-2-selective drugs have similar analgesic potency and produce less gastric irritation than the nonselective COX inhibitors. The use of COX-2-selective drugs does not appear to lower the risk of nephrotoxicity compared to nonselective NSAIDs. On the other hand, COX-2-selective drugs offer a significant benefit in the management of acute postoperative pain because they do not affect blood coagulation. Nonselective COX inhibitors (especially aspirin) are usually contraindicated postoperatively because they impair platelet-mediated blood clotting and are thus associated with increased bleeding at the operative site. COX-2 inhibitors, including celecoxib (Celebrex), are associated with increased cardiovascular risk, including cardiovascular death, myocardial infarction, stroke, heart failure, or a thromboembolic event. It appears that this is a class effect of NSAIDs, excluding aspirin. These drugs

are contraindicated in patients in the immediate period after coronary artery bypass surgery and should be used with caution in elderly patients and those with a history of or significant risk factors for cardiovascular disease.

OPIOID ANALGESICS

Opioids are the most potent pain-relieving drugs currently available. Of all analgesics, they have the broadest range of efficacy and provide the most reliable and effective treatment for rapid pain relief. Although side effects are common, most are reversible: nausea, vomiting, pruritus, sedation, and constipation are the most frequent and bothersome side effects. Respiratory depression is uncommon at standard analgesic doses but can be life-threatening. Opioid-related side effects can be reversed rapidly with the narcotic antagonist naloxone. Many physicians, nurses, and patients have a certain trepidation about using opioids that is based on a fear of initiating addiction in their patients. In fact, there is a very small chance of patients becoming addicted to narcotics as a result of their appropriate medical use. For chronic pain, particularly chronic noncancer pain, the risk of addiction in patients taking opioids on a chronic basis remains small, but the risk does appear to increase with dose escalation. The physician should not hesitate to use opioid analgesics in patients with acute severe pain. Table 13-1 lists the most commonly used opioid analgesics.

Opioids produce analgesia by actions in the CNS. They activate pain-inhibitory neurons and directly inhibit pain-transmission neurons. Most of the commercially available opioid analgesics act at the same opioid receptor (μ-receptor), differing mainly in potency, speed of onset, duration of action, and optimal route of administration. Some side effects are due to accumulation of nonopioid metabolites that are unique to individual drugs. One striking example of this is normeperidine, a metabolite of meperidine. At higher doses of meperidine, typically >1 g/d, accumulation of normeperidine can produce hyperexcitability and seizures that are not reversible with naloxone. Normeperidine accumulation is increased in patients with renal failure.

The most rapid pain relief is obtained by intravenous administration of opioids; relief with oral administration is significantly slower. Because of the potential for respiratory depression, patients with any form of respiratory compromise must be kept under close observation following opioid administration; an oxygen-saturation monitor may be useful, but only in a setting where the monitor is under constant surveillance. Opioid-induced respiratory depression is primarily manifest as a reduction in respiratory rate and is typically accompanied by sedation. A fall in oxygen saturation represents a critical level of respiratory depression and the need for immediate intervention to prevent life-threatening hypoxemia. Newer monitoring devices that incorporate capnography or pharyngeal air flow can detect apnea at the point of onset and should be used in hospitalized patients. Ventilatory assistance should be maintained until the opioid-induced respiratory depression has resolved. The opioid antagonist naloxone should be readily available whenever opioids are used at high doses or in patients with compromised pulmonary function. Opioid effects are dose-related, and there is great variability among patients in the doses that relieve pain and produce side effects. Synergistic respiratory depression is common when opioids are administered with other CNS depressants. Co-administration of benzodiazepines is particularly likely to produce respiratory depression and should be avoided, especially in outpatient pain management. Because of this variability in patient response, initiation of therapy requires titration to optimal dose and interval. The most important principle is to provide adequate pain relief. This requires determining whether the drug has adequately relieved the pain and timely reassessment to determine the optimal interval for dosing. *The most common error made by physicians in managing severe pain with opioids is to prescribe an inadequate dose. Because many patients are reluctant to complain, this practice leads to needless suffering*. In the absence of sedation at the expected time of peak effect, a physician should not hesitate to repeat the initial dose to achieve satisfactory pain relief.

A now standard approach to the problem of achieving adequate pain relief is the use of patient-controlled analgesia (PCA). PCA uses a microprocessor-controlled infusion device that can deliver a baseline continuous dose of an opioid drug as well as preprogrammed additional doses whenever the patient pushes a button. The patient can then titrate the dose to the optimal level. This approach is used most extensively for the management of postoperative pain, but there is no reason why it should not be used for any hospitalized patient with persistent severe pain. PCA is also used for short-term home care of patients with intractable pain, such as that caused by metastatic cancer.

It is important to understand that the PCA device delivers small, repeated doses to maintain pain relief; in patients with severe pain, the pain must first be brought under control with a loading dose before transitioning to the PCA device. The bolus dose of the drug (typically 1 mg of morphine, 0.2 mg of hydromorphone, or 10 μg of fentanyl) can then be delivered repeatedly as needed. To prevent overdosing, PCA devices are programmed with a lockout period after each demand dose is delivered (typically starting at 10 min) and a limit on the total dose delivered per hour. Although some have advocated the use of a simultaneous continuous or basal infusion of the PCA drug, this may increase the risk of respiratory depression and has not been shown to increase the overall efficacy of the technique.

The availability of new routes of administration has extended the usefulness of opioid analgesics. Most important is the availability of spinal administration. Opioids can be infused through a spinal catheter placed either intrathecally or epidurally. By applying opioids directly to the spinal or epidural space adjacent to the spinal cord, regional analgesia can be obtained using relatively low total doses. Indeed, the dose required to produce effective analgesia when using morphine intrathecally (0.1–0.3 mg) is a fraction of that required to produce similar analgesia when administered intravenously (5–10 mg). In this way, side effects such as sedation, nausea, and respiratory depression can be minimized. This approach has been used extensively during labor and delivery and for postoperative pain relief following surgical procedures. Continuous intrathecal delivery via implanted spinal drug-delivery systems is now commonly used, particularly for the treatment of cancer-related pain that would require sedating doses for adequate pain control if given systemically. Opioids can also be given intranasally (butorphanol), rectally, and transdermally (fentanyl and buprenorphine), or through the oral mucosa (fentanyl), thus avoiding the discomfort of frequent injections in patients who cannot be given oral medication. The fentanyl and buprenorphine transdermal patches have the advantage of providing fairly steady plasma levels, which may improve patient comfort.

Recent additions to the armamentarium for treating opioid-induced side effects are the peripherally acting opioid antagonists alvimopan (Entereg) and methylnaltrexone (Rellistor). Alvimopan is available as an orally administered agent that is restricted to the intestinal lumen by limited absorption; methylnaltrexone is available in a subcutaneously administered form that has virtually no penetration into the CNS. Both agents act by binding to peripheral μ-receptors, thereby inhibiting or reversing the effects of opioids at these peripheral sites. The action of both agents is restricted to receptor sites outside of the CNS; thus, these drugs can reverse the adverse effects of opioid analgesics that are mediated through their peripheral receptors without reversing their CNS-mediated analgesic effects. Alvimopan has proven effective in lowering the duration of persistent ileus following abdominal surgery in patients receiving opioid analgesics for postoperative pain control. Methylnaltrexone has proven effective for relief of opioid-induced constipation in patients taking opioid analgesics on a chronic basis.

Opioid and COX Inhibitor Combinations When used in combination, opioids and COX inhibitors have additive effects. Because a lower dose of each can be used to achieve the same degree of pain relief and their side effects are nonadditive, such combinations are used to lower the severity of dose-related side effects. However, fixed-ratio combinations of an opioid with acetaminophen carry an important risk. Dose escalation as a result of increased severity of pain or decreased opioid effect as a result of tolerance may lead to ingestion of levels of acetaminophen that are toxic to the liver. Although acetaminophen-related hepatotoxicity is uncommon, it remains a significant cause for liver failure. Thus, many practitioners have moved away from the use of opioid-acetaminophen combination analgesics to avoid the risk of excessive acetaminophen exposure as the dose of the analgesic is escalated.

CHRONIC PAIN

Managing patients with chronic pain is intellectually and emotionally challenging. Sensitization of the nervous system can occur without an obvious precipitating cause, e.g., fibromyalgia, or chronic headache. In many patients, chronic pain becomes a distinct disease unto itself. The pain-generating mechanism is often difficult or impossible to determine with certainty; such patients are demanding of the physician's time and often appear emotionally distraught. The traditional medical approach of seeking an obscure organic pathology is often unhelpful. On the other hand, psychological evaluation and behaviorally based treatment paradigms are frequently helpful, particularly in the setting of a multidisciplinary pain-management center. Unfortunately, this approach, while effective, remains largely underused in current medical practice.

There are several factors that can cause, perpetuate, or exacerbate chronic pain. First, of course, the patient may simply have a disease that is characteristically painful for which there is presently no cure. Arthritis, cancer, chronic daily headaches, fibromyalgia, and diabetic neuropathy are examples of this. Second, there may be secondary perpetuating factors that are initiated by disease and persist after that disease has resolved. Examples include damaged sensory nerves, sympathetic efferent activity, and painful reflex muscle contraction (spasm). Finally, a variety of psychological conditions can exacerbate or even cause pain.

There are certain areas to which special attention should be paid in a patient's medical history. Because depression is the most common emotional disturbance in patients with chronic pain, patients should be questioned about their mood, appetite, sleep patterns, and daily activity. A simple standardized questionnaire, such as the Beck Depression Inventory, can be a useful screening device. It is important to remember that major depression is a common, treatable, and potentially fatal illness.

Other clues that a significant emotional disturbance is contributing to a patient's chronic pain complaint include pain that occurs in multiple, unrelated sites; a pattern of recurrent, but separate, pain problems beginning in childhood or adolescence; pain beginning at a time of emotional trauma, such as the loss of a parent or spouse; a history of physical or sexual abuse; and past or present substance abuse.

On examination, special attention should be paid to whether the patient guards the painful area and whether certain movements or postures are avoided because of pain. Discovering a mechanical component to the pain can be useful both diagnostically and therapeutically. Painful areas should be examined for deep tenderness, noting whether this is localized to muscle, ligamentous structures, or joints. Chronic myofascial pain is very common, and in these patients, deep palpation may reveal highly localized trigger points that are firm bands or knots in muscle. Relief of the pain following injection of local anesthetic into these trigger points supports the diagnosis. A neuropathic component to the pain is indicated by evidence of nerve damage, such as sensory impairment, exquisitely sensitive skin (allodynia), weakness, and muscle atrophy, or loss of deep tendon reflexes. Evidence suggesting sympathetic nervous system involvement includes the presence of diffuse swelling, changes in skin color and temperature, and hypersensitive skin and joint tenderness compared with the normal side. Relief of the pain with a sympathetic block supports the diagnosis, but once the condition becomes chronic, the response to sympathetic blockade is of variable magnitude and duration; the role for repeated sympathetic blocks in the overall management of CRPS is unclear.

A guiding principle in evaluating patients with chronic pain is to assess both emotional and somatic causal and perpetuating factors before initiating therapy. Addressing these issues together, rather than waiting to address emotional issues after somatic causes of pain have been ruled out, improves compliance in part because it assures patients that a psychological evaluation does not mean that the physician is questioning the validity of their complaint. Even when a somatic cause for a patient's pain can be found, it is still wise to look for other factors. For example, a cancer patient with painful bony metastases may have additional pain due to nerve damage and may also be depressed. Optimal therapy requires that each of these factors be assessed and treated.

TREATMENT

Chronic Pain

Once the evaluation process has been completed and the likely causative and exacerbating factors identified, an explicit treatment plan should be developed. An important part of this process is to identify specific and realistic functional goals for therapy, such as getting a good night's sleep, being able to go shopping, or returning to work. A multidisciplinary approach that uses medications, counseling, physical therapy, nerve blocks, and even surgery may be required to improve the patient's quality of life. There are also some newer, minimally invasive procedures that can be helpful for some patients with intractable pain. These include image-guided interventions such as epidural injection of glucocorticoids for acute radicular pain and radiofrequency treatment of the facet joints for chronic facet-related back and neck pain. For patients with severe and persistent pain that is unresponsive to more conservative treatment, placement of electrodes on peripheral nerves or within the spinal canal on nerve roots or in the space overlying the dorsal columns of the spinal cord (spinal cord stimulation) or implantation of intrathecal drug-delivery systems has shown significant benefit. The criteria for predicting which patients will respond to these procedures continue to evolve. They are generally reserved for patients who have not responded to conventional pharmacologic approaches. Referral to a multidisciplinary pain clinic for a full evaluation should precede any invasive procedure. Such referrals are clearly not necessary for all chronic pain patients. For some, pharmacologic management alone can provide adequate relief.

ANTIDEPRESSANT MEDICATIONS

The tricyclic antidepressants (TCAs), particularly nortriptyline and desipramine (Table 13-1), are useful for the management of chronic pain. Although developed for the treatment of depression, the TCAs have a spectrum of dose-related biologic activities that include analgesia in a variety of chronic clinical conditions. Although the mechanism is unknown, the analgesic effect of TCAs has a more rapid onset and occurs at a lower dose than is typically required for the treatment of depression. Furthermore, patients with chronic pain who are not depressed obtain pain relief with antidepressants. There is evidence that TCAs potentiate opioid analgesia, so they may be useful adjuncts for the treatment of severe persistent pain such as occurs with malignant tumors. **Table 13-2** lists some of the painful conditions that respond to TCAs. TCAs are of particular value in the management of neuropathic pain such as occurs in diabetic neuropathy and postherpetic neuralgia, for which there are few other therapeutic options.

The TCAs that have been shown to relieve pain have significant side effects (Table 13-1; **Chap. 452**). Some of these side effects,

such as orthostatic hypotension, drowsiness, cardiac conduction delay, memory impairment, constipation, and urinary retention, are particularly problematic in elderly patients, and several are additive to the side effects of opioid analgesics. The selective serotonin reuptake inhibitors such as fluoxetine (Prozac) have fewer and less serious side effects than TCAs, but they are much less effective for relieving pain. It is of interest that venlafaxine (Effexor) and duloxetine (Cymbalta), which are nontricyclic antidepressants that block both serotonin and norepinephrine reuptake, appear to retain most of the pain-relieving effect of TCAs with a side effect profile more like that of the selective serotonin reuptake inhibitors. These drugs may be particularly useful in patients who cannot tolerate the side effects of TCAs.

ANTICONVULSANTS AND ANTIARRHYTHMICS

These drugs are useful primarily for patients with neuropathic pain. Phenytoin (Dilantin) and carbamazepine (Tegretol) were first shown to relieve the pain of trigeminal neuralgia **(Chap. 441)**. This pain has a characteristic brief, shooting, electric shock-like quality. In fact, anticonvulsants seem to be particularly helpful for pains that have such a lancinating quality. Newer anticonvulsants, the calcium channel alpha-2-delta subunit ligands gabapentin (Neurontin) and pregabalin (Lyrica), are effective for a broad range of neuropathic pains. Furthermore, because of their favorable side effect profile, these newer anticonvulsants are often used as first-line agents.

CANNABINOIDS

These agents are widely used for their analgesic properties, although published evidence suggests that any effects are likely to be modest, with small increases in pain threshold reported and variable reductions in clinical pain intensity. Cannabis more consistently reduces the unpleasantness of the pain experience and, in cancer-related pain, can lessen the nausea and vomiting associated with chemotherapy use. *Marijuana and related compounds are discussed in* ***Chap. 455***.

CHRONIC OPIOID MEDICATION

The long-term use of opioids is accepted for patients with pain due to malignant disease. Although opioid use for chronic pain of nonmalignant origin is controversial, it is clear that, for many patients, opioids are the only option that produces meaningful pain relief. This is understandable because opioids are the most potent and have the broadest range of efficacy of any analgesic medications. Although addiction is rare in patients who first use opioids for pain relief, some degree of tolerance and physical dependence is likely with long-term use. Furthermore, studies suggest that long-term opioid therapy may worsen pain in some individuals, termed *opioid-induced hyperalgesia*. Therefore, before embarking on opioid therapy, other options should be explored, and the limitations and risks of opioids should be explained to the patient. It is also important to point out that some opioid analgesic medications have mixed agonist-antagonist properties (e.g., butorphanol and buprenorphine). From a practical standpoint, this means that they may worsen pain by inducing an abstinence syndrome in patients who are actively being treated with other opioids and are physically dependent.

With long-term outpatient use of orally administered opioids, it may be desirable to use long-acting compounds such as levorphanol, methadone, extended-release morphine or oxycodone, or transdermal fentanyl (Table 13-1). The pharmacokinetic profiles of these drug preparations enable the maintenance of sustained analgesic blood levels, potentially minimizing side effects such as sedation that are associated with high peak plasma levels, and reducing the likelihood of rebound pain associated with a rapid fall in plasma opioid concentration. Extended-release opioid formulations are approved primarily for patients who are already taking other opioids and should not be used as first-line opioids for pain. Although long-acting opioid preparations may provide superior pain relief in patients with a continuous pattern of ongoing pain, others suffer from intermittent severe episodic pain and experience superior pain control and fewer side effects with the periodic use of short-acting opioid analgesics. Constipation is a virtually universal side effect of opioid use and should be treated expectantly. As noted earlier in the discussion of acute pain treatment, a recent advance for patients is the development of peripherally acting opioid antagonists that can reverse the constipation associated with opioid use without interfering with analgesia.

Soon after the introduction of an extended-release oxycodone formulation (OxyContin) in the late 1990s, a dramatic rise in emergency department visits and deaths associated with oxycodone ingestion appeared. This appears to be due primarily to individuals using a prescription opioid nonmedically. Drug-induced deaths have rapidly risen and are now the second leading cause of death in Americans, just behind motor vehicle fatalities. In 2011, the Office of National Drug Control Policy established a multifaceted approach to address prescription drug abuse, including prescription drug monitoring programs (PDMPs) that allow practitioners to determine if patients are receiving prescriptions from multiple providers and use of law enforcement to eliminate improper prescribing practices. In 2016, the Centers for Disease Control and Prevention (CDC) released the *CDC Guideline for Prescribing Opioids for Chronic Pain*, with recommendations for primary care clinicians who are prescribing opioids for chronic noncancer pain. A modified approach to opioid prescribing was published in 2019 by the Health and Human Services Task Force on chronic pain best medical practices. These guidelines address (1) when to initiate or continue opioids for chronic pain; (2) opioid selection, dosage, duration, follow-up, and discontinuation; and (3) assessing risk and addressing harms of opioid use. The recent increase in scrutiny leaves many practitioners hesitant to prescribe opioid analgesics, other than for brief periods to control pain associated with illness or injury. For now, the choice to begin chronic opioid therapy for a given patient is left to the individual practitioner. Pragmatic guidelines for properly selecting and monitoring patients receiving chronic opioid therapy are shown in **Table 13-3**; a checklist for primary care clinicians prescribing opioids for noncancer pain is shown in **Table 13-4**.

TREATMENT OF NEUROPATHIC PAIN

It is important to individualize treatment for patients with neuropathic pain. Several general principles should guide therapy: the first is to move quickly to provide relief, and the second is to minimize drug side effects. For example, in patients with postherpetic neuralgia and significant cutaneous hypersensitivity, topical lidocaine (Lidoderm patches) can provide immediate relief without side effects. The anticonvulsants gabapentin or pregabalin (see above) or antidepressants (nortriptyline, desipramine, duloxetine, or venlafaxine) can be used as first-line drugs for patients with neuropathic pain. Systemically administered antiarrhythmic drugs such as lidocaine and mexiletine are less likely to be effective. Although intravenous infusion of lidocaine can provide analgesia for patients with different types of neuropathic pain, the relief is usually transient,

TABLE 13-3 Guidelines for Selecting and Monitoring Patients Receiving Chronic Opioid Therapy (COT) for the Treatment of Chronic, Noncancer Pain

Patient Selection

- Conduct a history, physical examination, and appropriate testing, including an assessment of risk of substance abuse, misuse, or addiction.
- Consider a trial of COT if pain is moderate or severe, pain is having an adverse impact on function or quality of life, and potential therapeutic benefits outweigh potential harms.
- A benefit-to-harm evaluation, including a history, physical examination, and appropriate diagnostic testing, should be performed and documented before and on an ongoing basis during COT.

Informed Consent and Use of Management Plans

- Informed consent should be obtained. A continuing discussion with the patient regarding COT should include goals, expectations, potential risks, and alternatives to COT.
- Consider using a written COT management plan to document patient and clinician responsibilities and expectations and assist in patient education.

Initiation and Titration

- Initial treatment with opioids should be considered as a therapeutic trial to determine whether COT is appropriate.
- Opioid selection, initial dosing, and titration should be individualized according to the patient's health status, previous exposure to opioids, attainment of therapeutic goals, and predicted or observed harms.

Monitoring

- Reassess patients on COT periodically and as warranted by changing circumstances. Monitoring should include documentation of pain intensity and level of functioning, assessments of progress toward achieving therapeutic goals, presence of adverse events, and adherence to prescribed therapies.
- In patients on COT who are at high risk or who have engaged in aberrant drug-related behaviors, clinicians should periodically obtain urine drug screens or other information to confirm adherence to the COT plan of care.
- In patients on COT not at high risk and not known to have engaged in aberrant drug-related behaviors, clinicians should consider periodically obtaining urine drug screens or other information to confirm adherence to the COT plan of care.

TABLE 13-4 Centers for Disease Control and Prevention Checklist for Prescribing Opioids for Chronic Pain

For Primary Care Providers Treating Adults (18+) with Chronic Pain ≥3 months, Excluding Cancer, Palliative, and End-of-Life Care

CHECKLIST

WHEN CONSIDERING LONG-TERM OPIOID THERAPY

- Set realistic goals for pain and function based on diagnosis (e.g., walk around the block).
- Check that nonopioid therapies tried and optimized.
- Discuss benefits and risks (e.g., addiction, overdose) with patient.
- Evaluate risk of harm or misuse.
  - Discuss risk factors with patient.
  - Check prescription drug monitoring program (PDMP) data.
  - Check urine drug screen.
- Set criteria for stopping or continuing opioids.
- Assess baseline pain and function (e.g., Pain, Enjoyment, General Activity [PEG] scale).
- Schedule initial reassessment within 1–4 weeks.
- Prescribe short-acting opioids using lowest dosage on product labeling; match duration to scheduled reassessment.

IF RENEWING WITHOUT A PATIENT VISIT

- Check that return visit is scheduled ≤3 months from last visit.

WHEN REASSESSING AT A PATIENT VISIT

- Continue opioids only after confirming clinically meaningful improvements in pain and function without significant risks or harm.
- Assess pain and function (e.g., PEG); compare results to baseline.
- Evaluate risk of harm or misuse:
  - Observe patient for signs of oversedation or overdose risk. If yes: Taper dose.
  - Check PDMP.
  - Check for opioid use disorder if indicated (e.g., difficulty controlling use). If yes: Refer for treatment.
- Check that nonopioid therapies optimized. Determine whether to continue, adjust, taper, or stop opioids.
- Calculate opioid dosage morphine milligram equivalent (MME).
  - If ≥50 MME/day total (≥50 mg hydrocodone; ≥33 mg oxycodone), increase frequency of follow-up; consider offering naloxone.
  - Avoid ≥90 MME/day total (≥90 mg hydrocodone; ≥60 mg oxycodone), or carefully justify; consider specialist referral.
- Schedule reassessment at regular intervals (≤3 months).

typically lasting just hours after the cessation of the infusion. The oral lidocaine congener mexiletine is poorly tolerated, producing frequent gastrointestinal adverse effects. There is no consensus on which class of drug should be used as a first-line treatment for any chronically painful condition. However, because relatively high doses of anticonvulsants are required for pain relief, sedation is not uncommon. Sedation is also a problem with TCAs but is much less of a problem with serotonin/norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine and duloxetine). Thus, in the elderly or in patients whose daily activities require high-level mental activity, these drugs should be considered the first line. In contrast, opioid medications should be used as a second- or third-line drug class. Although highly effective for many painful conditions, opioids are sedating, and their effect tends to lessen over time, leading to dose escalation and, occasionally, a worsening of pain. A couple of interesting alternatives to pure opioids are two drugs with mixed opioid and norepinephrine reuptake action: tramadol and tapentadol. Tramadol is a relatively weak opioid but is sometimes effective for pain unresponsive to nonopioid analgesics. Tapentadol is a stronger opioid, but its analgesic action is apparently enhanced by the norepinephrine reuptake blockade. Similarly, drugs of different classes can be used in combination to optimize pain control. Repeated injection of botulinum toxin is an emerging approach that is showing some promise in treating focal neuropathic pain, particularly post-herpetic, trigeminal, and post-traumatic neuralgias.

It is worth emphasizing that many patients, especially those with chronic pain, seek medical attention primarily because they are suffering and because only physicians can provide the medications required for pain relief. A primary responsibility of all physicians is to minimize the physical and emotional discomfort of their patients. Familiarity with pain mechanisms and analgesic medications is an important step toward accomplishing this aim.

14 Chest Discomfort

David A. Morrow

Chest discomfort is among the most common reasons for which patients present for medical attention at either an emergency department (ED) or an outpatient clinic. The evaluation of nontraumatic chest discomfort is inherently challenging owing to the broad variety of possible causes, a minority of which are life-threatening conditions that should not be missed. It is helpful to frame the initial diagnostic assessment and triage of patients with acute chest discomfort around three categories: (1) myocardial ischemia; (2) other cardiopulmonary causes (myopericardial disease, aortic emergencies, and pulmonary conditions); and (3) noncardiopulmonary causes. Although rapid identification of high-risk conditions is a priority of the initial assessment, strategies that incorporate routine liberal use of testing carry the potential for adverse effects of unnecessary investigations.

EPIDEMIOLOGY AND NATURAL HISTORY

Chest discomfort is one of the three most common reason for visits to the ED in the United States, resulting in 6 to 7 million emergency visits each year. More than 60% of patients with this presentation are hospitalized for further testing, and most of the remainder undergo additional investigation in the ED. Fewer than 15% of evaluated patients are eventually diagnosed with acute coronary syndrome (ACS), with rates of 10–20% in most series of unselected populations, and a rate as low as 5% in some studies. The most common diagnoses are gastrointestinal causes **(Fig. 14-1)**, and as few as 5% are other life-threatening cardiopulmonary conditions. In a large proportion of patients with transient acute chest discomfort, ACS or another acute cardiopulmonary cause is excluded but the cause is not determined. Therefore, the resources and time devoted to the evaluation of chest discomfort *in the absence of a severe cause* are substantial. Nevertheless, historically, a disconcerting 2–6% of patients with chest discomfort of presumed nonischemic etiology who are discharged from the ED were later deemed to have had a missed myocardial infarction (MI). Patients with a missed diagnosis of MI have a 30-day risk of death that is double that of their counterparts who are hospitalized.

The natural histories of ACS, myocarditis, acute pericardial diseases, pulmonary embolism, and aortic emergencies are discussed in **Chaps. 270, 273, 274, 275, 279, and 280**, respectively. In a study of more than 350,000 patients with unspecified presumed noncardiopulmonary chest discomfort, the mortality rate 1 year after discharge was <2% and did not differ significantly from age-adjusted mortality in the general population. The estimated rate of major cardiovascular events through 30 days in patients with acute chest pain who had been stratified as low risk was 2.5% in a large population-based study that excluded patients with ST-segment elevation or definite noncardiac chest pain.

CAUSES OF CHEST DISCOMFORT

The major etiologies of chest discomfort are discussed in this section and summarized in **Table 14-1**. Additional elements of the history, physical examination, and diagnostic testing that aid in distinguishing these causes are discussed in a later section (see "Approach to the Patient").

MYOCARDIAL ISCHEMIA/INJURY

Myocardial ischemia causing chest discomfort, termed *angina pectoris*, is a primary clinical concern in patients presenting with chest symptoms. Myocardial ischemia is precipitated by an imbalance between myocardial oxygen requirements and myocardial oxygen supply, resulting in insufficient delivery of oxygen to meet the heart's metabolic demands. Myocardial oxygen consumption may be elevated by increases in heart rate, ventricular wall stress, and myocardial contractility, whereas myocardial oxygen supply is determined by coronary blood flow and coronary arterial oxygen content. When myocardial ischemia is sufficiently severe and prolonged in duration (as little as 20 min), irreversible cellular injury occurs, resulting in MI.

Ischemic heart disease is most commonly caused by atheromatous plaque that obstructs one or more of the epicardial coronary arteries. Stable ischemic heart disease **(Chap. 273)** usually results from the gradual atherosclerotic narrowing of the coronary arteries. *Stable angina* is characterized by ischemic episodes that are typically precipitated by a superimposed increase in oxygen demand during physical exertion and relieved upon resting. Ischemic heart disease becomes unstable, manifest by ischemia at rest or with an escalating pattern, most commonly when rupture or erosion of one or more atherosclerotic lesions triggers coronary thrombosis. Unstable ischemic heart disease is further classified clinically by the presence or absence of detectable acute myocardial injury and the presence or absence of ST-segment elevation on the patient's electrocardiogram (ECG). When acute coronary atherothrombosis occurs, the intracoronary thrombus may be partially obstructive, generally leading to myocardial ischemia in the absence of ST-segment elevation. Unstable ischemic heart disease is classified as *unstable angina* when there is no detectable acute myocardial injury and as *non–ST elevation MI* (NSTEMI) when there is evidence of acute myocardial necrosis **(Chap. 274)**. When the coronary thrombus is acutely and completely occlusive, transmural myocardial ischemia usually ensues, with ST-segment elevation on the ECG and myocardial necrosis leading to a diagnosis of *ST elevation MI* (STEMI; see **Chap. 275**).

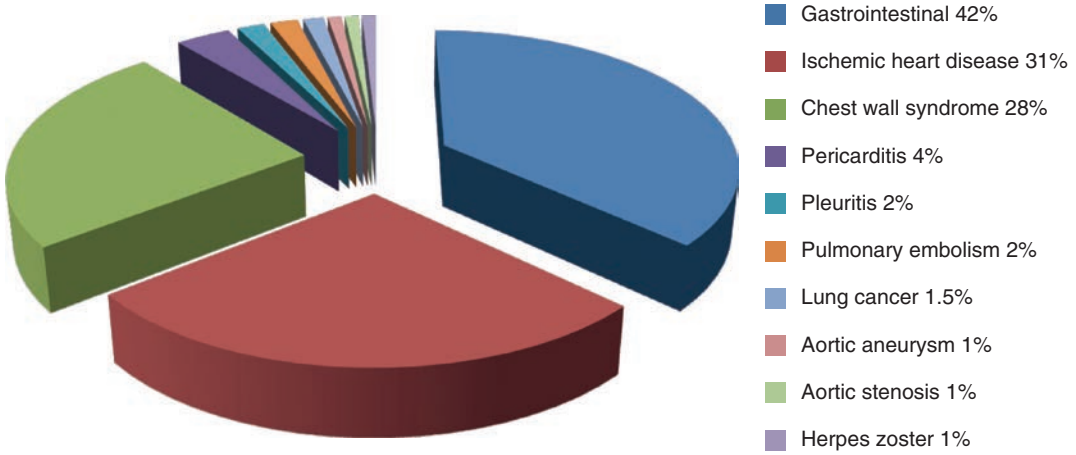

FIGURE 14-1 Distribution of final discharge diagnoses in patients with nontraumatic acute chest pain. *(Figure prepared from data in P Fruergaard et al: Eur Heart J 17:1028, 1996.)*

TABLE 14-1 Typical Clinical Features of Major Causes of Acute Chest Discomfort

SYSTEM	CONDITION	ONSET/DURATION	QUALITY	LOCATION	ASSOCIATED FEATURES
Cardiopulmonary					
Cardiac	Myocardial ischemia	*Stable angina:* Precipitated by exertion, cold, or stress; 2–10 min *Unstable angina:* Increasing pattern or at rest *Myocardial infarction:* Usually >30 min	Pressure, tightness, squeezing, heaviness, burning	Retrosternal; often radiation to neck, jaw, shoulders, or arms; sometimes epigastric	S_4 gallop or mitral regurgitation murmur (rare) during pain; S_3 or rales if severe ischemia or complication of myocardial infarction
	Pericarditis	Variable; hours to days; may be episodic	Pleuritic, sharp	Retrosternal or toward cardiac apex; may radiate to left shoulder	May be relieved by sitting up and leaning forward; pericardial friction rub
Vascular	Acute aortic syndrome	Sudden onset of unrelenting pain	Tearing or ripping; knifelike	Anterior chest, often radiating to back, between shoulder blades	Associated with hypertension and/or underlying connective tissue disorder; murmur of aortic insufficiency; loss of peripheral pulses
	Pulmonary embolism	Sudden onset	Pleuritic; may manifest as heaviness with massive pulmonary embolism	Often lateral, on the side of the embolism	Dyspnea, tachypnea, tachycardia, and hypotension
	Pulmonary hypertension	Variable; often exertional	Pressure	Substernal	Dyspnea, signs of increased venous pressure
Pulmonary	Pneumonia or pleuritis	Variable	Pleuritic	Unilateral, often localized	Dyspnea, cough, fever, rales, occasional rub
	Spontaneous pneumothorax	Sudden onset	Pleuritic	Lateral to side of pneumothorax	Dyspnea, decreased breath sounds on side of pneumothorax
Noncardiopulmonary					
Gastrointestinal	Esophageal reflux	10–60 min	Burning	Substernal, epigastric	Worsened by postprandial recumbency; relieved by antacids
	Esophageal spasm	2–30 min	Pressure, tightness, burning	Retrosternal	Can closely mimic angina
	Peptic ulcer	Prolonged; 60–90 min after meals	Burning	Epigastric, substernal	Relieved with food or antacids
	Gallbladder disease	Prolonged	Aching or colicky	Epigastric, right upper quadrant; sometimes to the back	May follow meal
Neuromuscular	Costochondritis	Variable	Aching	Sternal	Sometimes swollen, tender, warm over joint; may be reproduced by localized pressure on examination
	Cervical disk disease	Variable; may be sudden	Aching; may include numbness	Arms and shoulders	May be exacerbated by movement of neck
	Trauma or strain	Usually constant	Aching	Localized to area of strain	Reproduced by movement or palpation
	Herpes zoster	Usually prolonged	Sharp or burning	Dermatomal distribution	Vesicular rash in area of discomfort
Psychological	Emotional and psychiatric conditions	Variable; may be fleeting or prolonged	Variable; often manifests as tightness and dyspnea with feeling of panic or doom	Variable; may be retrosternal	Situational factors may precipitate symptoms; history of panic attacks, depression

Clinicians should be aware that unstable ischemic symptoms may also occur predominantly because of increased myocardial oxygen demand (e.g., during intense psychological stress or fever) or because of decreased oxygen delivery due to anemia, hypoxia, or hypotension. However, the term *acute coronary syndrome*, which encompasses unstable angina, NSTEMI, and STEMI, is in general reserved for ischemia precipitated by acute coronary atherothrombosis. In order to guide therapeutic strategies, a standardized system for classification of MI has been expanded to discriminate MI resulting from acute coronary thrombosis (type 1 MI) from MI occurring secondary to other imbalances of myocardial oxygen supply and demand (type 2 MI; see **Chap. 274**). These conditions are additionally distinguished from nonischemic causes of acute myocardial injury, such as myocarditis.

Other contributors to stable and unstable ischemic heart disease, such as endothelial dysfunction, microvascular disease, and vasospasm, may exist alone or in combination with coronary atherosclerosis and may be the dominant cause of myocardial ischemia in some patients. Moreover, nonatherosclerotic processes, including congenital abnormalities of the coronary vessels, myocardial bridging, coronary arteritis, and radiation-induced coronary disease, can lead to coronary obstruction. In addition, conditions associated with extreme myocardial oxygen demand and impaired endocardial blood flow, such as aortic valve disease **(Chap. 280)**, hypertrophic cardiomyopathy, or idiopathic dilated cardiomyopathy **(Chap. 259)**, can precipitate myocardial ischemia in patients with or without underlying obstructive atherosclerosis.

Characteristics of Ischemic Chest Discomfort The clinical characteristics of angina pectoris, often referred to simply as "angina," are highly similar whether the ischemic discomfort is a manifestation of stable ischemic heart disease, unstable angina, or MI; the exceptions are differences in the pattern and duration of symptoms associated with these syndromes (Table 14-1). Heberden initially described angina as a sense of "strangling and anxiety." Chest discomfort characteristic of myocardial ischemia is typically described as aching, heavy, squeezing, crushing, or constricting. However, in a substantial minority of patients, the quality of discomfort is extremely vague and may be described as a mild tightness, or merely an uncomfortable feeling, that sometimes is experienced as numbness or a burning sensation. The site of the discomfort is usually retrosternal, but radiation is common and generally occurs down the ulnar surface of the left arm; the right arm, both arms, neck, jaw, or shoulders may also be involved. These and other characteristics of ischemic chest discomfort pertinent to discrimination from other causes of chest pain are discussed later in this chapter (see "Approach to the Patient").

Stable angina usually begins gradually and reaches its maximal intensity over a period of minutes before dissipating within several minutes with rest or with nitroglycerin. The discomfort typically occurs predictably at a characteristic level of exertion or psychological stress. By definition, unstable angina is manifest by anginal chest discomfort that occurs with progressively lower intensity of physical activity or even at rest. Chest discomfort associated with MI is commonly more severe, is prolonged (usually lasting ≥30 min), and is not relieved by rest.

Mechanisms of Cardiac Pain The neural pathways involved in ischemic cardiac pain are poorly understood. Ischemic episodes are thought to excite local chemosensitive and mechanoreceptive receptors that, in turn, stimulate release of adenosine, bradykinin, and other substances that activate the sensory ends of sympathetic and vagal afferent fibers. The afferent fibers traverse the nerves that connect to the upper five thoracic sympathetic ganglia and upper five distal thoracic roots of the spinal cord. From there, impulses are transmitted to the thalamus. Within the spinal cord, cardiac sympathetic afferent impulses may converge with impulses from somatic thoracic structures, and this convergence may be the basis for referred cardiac pain. In addition, cardiac vagal afferent fibers synapse in the nucleus tractus solitarius of the medulla and then descend to the upper cervical spinothalamic tract, and this route may contribute to anginal pain experienced in the neck and jaw.

OTHER CARDIOPULMONARY CAUSES

Pericardial and Other Myocardial Diseases (See also Chap. 270) Inflammation of the pericardium due to infectious or noninfectious causes can be responsible for acute or chronic chest discomfort. The visceral surface and most of the parietal surface of the pericardium are insensitive to pain. Therefore, the pain of pericarditis is thought to arise principally from associated pleural inflammation. Because of this pleural association, the discomfort of pericarditis is usually pleuritic pain that is exacerbated by breathing, coughing, or changes in position. Moreover, owing to the overlapping sensory supply of the central diaphragm via the phrenic nerve with somatic sensory fibers originating in the third to fifth cervical segments, the pain of pleural and pericardial inflammation is often referred to the shoulder and neck. Involvement of the pleural surface of the lateral diaphragm can lead to pain in the upper abdomen.

Acute inflammatory and other nonischemic myocardial diseases can also produce chest discomfort. The symptoms of acute myocarditis are highly varied. Chest discomfort may either originate with inflammatory injury of the myocardium or be due to severe increases in wall stress related to poor ventricular performance. The symptoms of *Takotsubo (stress-related) cardiomyopathy* often start abruptly with chest pain and shortness of breath. This form of cardiomyopathy, in its most recognizable form, is triggered by an emotionally or physically stressful event and may mimic acute MI because of its commonly associated ECG abnormalities, including ST-segment elevation, and elevated biomarkers of myocardial injury. Observational studies support a predilection for women >50 years of age.

Diseases of the Aorta (See also Chap. 280) Acute aortic dissection (Fig. 14-1) is a less common cause of chest discomfort but is important because of the catastrophic natural history of certain subsets of cases when recognized late or left untreated. Acute aortic syndromes encompass a spectrum of acute aortic diseases related to disruption of the media of the aortic wall. *Aortic dissection* involves a tear in the aortic intima, resulting in separation of the media and creation of a separate "false" lumen. A *penetrating ulcer* has been described as ulceration of an aortic atheromatous plaque that extends through the intima and into the aortic media, with the potential to initiate an intramedial dissection or rupture into the adventitia. *Intramural hematoma* is an aortic wall hematoma with no demonstrable intimal flap, no radiologically apparent intimal tear, and no false lumen. Intramural hematoma can occur due to either rupture of the vasa vasorum or, less commonly, a penetrating ulcer.

Each of these subtypes of acute aortic syndrome typically presents with chest discomfort that is often severe, sudden in onset, and sometimes described as "tearing" in quality. Acute aortic syndromes involving the *ascending* aorta tend to cause pain in the midline of the anterior chest, whereas *descending* aortic syndromes most often present with pain in the back. Therefore, dissections that begin in the ascending aorta and extend to the descending aorta tend to cause pain in the front of the chest that extends toward the back, between the shoulder blades. Proximal aortic dissections that involve the ascending aorta (type A in the Stanford nomenclature) are at high risk for major complications that may influence the clinical presentation, including (1) compromise of the aortic ostia of the coronary arteries, resulting in MI; (2) disruption of the aortic valve, causing acute aortic insufficiency; and (3) rupture of the hematoma into the pericardial space, leading to pericardial tamponade.

Knowledge of the epidemiology of acute aortic syndromes can be helpful in maintaining awareness of this relatively uncommon group of disorders (estimated annual incidence, 3 cases per 100,000 population). Nontraumatic aortic dissections are very rare in the absence of hypertension or conditions associated with deterioration of the elastic or muscular components of the aortic media, including pregnancy, bicuspid aortic disease, or inherited connective tissue diseases, such as Marfan and Ehlers-Danlos syndromes.

Although aortic aneurysms are most often asymptomatic, thoracic aortic aneurysms can cause chest pain and other symptoms by compressing adjacent structures. This pain tends to be steady, deep, and occasionally severe. Aortitis, whether of noninfectious or infectious etiology, in the absence of aortic dissection is a rare cause of chest or back discomfort.

Pulmonary Conditions Pulmonary and pulmonary-vascular conditions that cause chest discomfort usually do so in conjunction with dyspnea and often produce symptoms that have a pleuritic nature.

PULMONARY EMBOLISM (SEE ALSO CHAP. 279) Pulmonary emboli (annual incidence, ~1 per 1000) can produce dyspnea and chest discomfort that is sudden in onset. Typically pleuritic in pattern, the chest discomfort associated with pulmonary embolism may result from (1) involvement of the pleural surface of the lung adjacent to a resultant pulmonary infarction; (2) distention of the pulmonary artery; or (3) possibly, right ventricular wall stress and/or subendocardial ischemia related to acute pulmonary hypertension. The pain associated with small pulmonary emboli is often lateral and pleuritic and is believed to be related to the first of these three possible mechanisms. In contrast, massive pulmonary emboli may cause severe substernal pain that may mimic an MI and that is plausibly attributed to the second and third of these potential mechanisms. Massive or submassive pulmonary embolism may also be associated with syncope, hypotension, and signs of right heart failure. Other typical characteristics that aid in the recognition of pulmonary embolism are discussed later in this chapter (see "Approach to the Patient").

PNEUMOTHORAX (SEE ALSO CHAP. 294) *Primary spontaneous pneumothorax* is a rare cause of chest discomfort, with an estimated annual incidence in the United States of 7 per 100,000 among men and <2 per 100,000 among women. Risk factors include male sex, smoking, family history, and Marfan syndrome. The symptoms are usually sudden in onset, and dyspnea may be mild; thus, presentation to medical attention is sometimes delayed. *Secondary spontaneous pneumothorax* may occur in patients with underlying lung disorders, such as chronic obstructive pulmonary disease, asthma, or cystic fibrosis, and usually produces symptoms that are more severe. Tension pneumothorax is a medical emergency caused by trapped intrathoracic air that precipitates hemodynamic collapse.

Other Pulmonary Parenchymal, Pleural, or Vascular Disease (See also Chaps. 283, 284, and 294) Most pulmonary diseases that produce chest pain, including pneumonia and malignancy, do so because of involvement of the pleura or surrounding structures. Pleurisy is typically described as a knifelike pain that is worsened by inspiration or coughing. In contrast, chronic pulmonary hypertension can manifest as chest pain that may be very similar to angina in its characteristics, suggesting right ventricular myocardial ischemia in some cases. Reactive airways diseases similarly can cause chest tightness associated with breathlessness rather than pleurisy.

NONCARDIOPULMONARY CAUSES

Gastrointestinal Conditions (See also Chap. 321) Gastrointestinal disorders are the most common cause of nontraumatic chest discomfort and often produce symptoms that are difficult to discern from more serious causes of chest pain, including myocardial ischemia. Esophageal disorders, in particular, may simulate angina in the character and location of the pain. Gastroesophageal reflux and disorders of esophageal motility are common and should be considered in the differential diagnosis of chest pain (Fig. 14-1 and Table 14-1). The pain of esophageal spasm is commonly an intense, squeezing discomfort that is retrosternal in location and, like angina, may be relieved by nitroglycerin or dihydropyridine calcium channel antagonists. Chest pain can also result from injury to the esophagus, such as a Mallory-Weiss tear or even an esophageal rupture (Boerhaave's syndrome) caused by severe vomiting. Peptic ulcer disease is most commonly epigastric in location but can radiate into the chest (Table 14-1).

Hepatobiliary disorders, including cholecystitis and biliary colic, may mimic acute cardiopulmonary diseases. Although the pain arising from these disorders usually localizes to the right upper quadrant of the abdomen, it is variable and may be felt in the epigastrium and radiate to the back and lower chest. This discomfort is sometimes referred to the scapula or may in rare cases be felt in the shoulder, suggesting diaphragmatic irritation. The pain is steady, usually lasts several hours, and subsides spontaneously, without symptoms between attacks. Pain resulting from pancreatitis is typically aching epigastric pain that radiates to the back.

Musculoskeletal and Other Causes (See also Chap. 360) Chest discomfort can be produced by any musculoskeletal disorder involving the chest wall or the nerves of the chest wall, neck, or upper limbs. Costochondritis causing tenderness of the costochondral junctions (*Tietze's syndrome*) is relatively common. Cervical radiculitis may manifest as a prolonged or constant aching discomfort in the upper chest and limbs. The pain may be exacerbated by motion of the neck. Occasionally, chest pain can be caused by compression of the brachial plexus by the cervical ribs, and tendinitis or bursitis involving the left shoulder may mimic the radiation of angina. Pain in a dermatomal distribution can also be caused by cramping of intercostal muscles or by herpes zoster (Chap. 193).

Emotional and Psychiatric Conditions As many as 10% of patients who present to EDs with acute chest discomfort have a panic disorder or related condition (Table 14-1). The symptoms may include chest tightness or aching that is associated with a sense of anxiety and difficulty breathing. The symptoms may be prolonged or fleeting.

APPROACH TO THE PATIENT

Chest Discomfort

Given the broad set of potential causes and the heterogeneous risk of serious complications in patients who present with acute nontraumatic chest discomfort, the priorities of the initial clinical encounter include assessment of (1) the patient's clinical stability and (2) the probability that the patient has an underlying cause of the discomfort that may be life-threatening. The high-risk conditions of principal concern are acute cardiopulmonary processes, including ACS, acute aortic syndrome, pulmonary embolism, tension pneumothorax, and pericarditis with tamponade. Fulminant myocarditis also carries a poor prognosis but is usually also manifest by heart failure symptoms. Among noncardiopulmonary causes of chest pain, esophageal rupture likely holds the greatest urgency for diagnosis. Patients with these conditions may deteriorate rapidly despite initially appearing well. The remaining population with noncardiopulmonary conditions has a more favorable prognosis during completion of the diagnostic workup. A rapid targeted assessment for a serious cardiopulmonary cause is of particular relevance for patients with acute ongoing pain who have presented for emergency evaluation. Among patients presenting in the outpatient setting with chronic pain or pain that has resolved, a general diagnostic assessment is reasonably undertaken (see "Outpatient Evaluation of Chest Discomfort," below). A series of questions that can be used to structure the clinical evaluation of patients with chest discomfort is shown in Table 14-2.

HISTORY

The evaluation of nontraumatic chest discomfort relies heavily on the clinical history and physical examination to direct subsequent diagnostic testing. The evaluating clinician should assess the quality, location (including radiation), and pattern (including onset and duration) of the pain as well as any provoking or alleviating factors. The presence of associated symptoms may also be useful in establishing a diagnosis.

Quality of Pain The quality of chest discomfort alone is never sufficient to establish a diagnosis. However, the characteristics of the pain are pivotal in formulating an initial clinical impression and assessing the likelihood of a serious cardiopulmonary process

TABLE 14-2 Considerations in the Assessment of the Patient with Chest Discomfort

1. Could the chest discomfort be due to an acute, potentially life-threatening condition that warrants urgent evaluation and management?			
Unstable ischemic heart disease	Aortic dissection	Pneumothorax	Pulmonary embolism
2. If not, could the discomfort be due to a chronic condition likely to lead to serious complications?			
Stable angina	Aortic stenosis	Pulmonary hypertension	
3. If not, could the discomfort be due to an acute condition that warrants specific treatment?			
Pericarditis	Pneumonia/ pleuritis	Herpes zoster	
4. If not, could the discomfort be due to another treatable chronic condition?			
Esophageal reflux		Cervical disk disease	
Esophageal spasm		Arthritis of the shoulder or spine	
Peptic ulcer disease		Costochondritis	
Gallbladder disease		Other musculoskeletal disorders	
Other gastrointestinal conditions		Anxiety state	

Source: Developed by Dr. Thomas H. Lee for the 18th edition of *Harrison's Principles of Internal Medicine.*

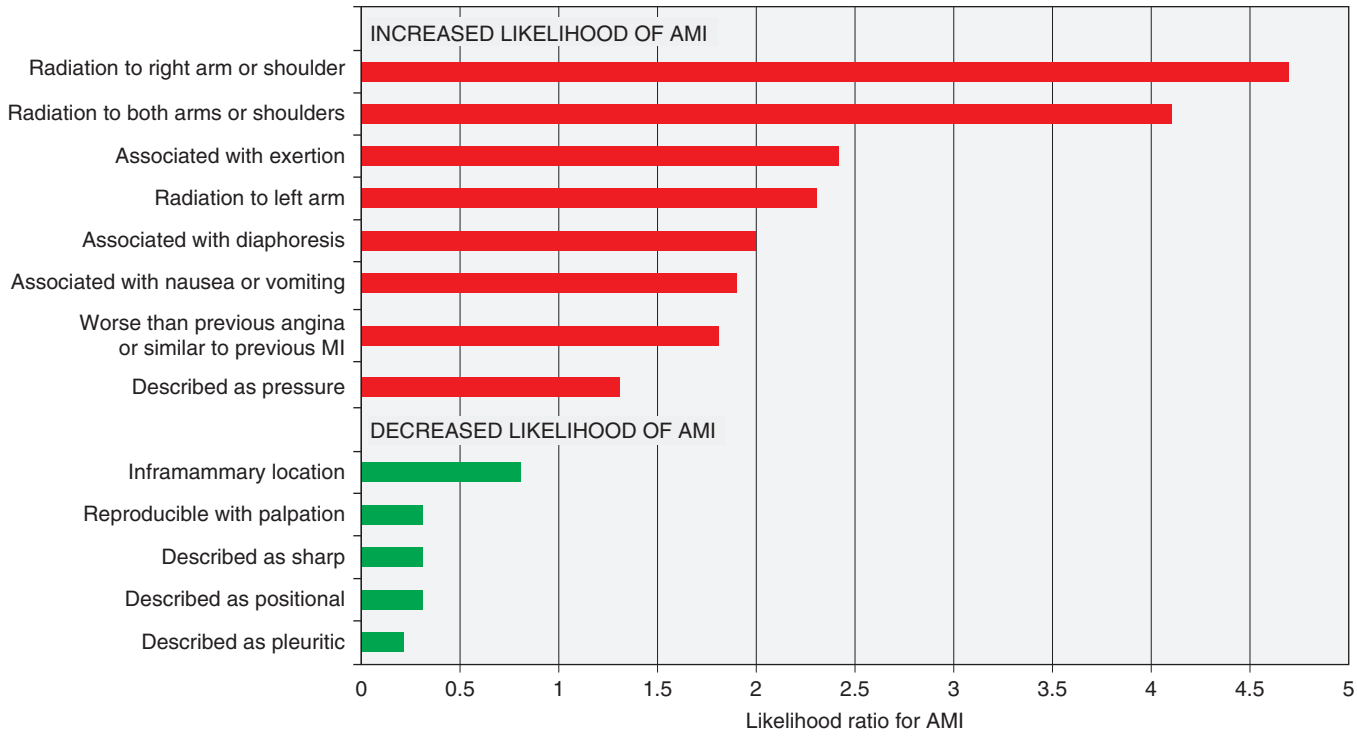

FIGURE 14-2 Association of chest pain characteristics with the probability of acute myocardial infarction (AMI). Note that a subsequent larger study showed a nonsignificant association with radiation to the right arm. *(Figure prepared from data in CJ Swap, JT Nagurney: JAMA 294:2623, 2005.)*

(Table 14-1), including ACS in particular (Fig. 14-2). Pressure or tightness is consistent with a typical presentation of myocardial ischemic pain. Nevertheless, the clinician must remember that some patients with ischemic chest symptoms deny any "pain" but rather complain of dyspnea or a vague sense of anxiety. The severity of the discomfort has poor diagnostic accuracy. It is often helpful to ask about the similarity of the discomfort to previous definite ischemic symptoms. It is unusual for angina to be sharp, as in knifelike, stabbing, or pleuritic; however, patients sometimes use the word "sharp" to convey the intensity of discomfort rather than the quality. Pleuritic discomfort is suggestive of a process involving the pleura, including pericarditis, pulmonary embolism, or pulmonary parenchymal processes. Less frequently, the pain of pericarditis or massive pulmonary embolism is a steady severe pressure or aching that can be difficult to discriminate from myocardial ischemia. "Tearing" or "ripping" pain is often described by patients with acute aortic dissection. However, acute aortic emergencies also present commonly with knifelike pain. A burning quality can suggest acid reflux or peptic ulcer disease but may also occur with myocardial ischemia. Esophageal pain, particularly with spasm, can be a severe squeezing discomfort identical to angina.

Location of Discomfort A substernal location with radiation to the neck, jaw, shoulder, or arms is typical of myocardial ischemic discomfort. Radiation to both arms has a particularly high association with MI as the etiology. Some patients present with aching in sites of radiated pain as their only symptoms of ischemia. However, pain that is highly localized—e.g., that which can be demarcated by the tip of one finger—is highly unusual for angina. A retrosternal location should prompt consideration of esophageal pain; however, other gastrointestinal conditions usually present with pain that is most intense in the abdomen or epigastrium, with possible radiation into the chest. Angina may also occur in an epigastric location. Pain that occurs solely above the mandible or below the epigastrium is rarely angina. Severe pain radiating to the back, particularly between the shoulder blades, should prompt consideration of an acute aortic syndrome. Radiation to the trapezius ridge is characteristic of pericardial pain and does not usually occur with angina.

Pattern Myocardial ischemic discomfort usually builds over minutes and is exacerbated by activity and mitigated by rest. In contrast, pain that reaches its peak intensity immediately is more suggestive of aortic dissection, pulmonary embolism, or spontaneous pneumothorax. Pain that is fleeting (lasting only a few seconds) is rarely ischemic in origin. Similarly, pain that is constant in intensity for a prolonged period (many hours to days) is unlikely to represent myocardial ischemia if it occurs in the absence of other clinical consequences, such as abnormalities of the ECG, elevation of cardiac biomarkers, or clinical sequelae (e.g., heart failure or hypotension). Both myocardial ischemia and acid reflux may have their onset in the morning.

Provoking and Alleviating Factors Patients with myocardial ischemic pain usually prefer to rest, sit, or stop walking. However, clinicians should be aware of the phenomenon of "warm-up angina" in which some patients experience relief of angina as they continue at the same or even a greater level of exertion (Chap. 273). Alterations in the intensity of pain with changes in position or movement of the upper extremities and neck are less likely with myocardial ischemia and suggest a musculoskeletal etiology. The pain of pericarditis, however, often is worse in the supine position and relieved by sitting upright and leaning forward. Gastroesophageal reflux may be exacerbated by alcohol, some foods, or a reclined position. Relief can occur with sitting.

Exacerbation by eating suggests a gastrointestinal etiology such as peptic ulcer disease, cholecystitis, or pancreatitis. Peptic ulcer disease tends to become symptomatic 60–90 min after meals. However, in the setting of severe coronary atherosclerosis, redistribution of blood flow to the splanchnic vasculature after eating can trigger postprandial angina. The discomfort of acid reflux and peptic ulcer disease is usually diminished promptly by acid-reducing therapies. In contrast with its impact in some patients with angina, physical exertion is very unlikely to alter symptoms from gastrointestinal causes of chest pain. Relief of chest discomfort within minutes after administration of nitroglycerin is suggestive of but not sufficiently sensitive or specific for a definitive diagnosis of myocardial ischemia. Esophageal spasm may also be relieved promptly with

nitroglycerin. A delay of >10 min before relief is obtained after nitroglycerin suggests that the symptoms either are not caused by ischemia or are caused by severe ischemia, such as during acute MI.

Associated Symptoms Symptoms that accompany myocardial ischemia may include diaphoresis, dyspnea, nausea, fatigue, faintness, and eructations. In addition, these symptoms may exist in isolation as anginal equivalents (i.e., symptoms of myocardial ischemia other than typical angina), particularly in women and the elderly. Dyspnea may occur with multiple conditions considered in the differential diagnosis of chest pain and thus is not discriminative, but the presence of dyspnea is important because it suggests a cardiopulmonary etiology. Sudden onset of significant respiratory distress should lead to consideration of pulmonary embolism and spontaneous pneumothorax. Hemoptysis may occur with pulmonary embolism or as blood-tinged frothy sputum in severe heart failure but usually points toward a pulmonary parenchymal etiology of chest symptoms. Presentation with syncope or presyncope should prompt consideration of hemodynamically significant pulmonary embolism or aortic dissection as well as ischemic arrhythmias. Although nausea and vomiting suggest a gastrointestinal disorder, these symptoms may occur in the setting of MI (more commonly inferior MI), presumably because of activation of the vagal reflex or stimulation of left ventricular receptors as part of the Bezold-Jarisch reflex.

Past Medical History The past medical history is useful in assessing the patient for risk factors for coronary atherosclerosis and venous thromboembolism **(Chap. 279)** as well as for conditions that may predispose the patient to specific disorders. For example, a history of connective tissue diseases such as Marfan syndrome should heighten the clinician's suspicion of an acute aortic syndrome or spontaneous pneumothorax. A careful history may elicit clues about depression or prior panic attacks.

PHYSICAL EXAMINATION

In addition to providing an initial assessment of the patient's clinical stability, the physical examination of patients with chest discomfort can provide direct evidence of specific etiologies of chest pain (e.g., unilateral absence of lung sounds) and can identify potential precipitants of acute cardiopulmonary causes of chest pain (e.g., uncontrolled hypertension), relevant comorbid conditions (e.g., obstructive pulmonary disease), and complications of the presenting syndrome (e.g., heart failure). However, because the findings on physical examination may be normal in patients with unstable ischemic heart disease, an unremarkable physical exam is not definitively reassuring.

General The patient's general appearance is helpful in establishing an initial impression of the severity of illness. Patients with acute MI or other acute cardiopulmonary disorders often appear anxious, uncomfortable, pale, cyanotic, or diaphoretic. Patients who are massaging or clutching their chests may describe their pain with a clenched fist held against the sternum (*Levine's sign*). Occasionally, body habitus is helpful—e.g., in patients with Marfan syndrome or the prototypical young, tall, thin man with spontaneous pneumothorax.

Vital Signs Significant tachycardia and hypotension are indicative of important hemodynamic consequences of the underlying cause of chest discomfort and should prompt a rapid survey for the most severe conditions, such as acute MI with cardiogenic shock, massive pulmonary embolism, pericarditis with tamponade, or tension pneumothorax. Acute aortic emergencies usually present with severe hypertension but may be associated with profound hypotension when there is coronary arterial compromise or dissection into the pericardium. Sinus tachycardia is an important manifestation of submassive pulmonary embolism. Tachypnea and hypoxemia point toward a pulmonary cause. The presence of low-grade fever is nonspecific because it may occur with MI and with thromboembolism in addition to infection.

Pulmonary Examination of the lungs may localize a primary pulmonary cause of chest discomfort, as in cases of pneumonia, asthma, or pneumothorax. Left ventricular dysfunction from severe ischemia/infarction as well as acute valvular complications of MI or aortic dissection can lead to pulmonary edema, which is an indicator of high risk.

Cardiac The jugular venous pulse is often normal in patients with acute myocardial ischemia but may reveal characteristic patterns with pericardial tamponade or acute right ventricular dysfunction **(Chaps. 239 and 270)**. Cardiac auscultation may reveal a third or, more commonly, a fourth heart sound, reflecting myocardial systolic or diastolic dysfunction. Murmurs of mitral regurgitation or a ventricular-septal defect may indicate mechanical complications of STEMI. A murmur of aortic insufficiency may be a complication of ascending aortic dissection. Other murmurs may reveal underlying cardiac disorders contributory to ischemia (e.g., aortic stenosis or hypertrophic cardiomyopathy). Pericardial friction rubs reflect pericardial inflammation.

Abdominal Localizing tenderness on the abdominal exam is useful in identifying a gastrointestinal cause of the presenting syndrome. Abdominal findings are infrequent with purely acute cardiopulmonary problems, except in the case of right-sided heart failure leading to hepatic congestion.

Extremities Vascular pulse deficits may reflect underlying chronic atherosclerosis, which increases the likelihood of coronary artery disease. However, evidence of acute limb ischemia with loss of the pulse and pallor, particularly in the upper extremities, can indicate catastrophic consequences of aortic dissection. Unilateral lower-extremity swelling should raise suspicion about venous thromboembolism.

Musculoskeletal Pain arising from the costochondral and chondrosternal articulations may be associated with localized swelling, redness, or marked localized tenderness. Pain on palpation of these joints is usually well localized and is a useful clinical sign, although deep palpation may elicit pain in the absence of costochondritis. Although palpation of the chest wall often elicits pain in patients with various musculoskeletal conditions, it should be appreciated that chest wall tenderness does not exclude myocardial ischemia. Sensory deficits in the upper extremities may be indicative of cervical disk disease.

ELECTROCARDIOGRAPHY

Electrocardiography is crucial in the evaluation of nontraumatic chest discomfort. The ECG is pivotal for identifying patients with ongoing ischemia as the principal reason for their presentation as well as secondary cardiac complications of other disorders. Professional society guidelines recommend that an ECG be obtained within 10 min of presentation, with the primary goal of identifying patients with ST-segment elevation diagnostic of MI who are candidates for immediate interventions to restore flow in the occluded coronary artery. ST-segment depression and symmetric T-wave inversions at least 0.2 mV in depth are useful for detecting myocardial ischemia in the absence of STEMI and are also indicative of higher risk of death or recurrent ischemia. Serial performance of ECGs (every 30–60 min) is recommended in the ED evaluation of suspected ACS. In addition, an ECG with right-sided lead placement should be considered in patients with clinically suspected ischemia and a nondiagnostic standard 12-lead ECG. Despite the value of the resting ECG, its sensitivity for ischemia is poor—as low as 20% in some studies.

Abnormalities of the ST segment and T wave may occur in a variety of conditions, including pulmonary embolism, ventricular hypertrophy, acute and chronic pericarditis, myocarditis, electrolyte imbalance, and metabolic disorders. Notably, hyperventilation associated with panic disorder can also lead to nonspecific ST and T-wave abnormalities. Pulmonary embolism is most often associated with sinus tachycardia but can also lead to rightward shift of the ECG axis, manifesting as an S-wave in lead I, with a Q-wave

and T-wave in lead III **(Chaps. 240 and 279)**. In patients with ST-segment elevation, the presence of diffuse lead involvement not corresponding to a specific coronary anatomic distribution and PR-segment depression can aid in distinguishing pericarditis from acute MI.

CHEST RADIOGRAPHY

(See **Chap. A12**) Plain radiography of the chest is performed routinely when patients present with acute chest discomfort and selectively when individuals who are being evaluated as outpatients have subacute or chronic pain. The chest radiograph is most useful for identifying pulmonary processes, such as pneumonia or pneumothorax. Findings are often unremarkable in patients with ACS, but pulmonary edema may be evident. Other specific findings include widening of the mediastinum in some patients with aortic dissection, Hampton's hump or Westermark's sign in patients with pulmonary embolism **(Chaps. 279 and A12)**, or pericardial calcification in chronic pericarditis.

CARDIAC BIOMARKERS

Laboratory testing in patients with acute chest pain is focused on the detection of myocardial injury. Such injury can be detected by the presence of circulating proteins released from damaged cardiomyocytes. Owing to the time necessary for this release, initial biomarkers of injury may be in the normal range, even in patients with STEMI. Cardiac troponin is the preferred biomarker for the diagnosis of MI and should be measured in all patients with suspected ACS. It is not necessary or advisable to measure troponin in patients without suspicion of ACS unless this test is being used specifically for risk stratification (e.g., in pulmonary embolism or heart failure).

The development of cardiac troponin assays with progressively greater analytical sensitivity has facilitated detection of substantially lower blood concentrations of troponin than was previously possible. This evolution permits earlier detection of myocardial injury and more reliable discrimination of changing values, enhances the overall accuracy of a diagnosis of MI, and improves risk stratification in suspected ACS. For these reasons, high-sensitivity assays are generally preferred over prior generation troponin assays. The greater negative predictive value of a negative troponin result with high-sensitivity assays is an advantage in the evaluation of chest pain in the ED. Rapid rule-out protocols that use serial testing and changes in troponin concentration over as short a period as 1–2 h appear to perform well for diagnosis of ACS when using a high-sensitivity troponin assay. Troponin should be measured at presentation and repeated at 1–3 h using high-sensitivity troponin and 3–6 h using conventional troponin assays. Additional troponin measurements may be warranted beyond 3–6 h when the clinical condition still suggests possible ACS or if there is diagnostic uncertainty. In patients presenting more than 2–3 h after symptom onset, a concentration of cardiac troponin, at the time of hospital presentation, below the limit of detection using a high-sensitivity assay may be sufficient to exclude MI with a negative predictive value >99%.

With the use of high-sensitivity assays for troponin, myocardial injury is detected in a larger proportion of patients who have non-ACS cardiopulmonary conditions than with previous, less sensitive assays. Therefore, other aspects of the clinical evaluation are critical to the practitioner's determination of the probability that the symptoms represent ACS. In addition, observation of a change in cardiac troponin concentration between serial samples is necessary for discriminating acute causes of myocardial injury from chronic elevation due to underlying structural heart disease, end-stage renal disease, or the rare presence of interfering antibodies. The diagnosis of MI is reserved for acute myocardial injury that is marked by a rising and/or falling pattern—with at least one value exceeding the 99th percentile reference limit—*and that is caused by ischemia.* Other nonischemic insults, such as myocarditis, may result in acute myocardial injury but should not be labeled MI **(Fig. 14-3)**.

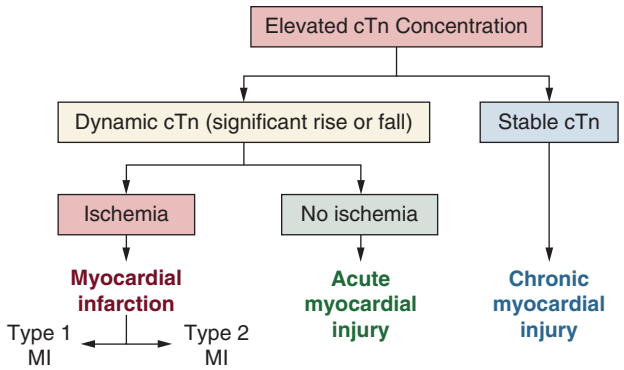

FIGURE 14-3 Clinical classification of patients with elevated cardiac troponin (cTn). MI, myocardial infarction.

Other laboratory assessments may include the D-dimer test to aid in exclusion of pulmonary embolism **(Chap. 279)**. Measurement of a B-type natriuretic peptide is useful when considered in conjunction with the clinical history and exam for the diagnosis of heart failure. B-type natriuretic peptides also provide prognostic information among patients with ACS and those with pulmonary embolism.

INTEGRATIVE DECISION-AIDS

Multiple clinical algorithms have been developed to aid in decision-making during the evaluation and disposition of patients with acute nontraumatic chest pain. Such decision-aids estimate either of two closely related but not identical probabilities: (1) the probability of a final diagnosis of ACS and (2) the probability of major cardiac events during short-term follow-up. Such decision-aids are used most commonly to identify patients with a low clinical probability of ACS who are candidates for discharge from the ED, with or without additional noninvasive testing. Goldman and Lee developed one of the first such decision-aids, using only the ECG and risk indicators—hypotension, pulmonary rales, and known ischemic heart disease—to categorize patients into four risk categories ranging from a <1% to a >16% probability of a major cardiovascular complication. Decision-aids used more commonly in current practice are shown in **Fig. 14-4**. Elements common across multiple risk stratification tools are (1) symptoms typical for ACS; (2) older age; (3) risk factors for or known atherosclerosis; (4) ischemic ECG abnormalities; and (5) elevated cardiac troponin level. Although, because of very low specificity, the overall diagnostic performance of such decision-aids is poor (area under the receiver operating curve, 0.55–0.65), in conjunction with the ECG and serial high-sensitivity cardiac troponin, they can help identify patients with a very low probability of ACS (e.g., <1%) or adverse cardiovascular events (<2% at 30 days). Clinical application of such integrated decision-aids or "accelerated diagnostic protocols" has been reported to achieve overall "miss rates" for ACS of <0.5% and may be useful for identifying patients who may be discharged without the need for additional cardiac testing.

Clinicians should differentiate between the algorithms discussed above and risk scores derived for stratification of prognosis (e.g., the TIMI and GRACE risk scores, **Chap. 275**) in patients *who already have an established diagnosis of ACS.* The latter risk scores were not designed to be used for *diagnostic* assessment.

CORONARY AND MYOCARDIAL STRESS IMAGING

Among patients for whom other life-threatening causes of chest pain have been reasonably excluded and serial biomarker and clinical assessment have determined the patient to remain eligible for further testing because of intermediate or undetermined risk, diagnostic coronary imaging with coronary computed tomographic (CT) angiography or functional testing, preferably with nuclear or echocardiographic imaging, is recommended. Patient characteristics (e.g., body habitus and renal function), prior cardiac testing,

HEART Score (without cTn)

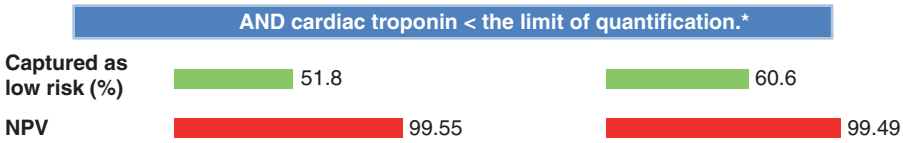

FIGURE 14-4 Examples of decision-aids used in conjunction with serial measurement of cardiac troponin (cTn) for evaluation of acute chest pain. The HEART score was modified by the authors in the presented study and omitting the assignment of 0, 1, or 2 points based on troponin. The negative predictive value (NPV) reported is for the composite endpoint of myocardial infarction (MI), cardiogenic shock, cardiac arrest, and all-cause mortality by 60 days. *Limit of quantification is the lowest analyte concentration that can be quantitatively detected with a total imprecision of ≤20%. CABG, coronary artery bypass graft; CAD, coronary artery disease; ECG, electrocardiogram; PCI, percutaneous coronary intervention. *(Figure prepared from data in DG Mark et al: J Am Coll Cardiol 13:606, 2018.)*

history of known coronary artery disease, existing contraindications for a given test modality, and patient preferences are considerations when choosing among these diagnostic tests **(Chaps. 241 and A9)**.

CT Angiography (See Chap. 241) CT angiography has emerged as a preferred modality for the evaluation of patients with acute chest discomfort who are candidates for further testing after biomarker and clinical risk assessment. Coronary CT angiography is a sensitive technique for detection of obstructive coronary disease. CT appears to enhance the speed to disposition of patients with a low-intermediate probability for ACS, with its major strength being the negative predictive value of a finding of no significant stenosis or coronary plaque. In addition, contrast-enhanced CT can detect focal areas of myocardial injury in the acute setting. At the same time, CT angiography can exclude aortic dissection, pericardial effusion, and pulmonary embolism.

Stress Nuclear Perfusion Imaging or Stress Echocardiography (See Chaps. 241 and A9) Functional testing with stress nuclear perfusion imaging and stress echocardiography are alternatives for the evaluation of patients with acute chest pain who are candidates for further testing and are preferred over coronary CT angiography in patients with known obstructive epicardial disease. The selection of stress test modality may depend on institutional availability and expertise. Stress testing with myocardial imaging, either with nuclear perfusion imaging or echocardiography, offers superior diagnostic performance over exercise ECG. In patients selected for stress myocardial imaging who are able to exercise, exercise stress is preferred over pharmacologic testing. When available, positron emission tomography offers advantages of improved diagnostic performance and fewer nondiagnostic studies than single-photon emission CT.

Although functional testing is generally contraindicated in patients with ongoing chest pain, in selected patients with persistent pain and nondiagnostic ECG and biomarker data, resting myocardial perfusion images can be obtained; the absence of any perfusion abnormality substantially reduces the likelihood of coronary artery disease. In such a strategy, used in some centers, those with abnormal rest perfusion imaging, which cannot discriminate between old or new myocardial defects, usually must undergo additional evaluation.

EXERCISE ELECTROCARDIOGRAPHY

Exercise electrocardiography has historically been commonly employed for completion of risk stratification of patients who have undergone an initial evaluation that has not revealed a specific cause of chest discomfort and has identified a low risk of ACS. Early exercise testing is safe in patients without ongoing chest pain or high-risk findings and may assist in refining their prognostic assessment. However, for patients with chest pain for whom both cardiac troponin and clinical risk stratification have determined the patient to have *low* probability of ACS, there is insufficient evidence that stress testing or cardiac imaging improves their outcomes. This evolution in evidence supports a change from past practice in which outpatient stress testing within 72 hours was broadly used for patients with acute chest pain.

OTHER NONINVASIVE STUDIES

Other noninvasive imaging studies of the chest can be used selectively to provide additional diagnostic and prognostic information on patients with chest discomfort.

Echocardiography Echocardiography (nonstress) is not necessarily routine in patients with chest discomfort. However, in patients with an uncertain diagnosis, particularly those with nondiagnostic ST elevation, ongoing symptoms, or hemodynamic instability, detection of abnormal regional wall motion provides evidence of possible ischemic dysfunction. Echocardiography is diagnostic in patients with mechanical complications of MI or in patients with pericardial tamponade. Transthoracic echocardiography is poorly sensitive for aortic dissection, although an intimal flap may sometimes be detected in the ascending aorta.

MRI (See Chap. 241) Cardiac magnetic resonance (CMR) imaging is an evolving, versatile technique for structural and functional evaluation of the heart and the vasculature of the chest. CMR can be performed as a modality for pharmacologic stress perfusion imaging. Gadolinium-enhanced CMR can provide early detection of MI, defining areas of myocardial necrosis accurately, and can delineate patterns of myocardial disease that are often useful in discriminating ischemic from nonischemic myocardial injury. Although usually not practical for the urgent evaluation of acute chest discomfort, CMR can be a useful modality for cardiac structural evaluation of patients with elevated cardiac troponin levels in the absence of definite coronary artery disease. CMR coronary angiography is in its early stages. MRI also permits highly accurate assessment for aortic dissection but is infrequently used as the first test because CT and transesophageal echocardiography are usually more practical.

CRITICAL PATHWAYS FOR ACUTE CHEST DISCOMFORT

Because of the challenges inherent in reliably identifying the small proportion of patients with serious causes of acute chest discomfort while not exposing the larger number of low-risk patients to unnecessary testing and extended ED or hospital evaluations, many medical centers have adopted critical pathways to expedite the assessment and management of patients with nontraumatic chest pain, often in dedicated chest pain units. Such pathways are generally aimed at (1) rapid identification, triage, and treatment of high-risk cardiopulmonary conditions (e.g., STEMI); (2) accurate identification of low-risk patients who can be safely observed in units with less intensive monitoring, undergo early noninvasive testing, or be discharged home; and (3) through more efficient and systematic accelerated diagnostic protocols, safe reduction in costs associated with overuse of testing and unnecessary hospitalizations. In some studies, provision of protocol-driven care in chest pain units has decreased costs and overall duration of hospital evaluation with no detectable excess of adverse clinical outcomes.

OUTPATIENT EVALUATION OF CHEST DISCOMFORT

Chest pain is common in outpatient practice, with a lifetime prevalence of 20–40% in the general population. More than 25% of patients with MI have had a related visit with a primary care physician in the previous month. The diagnostic principles are the same as in the ED. However, the pretest probability of an acute cardiopulmonary cause is significantly lower. Therefore, testing paradigms are less intense, with an emphasis on the history, physical examination, and ECG. Moreover, decision-aids developed for settings with a high prevalence of significant cardiopulmonary disease have lower positive predictive value when applied in the practitioner's office. However, in general, if the level of clinical suspicion of ACS is sufficiently high to consider troponin testing, the patient should be referred to the ED for evaluation.

15 Abdominal Pain

Danny O. Jacobs

Correctly diagnosing acute abdominal pain can be quite challenging. Few clinical situations require greater judgment, because the most catastrophic of events may be forecast by the subtlest of symptoms and signs. In every instance, the clinician must distinguish those conditions that require urgent intervention from those that do not and can best be managed nonoperatively. A meticulously executed, detailed history and physical examination are critically important for focusing the differential diagnosis and allowing the diagnostic evaluation to proceed expeditiously **(Table 15-1)**.

The etiologic classification in **Table 15-2**, although not complete, provides a useful framework for evaluating patients with abdominal pain.

Any patient with abdominal pain of recent onset requires an early and thorough evaluation. The most common causes of abdominal pain on admission are nonspecific abdominal pain, acute appendicitis, pain of urologic origin, and intestinal obstruction. A diagnosis of "acute or surgical abdomen" is not acceptable because of its often misleading and erroneous connotations. Most patients who present with acute abdominal pain will have self-limited disease processes. However, it is important to remember that pain severity does not necessarily correlate with the severity of the underlying condition. And, the presence or absence of various degrees of "hunger" is unreliable as a sole indicator of the severity of intraabdominal disease. The most obvious of "acute abdomens" may not require operative intervention, and the mildest of abdominal pains may herald an urgently correctable disease.

SOME MECHANISMS OF PAIN ORIGINATING IN THE ABDOMEN

Inflammation of the Parietal Peritoneum The pain of parietal peritoneal inflammation is steady and aching in character and is located directly over the inflamed area, its exact reference being possible because it is transmitted by somatic nerves supplying the parietal peritoneum. The intensity of the pain is dependent on the type and amount of material to which the peritoneal surfaces are exposed in a given time period. For example, the sudden release of a small quantity

TABLE 15-1 Some Key Components of the Patient's History

Age
Time and mode of onset of the pain
Pain characteristics
Duration of symptoms
Location of pain and sites of radiation
Associated symptoms and their relationship to the pain
Nausea, emesis, and anorexia
Diarrhea, constipation, or other changes in bowel habits
Menstrual history

TABLE 15-2 Some Important Causes of Abdominal Pain

Pain Originating in the Abdomen	
Parietal peritoneal inflammation	Vascular disturbances
Bacterial contamination	Embolism or thrombosis
Perforated appendix or other perforated viscus	Vascular rupture
Pelvic inflammatory disease	Pressure or torsional occlusion
Chemical irritation	Sickle cell anemia
Perforated ulcer	Abdominal wall
Pancreatitis	Distortion or traction of mesentery
Mittelschmerz	Trauma or infection of muscles
Mechanical obstruction of hollow viscera	Distension of visceral surfaces, e.g., by hemorrhage
Obstruction of the small or large intestine	Hepatic or renal capsules
Obstruction of the biliary tree	Inflammation
Obstruction of the ureter	Appendicitis
	Typhoid fever
	Neutropenic enterocolitis or "typhlitis"
Pain Referred from Extraabdominal Source	
Cardiothoracic	Pleurodynia
Acute myocardial infarction	Pneumothorax
Myocarditis, endocarditis, pericarditis	Empyema
Congestive heart failure	Esophageal disease, including spasm, rupture, or inflammation
Pneumonia (especially lower lobes)	Genitalia
Pulmonary embolus	Torsion of the testis
Metabolic Causes	
Diabetes	Acute adrenal insufficiency
Uremia	Familial Mediterranean fever
Hyperlipidemia	Porphyria
Hyperparathyroidism	C1 esterase inhibitor deficiency (angioneurotic edema)
Neurologic/Psychiatric Causes	
Herpes zoster	Spinal cord or nerve root compression
Tabes dorsalis	Functional disorders
Causalgia	Psychiatric disorders
Radiculitis from infection or arthritis	
Toxic Causes	
Lead poisoning	
Insect or animal envenomation	
Black widow spider bites	
Snake bites	
Uncertain Mechanisms	
Narcotic withdrawal	
Heat stroke	

of *sterile* acidic gastric juice into the peritoneal cavity causes much more pain than the same amount of grossly contaminated neutral feces. Enzymatically active pancreatic juice incites more pain and inflammation than does the same amount of sterile bile containing no potent enzymes. Blood is normally only a mild irritant, and the response to urine is also typically bland, so exposure of blood and urine to the peritoneal cavity may go unnoticed unless it is sudden and massive. Bacterial contamination, such as may occur with pelvic inflammatory disease or perforated distal intestine, causes low-intensity pain until multiplication causes significant amounts of inflammatory mediators to be released. Patients with perforated upper gastrointestinal ulcers may present entirely differently depending on how quickly gastric juices enter the peritoneal cavity and their pH. Thus, the rate at which any inflammatory material irritates the peritoneum is important.

The pain of peritoneal inflammation is invariably accentuated by pressure or changes in tension of the peritoneum, whether produced by palpation or by movement such as with coughing or sneezing. The patient with peritonitis characteristically lies quietly in bed, preferring to avoid motion, in contrast to the patient with colic, who may be thrashing in discomfort.

Another characteristic feature of peritoneal irritation is tonic reflex spasm of the abdominal musculature, localized to the involved body segment. Its intensity depends on the integrity of the nervous system, the location of the inflammatory process, and the rate at which it develops. Spasm over a perforated retrocecal appendix or perforation into the lesser peritoneal sac may be minimal or absent because of the protective effect of overlying viscera. Catastrophic abdominal emergencies may be associated with minimal or no detectable pain or muscle spasm in obtunded, seriously ill, debilitated, immunosuppressed, or psychotic patients. A slowly developing process also often greatly attenuates the degree of muscle spasm.

Obstruction of Hollow Viscera Intraluminal obstruction classically elicits intermittent or colicky abdominal pain that is not as well localized as the pain of parietal peritoneal irritation. However, the absence of cramping discomfort can be misleading because distention of a hollow viscus may also produce steady pain with only rare paroxysms.

Small-bowel obstruction often presents as poorly localized, intermittent periumbilical or supraumbilical pain. As the intestine progressively dilates and loses muscular tone, the colicky nature of the pain may diminish. With superimposed strangulating obstruction, pain may spread to the lower lumbar region if there is traction on the root of the mesentery. The colicky pain of colonic obstruction is of lesser intensity, is commonly located in the infraumbilical area, and may often radiate to the lumbar region.

Sudden distention of the biliary tree produces a steady rather than colicky type of pain; hence, the term *biliary colic* is misleading. Acute distention of the gallbladder typically causes pain in the right upper quadrant with radiation to the right posterior region of the thorax or to the tip of the right scapula, but discomfort is also not uncommonly found near the midline. Distention of the common bile duct often causes epigastric pain that may radiate to the upper lumbar region. Considerable variation is common, however, so that differentiation between gallbladder or common ductal disease may be impossible.

Gradual dilatation of the biliary tree, as can occur with carcinoma of the head of the pancreas, may cause no pain or only a mild aching sensation in the epigastrium or right upper quadrant. The pain of distention of the pancreatic ducts is similar to that described for distention of the common bile duct but, in addition, is very frequently accentuated by recumbency and relieved by the upright position.

Obstruction of the urinary bladder usually causes dull, low-intensity pain in the suprapubic region. Restlessness, without specific complaint of pain, may be the only sign of a distended bladder in an obtunded patient. In contrast, acute obstruction of the intravesicular portion of the ureter is characterized by severe suprapubic and flank pain that radiates to the penis, scrotum, or inner aspect of the upper thigh. Obstruction of the ureteropelvic junction manifests as pain near the costovertebral angle, whereas obstruction of the remainder of the ureter is associated with flank pain that often extends into the same side of the abdomen.

Vascular Disturbances A frequent misconception is that pain due to intraabdominal vascular disturbances is sudden and catastrophic in nature. Certain disease processes, such as embolism or thrombosis of the superior mesenteric artery or impending rupture of an abdominal aortic aneurysm, can certainly be associated with diffuse, severe pain. Yet, just as frequently, the patient with occlusion of the superior mesenteric artery only has mild continuous or cramping diffuse pain for 2 or 3 days before vascular collapse or findings of peritoneal inflammation appear. The early, seemingly insignificant discomfort is caused by hyperperistalsis rather than peritoneal inflammation. Indeed, absence of tenderness and rigidity in the presence of continuous, diffuse pain (e.g., "pain out of proportion to physical findings") in a patient likely to have vascular disease is quite characteristic of occlusion of the superior mesenteric artery. Abdominal pain with radiation to the sacral region,

flank, or genitalia should always signal the possible presence of a rupturing abdominal aortic aneurysm. This pain may persist over a period of several days before rupture and collapse occur.

Abdominal Wall Pain arising from the abdominal wall is usually constant and aching. Movement, prolonged standing, and pressure accentuate the discomfort and associated muscle spasm. In the relatively rare case of hematoma of the rectus sheath, now most frequently encountered in association with anticoagulant therapy, a mass may be present in the lower quadrants of the abdomen. Simultaneous involvement of muscles in other parts of the body usually serves to differentiate myositis of the abdominal wall from other processes that might cause pain in the same region.

REFERRED PAIN IN ABDOMINAL DISEASE

Pain referred to the abdomen from the thorax, spine, or genitalia may present a diagnostic challenge because diseases of the upper part of the abdominal cavity such as acute cholecystitis or perforated ulcer may be associated with intrathoracic complications. A most important, yet often forgotten, dictum is that the possibility of intrathoracic disease must be considered in every patient with abdominal pain, especially if the pain is in the upper abdomen.

Systematic questioning and examination directed toward detecting myocardial or pulmonary infarction, pneumonia, pericarditis, or esophageal disease (the intrathoracic diseases that most often masquerade as abdominal emergencies) will often provide sufficient clues to establish the proper diagnosis. Diaphragmatic pleuritis resulting from pneumonia or pulmonary infarction may cause pain in the right upper quadrant and pain in the supraclavicular area, the latter radiation to be distinguished from the referred subscapular pain caused by acute distention of the extrahepatic biliary tree. The ultimate decision as to the origin of abdominal pain may require deliberate and planned observation over a period of several hours, during which repeated questioning and examination will provide the diagnosis or suggest the appropriate studies.

Referred pain of thoracic origin is often accompanied by splinting of the involved hemithorax with respiratory lag and a decrease in excursion more marked than that seen in the presence of intraabdominal disease. In addition, apparent abdominal muscle spasm caused by referred pain will diminish during the inspiratory phase of respiration, whereas it persists throughout both respiratory phases if it is of abdominal origin. Palpation over the area of referred pain in the abdomen also does not usually accentuate the pain and, in many instances, actually seems to relieve it.

Thoracic disease and abdominal disease frequently coexist and may be difficult or impossible to differentiate. For example, the patient with known biliary tract disease often has epigastric pain during myocardial infarction, or biliary colic may be referred to the precordium or left shoulder in a patient who has suffered previously from angina pectoris. **For an explanation of the radiation of pain to a previously diseased area, see Chap. 13.**

Referred pain from the spine, which usually involves compression or irritation of nerve roots, is characteristically intensified by certain motions such as cough, sneeze, or strain and is associated with hyperesthesia over the involved dermatomes. Pain referred to the abdomen from the testes or seminal vesicles is generally accentuated by the slightest pressure on either of these organs. The abdominal discomfort experienced is of dull, aching character and is poorly localized.

METABOLIC ABDOMINAL CRISES

Pain of metabolic origin may simulate almost any other type of intraabdominal disease. Several mechanisms may be at work. In certain instances, such as hyperlipidemia, the metabolic disease itself may be accompanied by an intraabdominal process such as pancreatitis, which can lead to unnecessary laparotomy unless recognized. C1 esterase deficiency associated with angioneurotic edema is often associated with episodes of severe abdominal pain. Whenever the cause of abdominal pain is obscure, a metabolic origin always must be considered. Abdominal pain is also the hallmark of familial Mediterranean fever **(Chap. 369)**.

The pain of porphyria and of lead colic is usually difficult to distinguish from that of intestinal obstruction, because severe hyperperistalsis is a prominent feature of both. The pain of uremia or diabetes is nonspecific, and the pain and tenderness frequently shift in location and intensity. Diabetic acidosis may be precipitated by acute appendicitis or intestinal obstruction, so if prompt resolution of the abdominal pain does not result from correction of the metabolic abnormalities, an underlying organic problem should be suspected. Black widow spider bites produce intense pain and rigidity of the abdominal muscles and back, an area infrequently involved in intraabdominal disease.

IMMUNOCOMPROMISE

Evaluating and diagnosing causes of abdominal pain in immunosuppressed or otherwise immunocompromised patients is very difficult. This includes those who have undergone organ transplantation; who are receiving immunosuppressive treatments for autoimmune diseases, chemotherapy, or glucocorticoids; who have AIDS; and who are very old. In these circumstances, normal physiologic responses may be absent or masked. In addition, unusual infections may cause abdominal pain where the etiologic agents include cytomegalovirus, mycobacteria, protozoa, and fungi. These pathogens may affect all gastrointestinal organs, including the gallbladder, liver, and pancreas, as well as the gastrointestinal tract, causing occult or overtly symptomatic perforations of the latter. Splenic abscesses due to *Candida* or *Salmonella* infection should also be considered, especially when evaluating patients with left upper quadrant or left flank pain. Acalculous cholecystitis may be observed in immunocompromised patients or those with AIDS, where it is often associated with cryptosporidiosis or cytomegalovirus infection.

Neutropenic enterocolitis (typhlitis) is often identified as a cause of abdominal pain and fever in some patients with bone marrow suppression due to chemotherapy. Acute graft-versus-host disease should be considered in this circumstance. Optimal management of these patients requires meticulous follow-up including serial examinations to assess the need for more surgical intervention, for example, to address perforation.

NEUROGENIC CAUSES

Diseases that injure sensory nerves may cause causalgic pain. This pain has a burning character and is usually limited to the distribution of a given peripheral nerve. Stimuli that are normally not painful such as touch or a change in temperature may be causalgic and are often present even at rest. The demonstration of irregularly spaced cutaneous "pain spots" may be the only indication that an old nerve injury exists. Even though the pain may be precipitated by gentle palpation, rigidity of the abdominal muscles is absent, and the respirations are not usually disturbed. Distention of the abdomen is uncommon, and the pain has no relationship to food intake.

Pain arising from spinal nerves or roots comes and goes suddenly and is of a lancinating type **(Chap. 17)**. It may be caused by herpes zoster, impingement by arthritis, tumors, a herniated nucleus pulposus, diabetes, or syphilis. It is not associated with food intake, abdominal distention, or changes in respiration. Severe muscle spasms, when present, may be relieved by, but are certainly not accentuated by, abdominal palpation. The pain is made worse by movement of the spine and is usually confined to a few dermatomes. Hyperesthesia is very common.

Pain due to functional causes conforms to none of the aforementioned patterns. Mechanisms of disease are not clearly established. Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by abdominal pain and altered bowel habits. The diagnosis is made on the basis of clinical criteria **(Chap. 327)** and after exclusion of demonstrable structural abnormalities. The episodes of abdominal pain may be brought on by stress, and the pain varies considerably in type and location. Nausea and vomiting are rare. Localized

tenderness and muscle spasm are inconsistent or absent. The causes of IBS or related functional disorders are not yet fully understood.

APPROACH TO THE PATIENT

Abdominal Pain

Few abdominal conditions require such urgent operative intervention that an orderly approach needs to be abandoned, no matter how ill the patient is. Only patients with exsanguinating intraabdominal hemorrhage (e.g., ruptured aneurysm) must be rushed to the operating room immediately, but in such instances, only a few minutes are required to assess the critical nature of the problem. Under these circumstances, all obstacles must be swept aside, adequate venous access for fluid replacement obtained, and the operation begun. Unfortunately, many of these patients may die in the radiology department or the emergency room while awaiting unnecessary examinations. *There are no absolute contraindications to operation when massive intraabdominal hemorrhage is present.* Fortunately, this situation is relatively rare. This statement does not necessarily apply to patients with intraluminal gastrointestinal hemorrhage, who can often be managed by other means **(Chap. 48)**. In these patients, obtaining a *detailed history when possible* can be extremely helpful even though it can be laborious and time-consuming. Decision-making regarding next steps is facilitated and a reasonably accurate diagnosis can be made before any further diagnostic testing is undertaken.

In cases of *acute* abdominal pain, a diagnosis can be readily established in most instances, whereas success is not so frequent in patients with *chronic* pain. IBS is one of the most common causes of abdominal pain and must always be kept in mind **(Chap. 327)**. The location of the pain can assist in narrowing the differential diagnosis **(Table 15-3)**; however, the *chronological sequence of events* in the patient's history is often more important than the pain's location. Careful attention should be paid to the extraabdominal regions. Narcotics or analgesics should *not* be withheld until a definitive diagnosis or a definitive plan has been formulated; obfuscation of the diagnosis by adequate analgesia is unlikely.

TABLE 15-3 Differential Diagnoses of Abdominal Pain by Location

Right Upper Quadrant	Epigastric	Left Upper Quadrant
Cholecystitis	Peptic ulcer disease	Splenic infarct
Cholangitis	Gastritis	Splenic rupture
Pancreatitis	GERD	Splenic abscess
Pneumonia/empyema	Pancreatitis	Gastritis
Pleurisy/pleurodynia	Myocardial infarction	Gastric ulcer
Subdiaphragmatic abscess	Pericarditis	Pancreatitis
Hepatitis	Ruptured aortic aneurysm	Subdiaphragmatic abscess
Budd-Chiari syndrome	Esophagitis	
Right Lower Quadrant	**Periumbilical**	**Left Lower Quadrant**
Appendicitis	Early appendicitis	Diverticulitis
Salpingitis	Gastroenteritis	Salpingitis
Inguinal hernia	Bowel obstruction	Inguinal hernia
Ectopic pregnancy	Ruptured aortic aneurysm	Ectopic pregnancy
Nephrolithiasis		Nephrolithiasis
Inflammatory bowel disease		Irritable bowel syndrome
Mesenteric lymphadenitis		Inflammatory bowel disease
Typhlitis		
Diffuse Nonlocalized Pain		
Gastroenteritis	Malaria	
Mesenteric ischemia	Familial Mediterranean fever	
Bowel obstruction	Metabolic diseases	
Irritable bowel syndrome	Psychiatric disease	
Peritonitis		
Diabetes		

Abbreviation: GERD, gastroesophageal reflux disease.

An accurate menstrual history in a female patient is essential. It is important to remember that normal anatomic relationships can be significantly altered by the gravid uterus. Abdominal and pelvic pain may occur during pregnancy due to conditions that do not require operation. Lastly, some otherwise noteworthy laboratory values (e.g., leukocytosis) may represent the normal physiologic changes of pregnancy.

In the examination, simple critical inspection of the patient, for example, of facies, position in bed, and respiratory activity, provides valuable clues. The amount of information to be gleaned is directly proportional to the *gentleness* and thoroughness of the examiner. Once a patient with peritoneal inflammation has been examined brusquely, accurate assessment by the next examiner becomes almost impossible. Eliciting rebound tenderness by sudden release of a deeply palpating hand in a patient with suspected peritonitis is cruel and unnecessary. The same information can be obtained by gentle percussion of the abdomen (rebound tenderness on a miniature scale), a maneuver that can be far more precise and localizing. Asking the patient to cough will elicit true rebound tenderness without the need for placing a hand on the abdomen. Furthermore, the forceful demonstration of rebound tenderness will startle and induce protective spasm in a nervous or worried patient in whom true rebound tenderness is not present. A palpable gallbladder will be missed if palpation is so aggressive that voluntary muscle spasm becomes superimposed on involuntary muscular rigidity.

As with history taking, sufficient time should be spent in the examination. Abdominal signs may be minimal but, nevertheless, if accompanied by consistent symptoms, may be exceptionally meaningful. Abdominal signs may be virtually or totally absent in cases of pelvic peritonitis, so careful *pelvic and rectal examinations are mandatory in every patient with abdominal pain.* Tenderness on pelvic or rectal examination in the absence of other abdominal signs can be caused by operative indications such as perforated appendicitis, diverticulitis, twisted ovarian cyst, and many others. Much attention has been paid to the presence or absence of peristaltic sounds, their quality, and their frequency. Auscultation of the abdomen is one of the least revealing aspects of the physical examination of a patient with abdominal pain. Catastrophes such as a strangulating small-intestinal obstruction or perforated appendicitis may occur in the presence of normal peristaltic sounds. Conversely, when the proximal part of the intestine above obstruction becomes markedly distended and edematous, peristaltic sounds may lose the characteristics of borborygmi and become weak or absent, even when peritonitis is not present. It is usually the severe chemical peritonitis of sudden onset that is associated with the truly silent abdomen.

Laboratory examinations may be valuable in assessing the patient with abdominal pain, yet, with few exceptions, they rarely establish a diagnosis. Leukocytosis should never be the single deciding factor as to whether or not operation is indicated. A white blood cell count >20,000/μL may be observed with perforation of a viscus, but pancreatitis, acute cholecystitis, pelvic inflammatory disease, and intestinal infarction may also be associated with marked leukocytosis. A normal white blood cell count is not rare in cases of perforation of abdominal viscera. A diagnosis of anemia may be more helpful than the white blood cell count, especially when combined with the history.

The urinalysis may reveal the state of hydration or rule out severe renal disease, diabetes, or urinary infection. Blood urea nitrogen, glucose, and serum bilirubin levels and liver function tests may be

helpful. Serum amylase levels may be increased by many diseases other than pancreatitis, for example, perforated ulcer, strangulating intestinal obstruction, and acute cholecystitis; thus, elevations of serum amylase do not rule in or rule out the need for an operation.

Plain and upright or lateral decubitus radiographs of the abdomen have limited utility and may be unnecessary in some patients who have substantial evidence of some diseases such as acute appendicitis or strangulated external hernia. Where the indications for surgical or medical intervention are not clear, low-dose computed tomography is preferred to abdominal radiography when evaluating nontraumatic acute abdominal pain.

Very rarely, barium or water-soluble contrast study of the upper part of the gastrointestinal tract is an appropriate radiographic investigation and may demonstrate partial intestinal obstruction that may elude diagnosis by other means. If there is any question of obstruction of the colon, oral administration of barium sulfate should be avoided. On the other hand, in cases of suspected colonic obstruction (without perforation), a contrast enema may be diagnostic.

In the absence of trauma, peritoneal lavage has been replaced as a diagnostic tool by CT scanning and laparoscopy. Ultrasonography has proved to be useful in detecting an enlarged gallbladder or pancreas, the presence of gallstones, an enlarged ovary, or a tubal pregnancy. Laparoscopy is especially helpful in diagnosing pelvic conditions, such as ovarian cysts, tubal pregnancies, salpingitis, acute appendicitis, and other disease processes. Laparoscopy has a particular advantage over imaging in that the underlying etiologic condition can often be definitively addressed.

Radioisotopic hepatobiliary iminodiacetic acid scans (HIDAs) may help differentiate acute cholecystitis or biliary colic from acute pancreatitis. A CT scan may demonstrate an enlarged pancreas, ruptured spleen, or thickened colonic or appendiceal wall and streaking of the mesocolon or mesoappendix characteristic of diverticulitis or appendicitis.

Sometimes, even under the best circumstances with all available aids and with the greatest of clinical skill, a definitive diagnosis cannot be established at the time of the initial examination. And, in some cases, operation may be indicated based on clinical grounds alone. Should that decision be questionable, watchful waiting with repeated questioning and examination will often elucidate the true nature of the illness and indicate the proper course of action.

Acknowledgment

The author gratefully acknowledges the enormous contribution to this chapter and the approach it espouses of William Silen, who wrote this chapter for many editions.

16 Headache

Peter J. Goadsby

Headache is among the most common reasons patients seek medical attention and is responsible, on a global basis, for more disability than any other neurologic problem. Diagnosis and management are based on a careful clinical approach augmented by an understanding of the anatomy, physiology, and pharmacology of the nervous system pathways mediating the various headache syndromes. This chapter will focus on the general approach to a patient with headache; migraine and other primary headache disorders are discussed in **Chap. 430**.

GENERAL PRINCIPLES

A classification system developed by the International Headache Society (*www.ihs-headache.org/en/resources/guidelines/*) characterizes headache as primary or secondary **(Table 16-1)**. *Primary headaches* are those in which headache and its associated features are the disorder itself, whereas *secondary headaches* are those caused by exogenous disorders (Headache Classification Committee of the International Headache Society, 2018). Primary headache often results in considerable disability and a decrease in the patient's quality of life. Mild secondary headache, such as that seen in association with upper respiratory tract infections, is common but rarely worrisome. Life-threatening headache is relatively uncommon, but vigilance is required in order to recognize and appropriately treat such patients.

ANATOMY AND PHYSIOLOGY OF HEADACHE

Pain usually occurs when peripheral nociceptors are stimulated in response to tissue injury, visceral distension, or other factors **(Chap. 13)**. In such situations, pain perception is a normal physiologic response mediated by a healthy nervous system. Pain can also result when pain-producing pathways of the peripheral or central nervous system (CNS) are damaged or activated inappropriately. Headache may originate from either or both mechanisms. Relatively few cranial structures are pain producing; these include the scalp, meningeal arteries, dural sinuses, falx cerebri, and proximal segments of the large pial arteries. The ventricular ependyma, choroid plexus, pial veins, and much of the brain parenchyma are not pain producing.

The key structures involved in primary headache are the following:

- The large intracranial vessels and dura mater, and the peripheral terminals of the trigeminal nerve that innervate these structures
- The caudal portion of the trigeminal nucleus, which extends into the dorsal horns of the upper cervical spinal cord and receives input from the first and second cervical nerve roots (the trigeminocervical complex)
- Rostral pain-processing regions, such as the ventroposteromedial thalamus and the cortex
- The pain-modulatory systems in the brain that modulate input from the trigeminal nociceptors at all levels of the pain-processing pathways and influence vegetative functions, such as the hypothalamus and brainstem

TABLE 16-1 Common Causes of Headache

PRIMARY HEADACHE		SECONDARY HEADACHE

Source: After J Olesen et al: *The Headaches*. Philadelphia, Lippincott Williams & Wilkins, 2005.

The *trigeminovascular system* innervates the large intracranial vessels and dura mater via the trigeminal nerve. Cranial autonomic symptoms, such as lacrimation, conjunctival injection, nasal congestion, rhinorrhea, periorbital swelling, aural fullness, and ptosis, are prominent in the trigeminal autonomic cephalalgias (TACs), including cluster headache and paroxysmal hemicrania, and may also be seen in migraine, even in children. These autonomic symptoms reflect activation of cranial parasympathetic pathways, and functional imaging studies indicate that vascular changes in migraine and cluster headache, when present, are similarly driven by these cranial autonomic systems. Thus, they are secondary, and not causative, events in the headache cascade. Moreover, they can often be mistaken for symptoms or signs of cranial sinus inflammation, which is then overdiagnosed and inappropriately managed. Migraine and other primary headache types are not "vascular headaches"; these disorders do not reliably manifest vascular changes, and treatment outcomes cannot be predicted by vascular effects. Migraine is a brain disorder and is best understood and managed as such.

CLINICAL EVALUATION OF ACUTE, NEW-ONSET HEADACHE

The patient who presents with a new, severe headache has a differential diagnosis that is quite different from the patient with recurrent headaches over many years. In new-onset and severe headache, the probability of finding a potentially serious cause is considerably greater than in recurrent headache. Patients with recent onset of pain require prompt evaluation and appropriate treatment. Serious causes to be considered include meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, tumor, and purulent sinusitis. When worrisome symptoms and signs are present **(Table 16-2)**, rapid diagnosis and management are critical.

A careful neurologic examination is an essential first step in the evaluation. In most cases, patients with an abnormal examination or a history of recent-onset headache should be evaluated by a computed tomography (CT) or magnetic resonance imaging (MRI) study of the brain. As an initial screening procedure for intracranial pathology in this setting, CT and MRI methods appear to be equally sensitive. In some circumstances, a lumbar puncture (LP) is also required, unless a benign etiology can be otherwise established. A general evaluation of acute headache might include cranial arteries by palpation; cervical spine by the effect of passive movement of the head and by imaging; the investigation of cardiovascular and renal status by blood pressure monitoring and urine examination; and eyes by funduscopy, intraocular pressure measurement, and refraction.

The patient's psychological state should also be evaluated because a relationship exists between head pain, depression, and anxiety. This is intended to identify comorbidity rather than provide an explanation for the headache, because troublesome headache is seldom simply caused by mood change. Although it is notable that medicines with antidepressant actions are also effective in the preventive treatment of both tension-type headache and migraine, each symptom must be treated optimally.

Underlying recurrent headache disorders may be activated by pain that follows otologic or endodontic surgical procedures. Thus, pain about the head as the result of diseased tissue or trauma may reawaken an otherwise quiescent migraine syndrome. Treatment of the headache is largely ineffective until the cause of the primary problem is addressed.

Serious underlying conditions that are associated with headache are described below. Brain tumor is a rare cause of headache and even less commonly a cause of severe pain. The vast majority of patients presenting with severe headache have a benign cause.

TABLE 16-2 Headache Symptoms That Suggest a Serious Underlying Disorder

Sudden-onset headache
First severe headache
"Worst" headache ever
Vomiting that precedes headache
Subacute worsening over days or weeks
Pain induced by bending, lifting, coughing
Pain that disturbs sleep or presents immediately upon awakening
Known systemic illness
Onset after age 55
Fever or unexplained systemic signs
Abnormal neurologic examination
Pain associated with local tenderness, e.g., region of temporal artery

SECONDARY HEADACHE

The management of secondary headache focuses on diagnosis and treatment of the underlying condition.

MENINGITIS

Acute, severe headache with stiff neck and fever suggests meningitis. LP is mandatory. Often there is striking accentuation of pain with eye movement. Meningitis can be easily mistaken for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are frequently present, perhaps reflecting the underlying biology of some of the patients.

Meningitis is discussed in Chaps. 138 and 139.

INTRACRANIAL HEMORRHAGE

Acute, maximal in <5 min, severe headache lasting >5 min with stiff neck but without fever suggests subarachnoid hemorrhage. A ruptured aneurysm, arteriovenous malformation, or intraparenchymal hemorrhage may also present with headache alone. Rarely, if the hemorrhage is small or below the foramen magnum, the head CT scan can be normal. Therefore, LP may be required to diagnose definitively subarachnoid hemorrhage.

Subarachnoid hemorrhage is discussed in Chap. 429, and intracranial hemorrhage in Chap. 428.

BRAIN TUMOR

Approximately 30% of patients with brain tumors consider headache to be their chief complaint. The head pain is usually nondescript—an intermittent deep, dull aching of moderate intensity, which may worsen with exertion or change in position and may be associated with nausea and vomiting. This pattern of symptoms results from migraine far more often than from brain tumor. The headache of brain tumor disturbs sleep in about 10% of patients. Vomiting that precedes the appearance of headache by weeks is highly characteristic of posterior fossa brain tumors. A history of amenorrhea or galactorrhea should lead one to question whether a prolactin-secreting pituitary adenoma (or polycystic ovary syndrome) is the source of headache. Headache arising de novo in a patient with known malignancy suggests either cerebral metastases or carcinomatous meningitis. Head pain appearing abruptly after bending, lifting, or coughing can be due to a posterior fossa mass, a Chiari malformation, or low cerebrospinal fluid (CSF) volume.

Brain tumors are discussed in Chap. 90.

TEMPORAL ARTERITIS (SEE ALSO CHAPS. 32 AND 363)

Temporal (giant cell) arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. It is a common disorder of the elderly; its annual incidence is 77 per 100,000 individuals aged ≥50. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches; indeed, the ischemic optic neuropathy induced by giant cell arteritis is the major cause of rapidly developing bilateral blindness in patients >60 years. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of the disorder is important.

Typical presenting symptoms include headache, polymyalgia rheumatica **(Chap. 363)**, jaw claudication, fever, and weight loss. Headache

is the dominant symptom and often appears in association with malaise and muscle aches. Head pain may be unilateral or bilateral and is located temporally in 50% of patients but may involve any and all aspects of the cranium. Pain usually appears gradually over a few hours before peak intensity is reached; occasionally, it is explosive in onset. The quality of pain is infrequently throbbing; it is almost invariably described as dull and boring, with superimposed episodic stabbing pains similar to the sharp pains that appear in migraine. Most patients can recognize that the origin of their head pain is superficial, external to the skull, rather than originating deep within the cranium (the pain site usually identified by migraineurs). Scalp tenderness is present, often to a marked degree; brushing the hair or resting the head on a pillow may be impossible because of pain. Headache is usually worse at night and often aggravated by exposure to cold. Additional findings may include reddened, tender nodules or red streaking of the skin overlying the temporal arteries, and tenderness of the temporal or, less commonly, the occipital arteries.

The erythrocyte sedimentation rate (ESR) is often, although not always, elevated; a normal ESR does not exclude giant cell arteritis. A temporal artery biopsy followed by immediate treatment with prednisone 80 mg daily for the first 4–6 weeks should be initiated when clinical suspicion is high; treatment should not be unreasonably delayed to obtain a biopsy. The prevalence of migraine among the elderly is substantial, considerably higher than that of giant cell arteritis. Migraineurs often report amelioration of their headache with prednisone; thus, caution must be used when interpreting the therapeutic response.

GLAUCOMA

Glaucoma may present with a prostrating headache associated with nausea and vomiting. The headache often starts with severe eye pain. On physical examination, the eye is often red with a fixed, moderately dilated pupil.

Glaucoma is discussed in Chap. 32.

PRIMARY HEADACHE DISORDERS

Primary headaches are disorders in which headache and associated features occur in the absence of any exogenous cause. The most common are migraine, tension-type headache, and the TACs, notably cluster headache. These entities are discussed in detail in **Chap. 430**.

CHRONIC DAILY OR NEAR-DAILY HEADACHE

The broad description of chronic daily headache (CDH) can be applied when a patient experiences headache on 15 days or more per month. CDH is neither a single entity nor a diagnosis; it encompasses a number of different headache syndromes, both primary and secondary **(Table 16-3)**. In aggregate, this group presents considerable disability and is thus specially mentioned here. Population-based estimates suggest that about 4% of adults have daily or near-daily headache.

TABLE 16-3 Classification of Daily or Near-Daily Headache

Primary		
>4 H DAILY	**<4 H DAILY**	**SECONDARY**
Chronic migraine[a]	Chronic cluster headache[b]	Posttraumatic Head injury Iatrogenic Postinfectious
Chronic tension-type headache[a]	Chronic paroxysmal hemicrania	Inflammatory, such as Giant cell arteritis Sarcoidosis Behçet's syndrome
Hemicrania continua[a]	SUNCT/SUNA	Chronic CNS infection
New daily persistent headache[a]	Hypnic headache	Medication-overuse headache[a]

[a]May be complicated by medication overuse. [b]Some patients may have headache >4 h/d.

Abbreviations: CNS, central nervous system; SUNA, *s*hort-lasting *u*nilateral *n*euralgiform headache *a*ttacks with cranial autonomic symptoms; SUNCT, *s*hort-lasting *u*nilateral *n*euralgiform headache attacks with *c*onjunctival injection and *t*earing.

APPROACH TO THE PATIENT

Chronic Daily Headache

The first step in the management of patients with CDH is to diagnose any secondary headache and treat that problem (Table 16-3). This can sometimes be a challenge when the underlying cause triggers worsening of a primary headache. For patients with primary headaches, diagnosis of the headache type will guide therapy. Preventive treatments such as tricyclics, either amitriptyline or nortriptyline, at doses up to 1 mg/kg, are very useful in patients with CDH arising from migraine or tension-type headache or where the secondary cause has activated the underlying primary headache. Tricyclics are started in low doses (10–25 mg daily) and may be given 12 h before the expected time of awakening in order to avoid excessive morning sleepiness. Medicines including topiramate, valproate, propranolol, flunarizine (not available in the United States), candesartan, and the newer calcitonin gene-related peptide (CGRP) pathway monoclonal antibodies, or gepants-CGRP receptor antagonists (see **Chap. 430**) are also useful when the underlying issue is migraine.

MANAGEMENT OF MEDICALLY INTRACTABLE DISABLING PRIMARY HEADACHE

The management of medically intractable headache is difficult, although recent developments in therapy are at hand. Monoclonal antibodies to CGRP or its receptor have been reported to be effective and well tolerated in chronic migraine and are now licensed for use in clinical practice. Noninvasive neuromodulatory approaches, such as single-pulse transcranial magnetic stimulation and noninvasive vagal nerve stimulation, which appear to modulate thalamic processing or brainstem mechanisms, respectively, in migraine have been used in clinical practice with success. Noninvasive vagal nerve stimulation has also shown promise particularly in chronic cluster headache, chronic paroxysmal hemicrania, and hemicrania continua, and possibly in short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) and short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) **(Chap. 430)**. Other modalities are discussed in **Chap. 430**.

MEDICATION-RELATED AND MEDICATION-OVERUSE HEADACHE

Overuse of analgesic medication for headache can aggravate headache frequency, markedly impair the effect of preventive medicines, and induce a state of refractory daily or near-daily headache called *medication-overuse headache*. A proportion of patients who stop taking analgesics will experience substantial improvement in the severity and frequency of their headache. However, even after cessation of analgesic use, many patients continue to have headache, although they may feel clinically improved in some way, especially if they have been using opioids or barbiturates regularly. The residual symptoms probably represent the underlying primary headache disorder, and most commonly this issue occurs in patients prone to migraine.

Management of Medication Overuse: Outpatients For patients who overuse analgesic medications, it is often helpful to reduce and eliminate the medications, although this approach is far from universally effective. One approach is to reduce the medication dose by 10% every 1–2 weeks. Immediate cessation of analgesic use is possible for some patients, provided there is no contraindication. Both approaches are facilitated by use of a medication diary maintained during the month or two before cessation; this helps to identify the scope of the problem. A small dose of a nonsteroidal anti-inflammatory drug (NSAID) such as naproxen, 500 mg bid, if tolerated, will help relieve residual pain as analgesic use is reduced.

NSAID overuse is not usually a problem for patients with daily headache when an NSAID with a longer half-life is taken once or twice daily; however, overuse problems may develop with shorter-acting NSAIDS. Once the patient has substantially reduced analgesic use, a preventive medication should be introduced. Another widely used approach is to commence the preventive at the same time the analgesic reduction is started. It must be emphasized that *preventives may not work in the presence of analgesic overuse, particularly with opioids*. The most common cause of unresponsiveness to treatment is the use of a preventive when analgesics continue to be used regularly. For some patients, discontinuing analgesics is very difficult; often the best approach is to inform the patient that some degree of headache is inevitable during this initial period.

Management of Medication Overuse: Inpatients Some patients will require hospitalization for detoxification. Such patients have typically failed efforts at outpatient withdrawal or have a significant medical condition, such as diabetes mellitus or epilepsy, which would complicate withdrawal as an outpatient. Following admission to the hospital, medications are withdrawn completely on the first day, in the absence of a contraindication. Antiemetics and fluids are administered as required; clonidine is used for opioid withdrawal symptoms. For acute intolerable pain during the waking hours, aspirin, 1 g IV (not approved in the United States), is useful. IM chlorpromazine can be helpful at night; patients must be adequately hydrated. Three to five days into the admission, as the effect of the withdrawn substance wears off, a course of IV dihydroergotamine (DHE) can be used. DHE, administered every 8 h for 5 consecutive days, a treatment that is not stopped short if headache settles, can induce a significant remission that allows a preventive treatment to be established. Serotonin 5-HT_3 receptor antagonists, such as ondansetron or granisetron, or the neurokinin receptor antagonist, aprepitant, may be required with DHE to prevent significant nausea, and domperidone (not approved in the United States) orally or by suppository can be very helpful. Avoiding sedating or otherwise side effect–prone antiemetics is helpful.

NEW DAILY PERSISTENT HEADACHE

New daily persistent headache (NDPH) is a clinically distinct syndrome with important secondary causes; these are listed in **Table 16-4**.

Clinical Presentation NDPH presents with headache on most if not all days, and the patient can clearly, and often vividly, recall the moment of onset. The headache usually begins abruptly, but onset may be more gradual; evolution over 3 days has been proposed as the upper limit for this syndrome. Patients typically recall the exact day and circumstances of the onset of headache; the new, persistent head pain does not remit. The first priority is to distinguish between a primary and a secondary cause of this syndrome. Subarachnoid hemorrhage is the most serious of the secondary causes and must be excluded either by history or appropriate investigation **(Chap. 429)**.

Secondary NDPH • **Low CSF Volume Headache** In these syndromes, head pain is positional: it begins when the patient sits or stands upright and resolves upon reclining. The pain, which is occipitofrontal, is usually a dull ache but may be throbbing. Patients with chronic low CSF volume headache typically present with a history of headache from one day to the next that is generally not present on waking but worsens during the day. Recumbency usually improves the headache within minutes, and it can take only minutes to an hour for the pain to return when the patient resumes an upright position.

The most common cause of headache due to persistent low CSF volume is CSF leak following LP **(Chap. S9)**. Post-LP headache usually begins within 48 h but may be delayed for up to 12 days. Its incidence is between 10% and 30%. Beverages with caffeine may provide temporary relief. Besides LP, index events may include epidural injection or a vigorous Valsalva maneuver, such as from lifting, straining, coughing, clearing the eustachian tubes in an airplane, or multiple orgasms. Spontaneous CSF leaks are well recognized, and the diagnosis should be considered whenever the headache history is typical, even when there is no obvious index event. As time passes from the index event, the postural nature may become less apparent; cases in which the index event occurred several years before the eventual diagnosis have been recognized. Symptoms appear to result from low volume rather than low pressure: although low CSF pressures, typically 0–50 mm CSF, are usually identified, a pressure as high as 140 mm CSF has been noted with a documented leak.

Postural orthostatic tachycardia syndrome (POTS; **Chap. 440**) can present with orthostatic headache similar to low CSF volume headache and is a diagnosis that needs consideration in this setting.

When imaging is indicated to identify the source of a presumed leak, an MRI with gadolinium is the initial study of choice **(Fig. 16-1)**. A striking pattern of diffuse meningeal enhancement is so typical that in the appropriate clinical context the diagnosis is established. Chiari malformations may sometimes be noted on MRI; in such cases, surgery to decompress the posterior fossa is *not* indicated and usually worsens the headache. Spinal MRI with T2 weighting may reveal a leak, and spinal MRI may demonstrate spinal meningeal cysts whose role in these syndromes is yet to be elucidated. The source of CSF leakage may be identified by spinal MRI with appropriate sequences, or by CT, preferably digital subtraction, myelography. In the absence of a directly identified site of leakage, 111In-DTPA CSF studies may demonstrate early emptying of the tracer into the bladder or slow progress of tracer across the brain suggesting a CSF leak; this procedure is now only rarely employed.

TABLE 16-4 Differential Diagnosis of New Daily Persistent Headache

PRIMARY	SECONDARY
Migrainous-type	Subarachnoid hemorrhage
Featureless (tension-type)	Low cerebrospinal fluid (CSF) volume headache
	Raised CSF pressure headache
	Posttraumatic headache[a]
	Chronic meningitis

[a]Includes postinfectious forms.

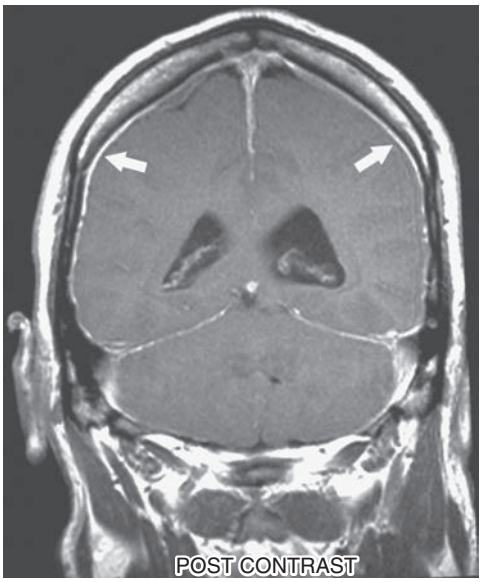

FIGURE 16-1 Magnetic resonance image showing diffuse meningeal enhancement after gadolinium administration in a patient with low cerebrospinal fluid (CSF) volume headache.

Initial treatment for low CSF volume headache is bed rest. For patients with persistent pain, IV caffeine (500 mg in 500 mL of saline administered over 2 h) can be very effective. An electrocardiogram (ECG) to screen for arrhythmia should be performed before administration. It is reasonable to administer at least two infusions of caffeine before embarking on additional tests to identify the source of the CSF leak. Because IV caffeine is safe and can be curative, it spares many patients the need for further investigations. If unsuccessful, an abdominal binder may be helpful. If a leak can be identified, an autologous blood patch is usually curative. A blood patch is also effective for post-LP headache; in this setting, the location is empirically determined to be the site of the LP. In patients with intractable headache, oral theophylline is a useful alternative that can take some months to be effective.

Raised CSF Pressure Headache Raised CSF pressure is well recognized as a cause of headache. Brain imaging can often reveal the cause, such as a space-occupying lesion.

Idiopathic intracranial hypertension (pseudotumor cerebri) NDPH due to raised CSF pressure can be the presenting symptom for patients with idiopathic intracranial hypertension, a disorder associated with obesity, female gender, and, on occasion, pregnancy. The syndrome can also occur without visual problems, particularly when the fundi are normal. These patients typically present with a history of generalized headache that is present on waking and improves as the day goes on. It is generally present on awakening in the morning and is worse with recumbency. Transient visual obscurations are frequent and may occur when the headaches are most severe. The diagnosis is relatively straightforward when papilledema is present, but the possibility must be considered even in patients without funduscopic changes. Formal visual field testing should be performed even in the absence of overt ophthalmic involvement. Partial obstructions of the cerebral venous sinuses are found in a small number of cases. In addition, persistently raised intracranial pressure can trigger a syndrome of chronic migraine. Other conditions that characteristically produce headache on rising in the morning or nocturnal headache are obstructive sleep apnea or poorly controlled hypertension.

Evaluation of patients suspected to have raised CSF pressure requires brain imaging. It is most efficient to obtain an MRI, including an MR venogram, as the initial study. If there are no contraindications, the CSF pressure should be measured by LP; this should be done when the patient is symptomatic so that both the pressure and the response to removal of 20–30 mL of CSF can be determined. An elevated opening pressure and improvement in headache following removal of CSF are diagnostic in the absence of fundal changes.

Initial treatment is with acetazolamide (250–500 mg bid); the headache may improve within weeks. If ineffective, topiramate is the next treatment of choice; it has many actions that may be useful in this setting, including carbonic anhydrase inhibition, weight loss, and neuronal membrane stabilization, likely mediated via effects on phosphorylation pathways. Severely disabled patients who do not respond to medical treatment require intracranial pressure monitoring and may require shunting. If appropriate, weight loss should be encouraged.

Posttraumatic Headache A traumatic event can trigger a headache process that lasts for many months or years after the event. The term *trauma* is used here in a very broad sense: headache can develop following an injury to the head, but it can also develop after an infectious episode, typically viral meningitis; a flulike illness; or a parasitic infection. Complaints of dizziness, vertigo, and impaired memory can accompany the headache. Symptoms may remit after several weeks or persist for months and even years after the injury. Typically, the neurologic examination is normal and CT or MRI studies are unrevealing. Chronic subdural hematoma may on occasion mimic this disorder. Posttraumatic headache may also be seen after carotid dissection and subarachnoid hemorrhage and after intracranial surgery. The underlying theme appears to be that a traumatic event involving the pain-producing meninges can trigger a headache process that lasts for many years.

Other Causes In one series, one-third of patients with NDPH reported headache beginning after a transient flulike illness characterized by fever, neck stiffness, photophobia, and marked malaise. Evaluation typically reveals no apparent cause for the headache. There is no convincing evidence that persistent Epstein-Barr virus infection plays a role in NDPH. A complicating factor is that many patients undergo LP during the acute illness; iatrogenic low CSF volume headache must be considered in these cases.

Treatment Treatment is largely empirical and directed at the headache phenotype. Tricyclic antidepressants, notably amitriptyline, and anticonvulsants, such as topiramate, valproate, candesartan, and gabapentin, have been used with reported benefit. The monoamine oxidase inhibitor phenelzine may also be useful in carefully selected patients. The headache usually resolves within 3–5 years, but it can be quite disabling.

PRIMARY CARE AND HEADACHE MANAGEMENT

Most patients with headache will be seen first in a primary care setting. The challenging task of the primary care physician is to identify the very few worrisome secondary headaches from the very great majority of primary and less dangerous secondary headaches **(Table 16-2)**.

Absent any warning signs, a reasonable approach is to treat when a diagnosis is established. As a general rule, the investigation should focus on identifying worrisome causes of headache or on helping the patient to gain confidence if no primary headache diagnosis can be made.

After treatment has been initiated, follow-up care is essential to identify whether progress has been made against the headache complaint. Not all headaches will respond to treatment, but, in general, worrisome headaches will progress and will be easier to identify.

When a primary care physician feels the diagnosis is a primary headache disorder, it is worth noting that >90% of patients who present to primary care with a complaint of headache will have migraine **(Chap. 430)**.

In general, patients who do not have a clear diagnosis, have a primary headache disorder other than migraine or tension-type headache, or are unresponsive to two or more standard therapies for the considered headache type, should be considered for referral to a specialist. In a practical sense, the threshold for referral is also determined by the experience of the primary care physician in headache medicine and the availability of secondary care options.

17 Back and Neck Pain

John W. Engstrom

The importance of back and neck pain in our society is underscored by the following: (1) the cost of chronic back pain in the United States is estimated at more than $200 billion annually; approximately one-third of this cost is due to direct health care expenses and two-thirds are indirect costs resulting from loss of wages and productivity; (2) back symptoms are the most common cause of disability in individuals <45 years of age; (3) low back pain (LBP) is the second most common reason for visiting a physician in the United States; and (4) more than four out of five people will experience significant back pain at some point in their lives.

ANATOMY OF THE SPINE

The anterior spine consists of cylindrical vertebral bodies separated by intervertebral disks and stabilized by the anterior and posterior longitudinal ligaments. The intervertebral disks are composed of a central gelatinous nucleus pulposus surrounded by a tough cartilaginous ring, the annulus fibrosis. Disks are responsible for 25% of spinal column length and allow the bony vertebrae to move easily upon each other **(Figs. 17-1 and 17-2)**. Desiccation of the nucleus pulposus and degeneration of the annulus fibrosus worsen with age, resulting in loss of disk height. The disks are largest in the cervical and lumbar regions where movements of the spine are greatest. The anterior spine absorbs the shock of bodily movements such as walking and running, and with the posterior spine protects the spinal cord and nerve roots in the spinal canal.

The posterior spine consists of the vertebral arches and processes. Each arch consists of paired cylindrical pedicles anteriorly and paired lamina posteriorly. The vertebral arch also gives rise to two transverse processes laterally, one spinous process posteriorly, plus two superior and two inferior articular facets. The apposition of a superior and inferior facet constitutes a *facet joint*. The posterior spine provides an anchor for the attachment of muscles and ligaments. The contraction of muscles attached to the spinous and transverse processes and lamina works like a system of pulleys and levers producing flexion, extension, rotation, and lateral bending movements of the spine.

Nerve root injury (*radiculopathy*) is a common cause of pain in the neck and arm, or low back and buttock, or leg **(see dermatomes in Figs. 25-2 and 25-3)**. Each nerve root exits just above its corresponding vertebral body in the cervical region (e.g., the C7 nerve root exits at the C6-C7 level), and just below the vertebral body in the thoracic and lumbar spine (e.g., the T1 nerve root exits at the T1-T2 level). The cervical nerve roots follow a short intraspinal course before exiting. In contrast, because the spinal cord ends at the L1 or L2 vertebral level, the lumbar nerve roots follow a long intraspinal course and can be injured anywhere along its path. For example, disk herniation at the L4-L5 level can produce L4 root compression laterally, but more often compression of the traversing L5 nerve root occurs **(Fig. 17-3)**. The lumbar nerve roots are mobile in the spinal canal, but eventually pass through the narrow *lateral recess* of the spinal canal and *intervertebral*

foramen (Figs. 17-2 and 17-3). When imaging the spine, both sagittal and axial views are needed to assess possible compression at these sites.

Beginning at the C3 level, each cervical (and the first thoracic) vertebral body projects a lateral bony process upward—the uncinate process. The uncinate process articulates with the cervical vertebral body above via the uncovertebral joint. The uncovertebral joint can hypertrophy with age and contribute to neural foraminal narrowing and cervical radiculopathy.

Pain-sensitive structures of the spine include the periosteum of the vertebrae, dura, facet joints, annulus fibrosus of the intervertebral disk, epidural veins and arteries, and the longitudinal ligaments. Disease of these diverse structures may explain many cases of back pain without nerve root compression. Under normal circumstances, the nucleus pulposus of the intervertebral disk is not pain sensitive.

APPROACH TO THE PATIENT

Back Pain

TYPES OF BACK PAIN

Delineating the type of pain reported by the patient is the essential first step. Attention is also focused on identifying risk factors for a serious underlying etiology. The most frequent serious causes of back pain are radiculopathy, fracture, tumor, infection, or referred pain from visceral structures **(Table 17-1)**.

Local pain is caused by injury to pain-sensitive structures that compress or irritate sensory nerve endings. The site of the pain is near the affected part of the back.

Pain referred to the back may arise from abdominal or pelvic viscera. The pain is usually described as primarily abdominal or pelvic, accompanied by back pain, and usually unaffected by posture. The patient may occasionally complain of back pain only.

Pain of spine origin may be located in the back or referred to the buttocks or legs. Diseases affecting the upper lumbar spine tend to refer pain to the lumbar region, groin, or anterior thighs. Diseases affecting the lower lumbar spine tend to produce pain referred to the buttocks, posterior thighs, calves, or feet. Referred pain often explains pain syndromes that cross multiple dermatomes without evidence of nerve or nerve root injury.

TABLE 17-1 Acute Low Back Pain: Risk Factors for an Important Structural Cause

History
Pain worse at rest or at night
Prior history of cancer
History of chronic infection (especially lung, urinary tract, skin, poor dentition)
History of trauma
Incontinence
Age >70 years
Intravenous drug use
Glucocorticoid use
History of a rapidly progressive neurologic deficit
Examination
Unexplained fever
Unexplained weight loss
Focal palpation/percussion tenderness over the midline spine
Abdominal, rectal, or pelvic mass
Internal/external rotation of the leg at the hip
Straight-leg or reverse straight-leg raising signs
Progressive focal neurologic deficit

Radicular pain is typically sharp and radiates from the low back to a leg within the territory of a nerve root (see "Lumbar Disk Disease," below). Coughing, sneezing, or voluntary contraction of abdominal muscles (lifting heavy objects or straining at stool) may elicit or worsen the radiating pain. The pain may also increase in postures that stretch the nerves and nerve roots. Sitting with the leg outstretched places traction on the sciatic nerve and L5 and S1 roots because the sciatic nerve passes posterior to the hip. The femoral nerve (L2, L3, and L4 roots) passes anterior to the hip and is not stretched by sitting. The description of the pain alone often fails to distinguish between referred pain and radiculopathy, although a burning or electric quality favors radiculopathy.

Pain associated with muscle spasm is commonly associated with many spine disorders. The spasms may be accompanied by an abnormal posture, tense paraspinal muscles, and dull or achy pain in the paraspinal region.

Knowledge of the circumstances associated with the onset of back pain is important when weighing possible serious underlying causes for the pain. Some patients involved in accidents or work-related injuries may exaggerate their pain for the purpose of compensation or for psychological reasons.

EXAMINATION

A complete physical examination including vital signs, heart and lungs, abdomen and rectum, and limbs is advisable. Back pain referred from visceral organs may be reproduced during palpation of the abdomen (pancreatitis, abdominal aortic aneurysm [AAA]) or percussion over the costovertebral angles (pyelonephritis).

The normal spine has a cervical and lumbar lordosis and a thoracic kyphosis. Exaggeration of these normal alignments may result in hyperkyphosis of the thoracic spine or hyperlordosis of the lumbar spine. Inspection of the back may reveal a lateral curvature of the spine (scoliosis). A midline hair tuft, skin dimpling or pigmentation, or a sinus tract may indicate a congenital spine anomaly. Asymmetry in the prominence of the paraspinal muscles suggests muscle spasm. Palpation over the spinous process transmits force to the entire vertebrae and suggests vertebral pathology.

Flexion at the hips is normal in patients with lumbar spine disease, but flexion of the lumbar spine is limited and sometimes painful. Lateral bending to the side opposite the injured spinal element may stretch the damaged tissues, worsen pain, and limit motion. Hyperextension of the spine (with the patient prone or standing) is limited when nerve root compression, facet joint pathology, or other bony spine disease is present.

Pain from hip disease may mimic the pain of lumbar spine disease. Hip pain can be reproduced by passive internal and external rotation at the hip with the knee and hip in flexion or by percussing the heel with the examiner's palm with the leg extended (heel percussion sign).

The *straight-leg raising (SLR)* maneuver is a simple bedside test for nerve root disease. With the patient supine, passive straight-leg flexion at the hip stretches the L5 and S1 nerve roots and the sciatic nerve; dorsiflexion of the foot during the maneuver adds to the stretch. In healthy individuals, flexion to at least 80° is normally possible without causing pain, although a tight, stretching sensation in the hamstring muscles is common. The SLR test is positive if the maneuver reproduces the patient's usual back or limb pain. Eliciting the SLR sign in both the supine and sitting positions can help determine if the finding is reproducible. The patient may describe pain in the low back, buttocks, posterior thigh, or lower leg, but the *key feature is reproduction of the patient's usual pain*. The *crossed SLR sign* is present when flexion of one leg reproduces the usual pain in the opposite leg or buttocks. In disk herniation, the crossed SLR sign is less sensitive but more specific than the SLR sign. The *reverse SLR sign* is elicited by standing the patient next to the examination table and passively extending each leg with the knee fully extended. This maneuver, which stretches the L2-L4 nerve roots, lumbosacral plexus, and femoral nerve, is considered positive if the patient's usual back or limb pain is reproduced. For all of these tests, the nerve or nerve root lesion is always on the side of the pain. Examination of the unaffected leg first provides a control test, ensures mutual understanding of test parameters, and enhances test utility.

The neurologic examination includes a search for focal weakness or muscle atrophy, localized reflex changes, diminished sensation in the legs, or signs of spinal cord injury. The examiner should be alert to the possibility of breakaway weakness, defined as fluctuations in the maximum power generated during muscle testing. Breakaway weakness may be due to pain, inattention, or a combination of pain and underlying true weakness. Breakaway weakness without pain is usually due to a lack of effort. In uncertain cases, electromyography (EMG) can determine if true weakness due to nerve tissue injury is present. Findings with specific lumbosacral nerve root lesions are shown in **Table 17-2** and are discussed below.

LABORATORY, IMAGING, AND EMG STUDIES

Laboratory studies are rarely needed for the initial evaluation of nonspecific acute (<3 months duration) low back pain (ALBP).

TABLE 17-2 Lumbosacral Radiculopathy: Neurologic Features

LUMBOSACRAL NERVE ROOT	EXAMINATION FINDINGS			PAIN DISTRIBUTION
	REFLEX	SENSORY	MOTOR	
L2[a]	—	Upper anterior thigh	Psoas (hip flexors)	Anterior thigh
L3[a]	—	Lower anterior thigh Anterior knee	Psoas (hip flexors) Quadriceps (knee extensors) Thigh adductors	Anterior thigh, knee
L4[a]	Quadriceps (knee)	Medial calf	Quadriceps (knee extensors)[b] Thigh adductors	Knee, medial calf Anterolateral thigh
L5[c]	—	Dorsal surface—foot Lateral calf	Peronei (foot evertors)[b] Tibialis anterior (foot dorsiflexors) Gluteus medius (leg abductors) Toe dorsiflexors	Lateral calf, dorsal foot, posterolateral thigh, buttocks
S1[c]	Gastrocnemius/soleus (ankle)	Plantar surface—foot Lateral aspect—foot	Gastrocnemius/soleus (foot plantar flexors)[b] Abductor hallucis (toe flexors)[b] Gluteus maximus (leg extensors)	Bottom foot, posterior calf, posterior thigh, buttocks

[a]Reverse straight-leg raising sign may be present—see "Examination of the Back." [b]These muscles receive the majority of innervation from this root. [c]Straight-leg raising sign may be present—see "Examination of the Back."

Risk factors for a serious underlying cause and for infection, tumor, or fracture in particular should be sought by history and examination. If risk factors are present (Table 17-1), then laboratory studies (complete blood count [CBC], erythrocyte sedimentation rate [ESR], urinalysis) are indicated. If risk factors are absent, then management is conservative (see "Treatment," below).

CT scanning is used as a primary screening modality for acute trauma that is moderate to severe. CT is superior to x-rays for detection of fractures involving posterior spine structures, craniocervical and cervicothoracic junctions, C1 and C2 vertebrae, bone fragments in the spinal canal, or misalignment. MRI or CT myelography is the radiologic test of choice for evaluation of most serious diseases involving the spine. MRI is superior for the definition of soft tissue structures, whereas CT myelography provides optimal imaging of the lateral recess of the spinal canal, defines bony abnormalities, and is tolerated by claustrophobic patients.

Population surveys in the United States suggest that patients with back pain report greater functional limitations in recent years, despite rapid increases in spine imaging, opioid prescribing, injections, and spine surgery. This suggests that more selective use of diagnostic and treatment modalities may be reasonable for many patients. One prospective case-control study found that older adults with back pain of less than 6 weeks duration who received spine imaging as part of a primary care visit had no better outcomes than the control group.

Spine imaging often reveals abnormalities of dubious clinical relevance that may alarm clinicians and patients alike and prompt further testing and unnecessary therapy. When imaging tests are reviewed, it is important to remember that degenerative findings are common in normal, pain-free individuals. Randomized trials and observational studies have suggested that imaging can have a "cascade effect," creating a gateway to other unnecessary care. Interventions have included physician education and computerized decision support within the electronic medical record to require specific indications for approval of imaging tests. Other strategies have included audit and feedback of individual practitioners' rates of ordering, more rapid access to physical therapy, or consultation with spine experts for patients without imaging indications.

Educational tools created by the America College of Physicians for patients and the public have included "Five Things Physicians and Patients Should Question": (1) Do not recommend advanced imaging (e.g., MRI) of the spine within the first 6 weeks in patients with nonspecific ALBP in the absence of red flags. (2) Do not perform elective spinal injections without imaging guidance, unless contraindicated. (3) Do not use bone morphogenetic protein (BMP) for routine anterior cervical spine fusion surgery. (4) Do not use EMG and nerve conduction studies (NCSs) to determine the cause of purely midline lumbar, thoracic, or cervical spine pain. (5) Do not recommend bed rest for >48 h when treating LBP. In an observational study, application of this strategy was associated with lower rates of repeat imaging, opioid use, and referrals for physical therapy.

Electrodiagnostic studies can be used to assess the functional integrity of the peripheral nervous system **(Chap. 446)**. Sensory NCSs are normal when focal sensory loss confirmed by examination is due to nerve root damage because the nerve roots are proximal to the nerve cell bodies in the dorsal root ganglia. Injury to nerve tissue distal to the dorsal root ganglion (e.g., plexus or peripheral nerve) results in reduced sensory nerve signals. Needle EMG complements NCSs by detecting denervation or reinnervation changes in a myotomal (segmental) distribution. Multiple muscles supplied by different nerve roots and nerves are sampled; the pattern of muscle involvement indicates the nerve root(s) responsible for the injury. Needle EMG provides objective information about motor nerve fiber injury when clinical evaluation of weakness is limited by pain or poor effort. EMG and NCSs will be normal when sensory nerve root injury or irritation is the pain source.

The COVID-19 pandemic has disrupted and complicated the care of patients with LBP. Paraspinal myalgias may result in LBP. The sedentary lifestyle resulting from quarantine is associated with an increased frequency or severity of LBP. Fear of infection risk has also prevented many patients from seeking needed care. Video-telemedicine visits can help identify patients with underlying risks for a serious cause and inform appropriate next steps in management.

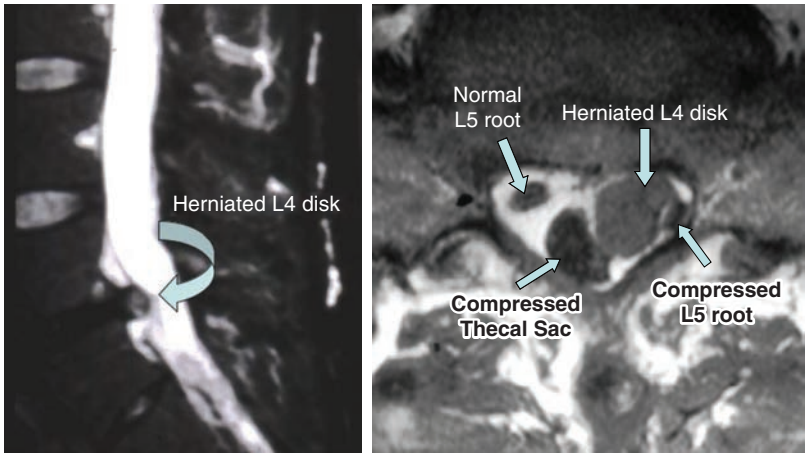
CAUSES OF BACK PAIN (TABLE 17-3)

LUMBAR DISK DISEASE

Lumbar disk disease is a common cause of acute, chronic, or recurrent low back and leg pain **(Figs. 17-3 and 17-4)**. Disk disease is most likely to occur at the L4-L5 or L5-S1 levels, but upper lumbar levels can also be involved. The cause is often unknown, but the risk is increased in overweight individuals. Disk herniation is unusual prior to age 20 years and is rare in the fibrotic disks of the elderly. Complex genetic factors may play a role in predisposition. The pain may be located in the low back only or referred to a leg, buttock, or hip. A sneeze, cough, or trivial movement may cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. With severe disk disease, the nucleus can protrude through the annulus (herniation) or become extruded to lie as a free fragment in the spinal canal.

TABLE 17-3 Causes of Back or Neck Pain

Lumbar or Cervical Disk Disease
Degenerative Spine Disease
Lumbar spinal stenosis without or with neurogenic claudication
Intervertebral foraminal or lateral recess narrowing
Disk-osteophyte complex
Facet or uncovertebral joint hypertrophy
Lateral disk protrusion
Spondylosis (osteoarthritis), spondylolisthesis, or spondylolysis
Spine Infection
Vertebral osteomyelitis
Spinal epidural abscess
Septic disk (diskitis)
Meningitis
Lumbar arachnoiditis
Neoplasms
Metastatic with/without pathologic fracture
Primary Nervous System: Meningioma, neurofibroma, schwannoma
Primary Bone: chordoma, osteoma
Trauma
Strain or sprain
Whiplash injury
Trauma/falls, motor vehicle accidents
Metabolic Spine Disease
Osteoporosis with/without pathologic fracture—hyperparathyroidism, immobility
Osteosclerosis (e.g., Paget's disease)
Congenital/Developmental
Spondylolysis
Kyphoscoliosis
Spina bifida occulta
Tethered spinal cord
Autoimmune Inflammatory Arthritis
Other Causes of Back Pain
Referred pain from visceral disease (e.g., abdominal aortic aneurysm)
Postural
Psychiatric, malingering, chronic pain syndromes



A *B*

FIGURE 17-4 Disk herniation. ***A***. Sagittal T2-weighted image on the left side of the spinal canal reveals disk herniation at the L4-L5 level. ***B***. Axial T1-weighted image shows paracentral disk herniation with displacement of the thecal sac medially and the left L5 nerve root posteriorly in the left lateral recess.

The mechanism by which intervertebral disk injury causes back pain is uncertain. The inner annulus fibrosus and nucleus pulposus are normally devoid of innervation. Inflammation and production of proinflammatory cytokines within a ruptured nucleus pulposus may trigger or perpetuate back pain. Ingrowth of nociceptive (pain) nerve fibers into the nucleus pulposus of a diseased disk may be responsible for some cases of chronic "diskogenic" pain. Nerve root injury (radiculopathy) from disk herniation is usually due to inflammation, but lateral herniation may produce compression in the lateral recess or intervertebral foramen.

A ruptured disk may be asymptomatic or cause back pain, limited spine motion (particularly flexion), a focal neurologic deficit, or radicular pain. A dermatomal pattern of sensory loss or a reduced or absent deep tendon reflex is more suggestive of a specific root lesion than is the pattern of pain. Motor findings (focal weakness, muscle atrophy, or fasciculations) occur less frequently than focal sensory or reflex changes. Symptoms and signs are usually unilateral, but bilateral involvement does occur with large central disk herniations that involve roots bilaterally or cause inflammation of nerve roots within the spinal canal. Clinical manifestations of specific nerve root lesions are summarized in Table 17-2.

The differential diagnosis covers a variety of serious and treatable conditions, including epidural abscess, hematoma, fracture, or tumor. Fever, constant pain uninfluenced by position, sphincter abnormalities, or signs of myelopathy suggest an etiology other than lumbar disk disease. Absent ankle reflexes can be a normal finding in persons >60 years or a sign of bilateral S1 radiculopathies. An absent deep tendon reflex or focal sensory loss may indicate injury to a nerve root, but other sites of injury along the nerve must also be considered. As examples, an absent knee reflex may be due to a femoral neuropathy or an L4 nerve root injury; loss of sensation over the foot and lateral lower calf may result from a peroneal or lateral sciatic neuropathy, or an L5 nerve root injury. Focal muscle atrophy may reflect injury to the anterior horn cells of the spinal cord, a nerve root, peripheral nerve, or disuse.

A lumbar spine MRI scan or CT myelogram can often confirm the location and type of pathology. Spine MRIs yield exquisite views of intraspinal and adjacent soft tissue anatomy, whereas bony lesions of the lateral recess or intervertebral foramen are optimally visualized by CT myelography. The correlation of neuroradiologic findings to clinical symptoms, particularly pain, is not simple. Contrast-enhancing tears in the annulus fibrosus or disk protrusions are widely accepted as common sources of back pain; however, studies have found that many asymptomatic adults have similar radiologic findings. Entirely asymptomatic disk protrusions are also common, occurring in up to one-third of adults, and these may also enhance with contrast. Furthermore, in patients with known disk herniation treated either medically or surgically, persistence of the herniation 10 years later had no relationship to the clinical outcome. In summary, MRI findings of disk protrusion, tears in the annulus fibrosus, or hypertrophic facet joints are common incidental findings that, by themselves, should not dictate management decisions for patients with back pain.

The diagnosis of nerve root injury is most secure when the history, examination, results of imaging studies, and the EMG are concordant. There is often good correlation between CT and EMG findings for localization of nerve root injury.

Management of lumbar disk disease is discussed below.

Cauda equina syndrome (*CES*) signifies an injury of multiple lumbosacral nerve roots within the spinal canal distal to the termination of the spinal cord at L1-L2. LBP, weakness and areflexia in the legs, saddle anesthesia, or loss of bladder function may occur. The problem must be distinguished from disorders of the lower spinal cord (conus medullaris syndrome), acute transverse myelitis **(Chap. 442)**, and Guillain-Barré syndrome **(Chap. 447)**. Combined involvement of the conus medullaris and cauda equina can occur. CES is most commonly due to a large ruptured lumbosacral intervertebral disk, but other causes include lumbosacral spine fracture, hematoma within the spinal canal (sometimes following lumbar puncture in patients with coagulopathy), and tumor or other compressive mass lesions. Treatment is usually surgical decompression, sometimes on an urgent basis in an attempt to restore or preserve motor or sphincter function, or radiotherapy for metastatic tumors **(Chap. 90)**.

DEGENERATIVE CONDITIONS

Lumbar spinal stenosis (*LSS*) describes a narrowed lumbar spinal canal. *Neurogenic claudication* consists of pain, typically in the back and buttocks or legs, that is brought on by walking or standing and relieved by sitting. Unlike vascular claudication, symptoms are often provoked by standing without walking. Unlike lumbar disk disease, symptoms are usually relieved by sitting. Patients with neurogenic claudication can often walk much farther when leaning over a shopping cart and can pedal a stationary bike with ease while sitting. These flexed positions increase the anteroposterior spinal canal diameter and reduce intraspinal venous hypertension, producing pain relief. Focal weakness, sensory loss, or reflex changes may occur when spinal stenosis is associated with neural foraminal narrowing and radiculopathy. Severe neurologic deficits, including paralysis and urinary incontinence, occur only rarely.

LSS by itself is common (6–7% of adults) and is usually asymptomatic. Symptoms are correlated with severe spinal canal stenosis. LSS is most often acquired (75%) but can also be congenital or due to a mixture of both etiologies. Congenital forms (achondroplasia and idiopathic) are characterized by short, thick pedicles that produce both spinal canal and lateral recess stenosis. Acquired factors that contribute to spinal stenosis include degenerative diseases (spondylosis, spondylolisthesis, and scoliosis), trauma, spine surgery, metabolic or endocrine disorders (epidural lipomatosis, osteoporosis, acromegaly, renal osteodystrophy, and hypoparathyroidism), and Paget's disease. MRI provides the best definition of the abnormal anatomy **(Fig. 17-5)**.

LSS accompanied by neurogenic claudication responds to surgical decompression of the stenotic segments. The same processes leading to LSS may cause lumbar foraminal or lateral recess narrowing resulting in coincident lumbar radiculopathy that may require treatment as well.

Conservative treatment of symptomatic LSS can include nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, exercise programs, and symptomatic treatment of acute pain episodes. There is insufficient evidence to support the routine use of epidural glucocorticoid injections. Surgery is considered when medical therapy does not relieve symptoms sufficiently to allow for resumption of activities of

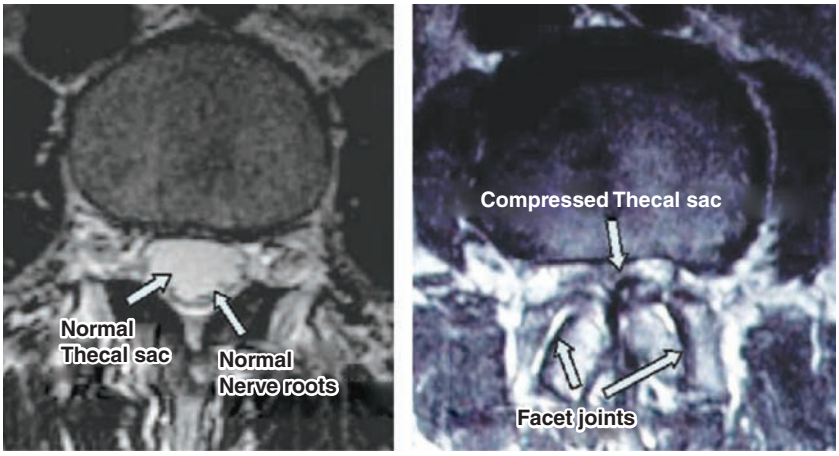


FIGURE 17-5 Spinal stenosis. ***A***. An axial T2-weighted image of the normal lumbar spine shows a normal thecal sac within the lumbar spinal canal. The thecal sac is bright. The lumbar roots are seen as dark punctate dots located posteriorly in the thecal sac. ***B***. The thecal sac is not well visualized due to severe lumbar spinal canal stenosis, partially the result of hypertrophic facet joints.

daily living or when focal neurologic signs are present. Most patients with neurogenic claudication who are treated medically do not improve over time. Surgical management with laminectomy, which increases the spinal canal diameter and reduces venous hypertension, can produce significant relief of exertional back and leg pain, leading to less disability and improved functional outcomes. Laminectomy and fusion is usually reserved for patients with LSS and spondylolisthesis. Predictors of a poor surgical outcome include impaired walking preoperatively, depression, cardiovascular disease, and scoliosis. Up to one-quarter of surgically treated patients develop recurrent stenosis at the same or an adjacent spinal level within 7–10 years; recurrent symptoms usually respond to a second surgical decompression.

Neural foraminal narrowing or lateral recess stenosis with radiculopathy is a common consequence of osteoarthritic processes that cause LSS (**Figs.** 17-1 and **17-6**), including osteophytes, lateral disk protrusion, calcified disk-osteophytes, facet joint hypertrophy, uncovertebral joint hypertrophy (in the cervical spine), congenitally shortened pedicles, or, frequently, a combination of these processes. Neoplasms (primary or metastatic), fractures, infections (epidural abscess), or hematomas are less frequent causes. Most common is bony foraminal narrowing leading to nerve root ischemia and persistent symptoms, in contrast to inflammation that is associated with a paracentral herniated disk and radiculopathy. These conditions can produce unilateral nerve root symptoms or signs due to compression at the intervertebral foramen or in the lateral recess; symptoms are indistinguishable from disk-related radiculopathy, but treatment may differ depending on the etiology. The history and neurologic examination alone cannot distinguish between these possibilities. Neuroimaging (CT or MRI) is required to identify the anatomic cause. Neurologic findings from the examination and EMG can help direct the attention of the radiologist to specific nerve roots, especially on axial images. For *facet joint hypertrophy with foraminal stenosis,* surgical foraminotomy produces long-term relief of leg and back pain in 80–90% of patients. Facet joint or medial branch blocks for back or neck pain are sometimes used to help determine the anatomic origin of back pain or for treatment, but there is a lack of clinical data to support their utility. Medical causes of lumbar or cervical radiculopathy unrelated to primary spine disease include infections (e.g., herpes zoster and Lyme disease), carcinomatous meningitis, diabetes, and root avulsion or traction (trauma).

SPONDYLOSIS AND SPONDYLOLISTHESIS

Spondylosis, or osteoarthritic spine disease, typically occurs in later life and primarily involves the cervical and lumbosacral spine. Patients often complain of back pain that increases with movement, is associated with stiffness, and is better with inactivity. The relationship between clinical symptoms and radiologic findings is usually not straightforward. Pain may be prominent when MRI, CT, or x-ray findings are minimal, and prominent degenerative spine disease can be seen in asymptomatic patients. Osteophytes, combined

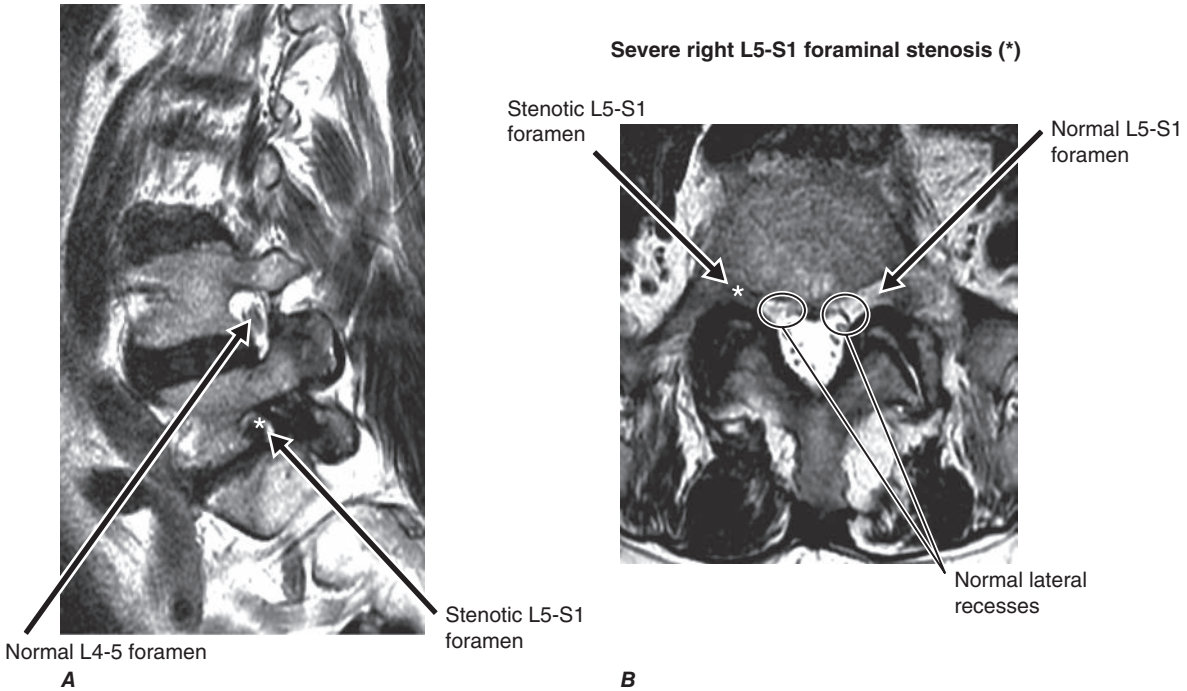

FIGURE 17-6 Foraminal stenosis. ***A***. Sagittal T2-weighted image reveals normal high signal around the exiting right L4 nerve root in the right neural foramen at L4-L5; effacement of the high signal is noted one level below at L5-S1, due to severe foraminal stenosis. ***B***. Axial T2-weighted image at the L5-S1 level demonstrates normal lateral recesses bilaterally, a normal intervertebral foramen on the left, but a severely stenotic foramen (*) on the right.

disk-osteophytes, or a thickened ligamentum flavum may cause or contribute to central spinal canal stenosis, lateral recess stenosis, or neural foraminal narrowing.

Spondylolisthesis is the anterior slippage of the vertebral body, pedicles, and superior articular facets, leaving the posterior elements behind. Spondylolisthesis can be associated with spondylolysis, congenital anomalies, degenerative spine disease, or other causes of mechanical weakness of the pars interarticularis (e.g., infection, osteoporosis, tumor, trauma, earlier surgery). The slippage may be asymptomatic or may cause LBP, nerve root injury (the L5 root most frequently), symptomatic spinal stenosis, or CES in rare severe cases. A "step-off" on palpation or tenderness may be elicited near the segment that has "slipped" (most often L4 on L5 or occasionally L5 on S1). Focal anterolisthesis or retrolisthesis can occur at any cervical or lumbar level and be the source of neck or LBP. Plain x-rays of the low back or neck in flexion and extension will reveal movement at the abnormal spinal segment. Surgery is performed for spinal instability (slippage 5–8 mm) and considered for pain symptoms that do not respond to conservative measures (e.g., rest, physical therapy), cases with a progressive neurologic deficit, or scoliosis.

NEOPLASMS

Back pain is the most common neurologic symptom in patients with systemic cancer and is the presenting symptom in 20%. The cause is usually vertebral body metastasis (85–90%) but can also result from spread of cancer through the intervertebral foramen (especially with lymphoma), carcinomatous meningitis, or metastasis to the spinal cord. The thoracic spine is most often affected. Cancer-related back pain tends to be constant, dull, unrelieved by rest, and worse at night. By contrast, mechanical causes of LBP usually improve with rest. MRI, CT, and CT myelography are the studies of choice when spinal metastasis is suspected. Once a metastasis is found, imaging of the entire spine is essential, as it reveals additional tumor deposits in one-third of patients. MRI is preferred for soft tissue definition, but the most rapidly available imaging modality is best because the patient's condition may worsen quickly without intervention. Early diagnosis is crucial. A strong predictor of outcome is baseline neurologic function prior to diagnosis. Half to three-quarters of patients are nonambulatory at the time of diagnosis and few regain the ability to walk. **The management of spinal metastasis is discussed in detail in Chap. 90.**

INFECTIONS/INFLAMMATION

Vertebral osteomyelitis is most often caused by hematogenous seeding of staphylococci, but other bacteria or tuberculosis (Pott's disease) may be responsible. The primary source of infection is usually the skin or urinary tract. Other common sources of bacteremia are IV drug use, poor dentition, endocarditis, lung abscess, IV catheters, or postoperative wound sites. Back pain at rest, tenderness over the involved vertebra, and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) are the most common findings in vertebral osteomyelitis. Fever or an elevated white blood cell count is found in a minority of patients. MRI and CT are sensitive and specific for early detection of osteomyelitis. The intervertebral disk can also be affected by infection (diskitis) and almost never by tumor. Extension of the infection posteriorly from the vertebral body can produce a spinal epidural abscess.

Spinal epidural abscess **(Chap. 442)** presents with back pain (aggravated by movement or palpation of the spinous process), fever, radiculopathy, or signs of spinal cord compression. The subacute development of two or more of these findings should increase suspicion for spinal epidural abscess. The abscess is best delineated by spine MRI and may track over multiple spinal levels.

Lumbar adhesive arachnoiditis with radiculopathy is due to fibrosis following inflammation within the subarachnoid space. The fibrosis results in nerve root adhesions and presents as back and leg pain associated with multifocal motor, sensory, or reflex changes. Causes of arachnoiditis include multiple lumbar operations (most common in the United States), chronic spinal infections (especially tuberculosis in the developing world), spinal cord injury, intrathecal hemorrhage, myelography (rare), intrathecal injections (glucocorticoids, anesthetics, or other agents), and foreign bodies. The MRI shows clumped nerve roots on axial views or loculations of cerebrospinal fluid within the thecal sac. Clumped nerve roots should be distinguished from enlarged nerve roots seen with demyelinating polyneuropathy or neoplastic infiltration. Treatment is usually unsatisfactory. Microsurgical lysis of adhesions, dorsal rhizotomy, dorsal root ganglionectomy, and epidural glucocorticoids have been tried, but outcomes have been poor. Dorsal column stimulation for pain relief has produced varying results.

TRAUMA

A patient complaining of back pain and an inability to move the legs may have a spine fracture or dislocation; fractures above L1 place the spinal cord at risk for compression. Care must be taken to avoid further damage to the spinal cord or nerve roots by immobilizing the back or neck pending the results of radiologic studies. Vertebral fractures frequently occur in the absence of trauma in association with osteoporosis, glucocorticoid use, osteomyelitis, or neoplastic infiltration.

Sprains and Strains The terms *low back sprain*, *strain*, and *mechanically induced muscle spasm* refer to minor, self-limited injuries associated with lifting a heavy object, a fall, or a sudden deceleration such as in an automobile accident. These terms are used loosely and do not correlate with specific underlying pathologies. The pain is usually confined to the lower back. Patients with paraspinal muscle spasm often assume unusual postures.

Traumatic Vertebral Fractures Most traumatic fractures of the lumbar vertebral bodies result from injuries producing anterior wedging or compression. With severe trauma, the patient may sustain a fracture-dislocation or a "burst" fracture involving the vertebral body and posterior elements. Traumatic vertebral fractures are caused by falls from a height, sudden deceleration in an automobile accident, or direct injury. Neurologic impairment is common, and early surgical treatment is indicated. In victims of blunt trauma, CT scans of the chest, abdomen, or pelvis can be reformatted to detect associated vertebral fractures. Rules have been developed to avoid unnecessary spine imaging associated with low-risk trauma, but these studies typically exclude patients aged >65 years—a group that can sustain fractures with minor trauma.

METABOLIC CAUSES

Osteoporosis and Osteosclerosis Immobilization, osteomalacia, the postmenopausal state, renal disease, multiple myeloma, hyperparathyroidism, hyperthyroidism, metastatic carcinoma, or glucocorticoid use may accelerate osteoporosis and weaken the vertebral body, leading to compression fractures and pain. Up to two-thirds of compression fractures seen on radiologic imaging are asymptomatic. The most common nontraumatic vertebral body fractures are due to a postmenopausal cause, or to osteoporosis in adults >75 years old **(Chap. 411)**. The risk of an additional vertebral fracture 1 year following a first vertebral fracture is 20%. The presence of fever, weight loss, fracture at a level above T4, any fracture in a young adult, or the predisposing conditions described above should increase suspicion for a cause other than typical osteoporosis. The sole manifestations of a compression fracture may be localized back or radicular pain exacerbated by movement and often reproduced by palpation over the spinous process of the affected vertebra.

Relief of acute pain can often be achieved with acetaminophen, NSAIDs, opioids, or a combination of these medications. Both pain and disability are improved with bracing. Antiresorptive drugs are not recommended in the setting of acute pain but are the preferred treatment to prevent additional fractures. Less than one-third of patients with prior compression fractures are adequately treated for osteoporosis despite the increased risk for future fractures; even fewer at-risk patients without a history of fracture are adequately treated. The literature for percutaneous vertebroplasty (PVP) or kyphoplasty for osteoporotic compression fractures associated with debilitating pain does not support their use.

Osteosclerosis, an abnormally increased bone density often due to Paget's disease, is readily identifiable on routine x-ray studies and can sometimes be a source of back pain. It may be associated with an isolated increase in alkaline phosphatase in an otherwise healthy older person. Spinal cord or nerve root compression can result from bony encroachment. The diagnosis of Paget's disease as the cause of a patient's back pain is a diagnosis of exclusion.

For further discussion of these bone disorders, see Chaps. 410, 411, and 412.

AUTOIMMUNE INFLAMMATORY ARTHRITIS

Autoimmune inflammatory disease of the spine can present with the insidious onset of low back, buttock, or neck pain. Examples include rheumatoid arthritis (RA) **(Chap. 358)**, ankylosing spondylitis, reactive arthritis and psoriatic arthritis **(Chap. 355)**, or inflammatory bowel disease **(Chap. 326)**.

CONGENITAL ANOMALIES OF THE LUMBAR SPINE

Spondylolysis is a bony defect in the vertebral pars interarticularis (a segment near the junction of the pedicle with the lamina), a finding present in up to 6% of adolescents. The cause is usually a stress microfracture in a congenitally abnormal segment. Multislice CT with multiplanar reformation is the most accurate modality for detecting spondylolysis in adults. Symptoms may occur in the setting of a single injury, repeated minor injuries, or during a growth spurt. Spondylolysis is the most common cause of persistent LBP in adolescents and is often associated with sports-related activities.

Scoliosis refers to an abnormal curvature in the coronal (lateral) plane of the spine. With *kyphoscoliosis,* there is, in addition, a forward curvature of the spine. The abnormal curvature may be congenital, due to abnormal spine development, acquired in adulthood due to degenerative spine disease, or progressive due to paraspinal neuromuscular disease. The deformity can progress until ambulation or pulmonary function is compromised.

Spina bifida occulta (closed spinal dysraphism) is a failure of closure of one or several vertebral arches posteriorly; the meninges and spinal cord are normal. A dimple or small lipoma may overlie the defect, but the skin is intact. Most cases are asymptomatic and discovered incidentally during a physical examination for back pain.

Tethered cord syndrome usually presents as a progressive cauda equina disorder (see below), although myelopathy may also be the initial manifestation. The patient is often a child or young adult who complains of perineal or perianal pain, sometimes following minor trauma. MRI studies typically reveal a low-lying conus (below L1 and L2) and a short and thickened filum terminale. The MRI findings also occur as incidental findings, sometimes during evaluation of unrelated LBP in adults.

REFERRED PAIN FROM VISCERAL DISEASE

Diseases of the thorax, abdomen, or pelvis may refer pain to the spinal segment that innervates the diseased organ. Occasionally, back pain may be the first and only manifestation. Upper abdominal diseases generally refer pain to the lower thoracic or upper lumbar region (eighth thoracic to the first and second lumbar vertebrae), lower abdominal diseases to the midlumbar region (second to fourth lumbar vertebrae), and pelvic diseases to the sacral region. Local signs (pain with spine palpation, paraspinal muscle spasm) are absent, and little or no pain accompanies routine movements.

Low Thoracic or Lumbar Pain with Abdominal Disease Tumors of the posterior wall of the stomach or duodenum typically produce epigastric pain **(Chaps. 80 and 324)**, but back pain may occur if retroperitoneal extension is present. Fatty foods occasionally induce back pain associated with biliary or pancreatic disease. Pathology in retroperitoneal structures (hemorrhage, tumors, and pyelonephritis) can produce paraspinal pain that radiates to the lower abdomen, groin, or anterior thighs. A mass in the iliopsoas region can produce unilateral lumbar pain with radiation toward the groin, labia, or testicle. The sudden appearance of lumbar pain in a patient receiving anticoagulants should prompt consideration of retroperitoneal hemorrhage.

Isolated LBP occurs in some patients with a contained rupture of an AAA. The classic clinical triad of abdominal pain, shock, and back pain occurs in <20% of patients. The diagnosis may be missed because the symptoms and signs can be nonspecific. Misdiagnoses include nonspecific back pain, diverticulitis, renal colic, sepsis, and myocardial infarction. A careful abdominal examination revealing a pulsatile mass (present in 50–75% of patients) is an important physical finding. Patients with suspected AAA should be evaluated with abdominal ultrasound, CT, or MRI **(Chap. 280)**.

Sacral Pain with Gynecologic and Urologic Disease Pelvic organs rarely cause isolated LBP. Uterine malposition (retroversion, descensus, and prolapse) may cause traction on the uterosacral ligament. The pain is referred to the sacral region, sometimes appearing after prolonged standing. Endometriosis or uterine cancers can invade the uterosacral ligaments. Pain associated with endometriosis is typically premenstrual and often continues until it merges with menstrual pain.

Menstrual pain with poorly localized, cramping pain can radiate down the legs. LBP that radiates into one or both thighs is common in the last weeks of pregnancy. Continuous and worsening pain unrelieved by rest or at night may be due to neoplastic infiltration of nerves or nerve roots.

Urologic sources of lumbosacral back pain include chronic prostatitis, prostate cancer with spinal metastasis **(Chap. 87)**, and diseases of the kidney or ureter. Infectious, inflammatory, or neoplastic renal diseases may produce ipsilateral lumbosacral pain, as can renal artery or vein thrombosis. Paraspinal lumbar pain may be a symptom of ureteral obstruction due to nephrolithiasis.

OTHER CAUSES OF BACK PAIN

Postural Back Pain There is a group of patients with nonspecific chronic low back pain (CLBP) in whom no specific anatomic lesion can be found despite exhaustive investigation. Exercises to strengthen the paraspinal and abdominal muscles are sometimes helpful. CLBP may be encountered in patients who seek financial compensation; in malingerers; or in those with concurrent substance abuse. Many patients with CLBP have a history of psychiatric illness (depression, anxiety states) or childhood trauma (physical or sexual abuse) that antedates the onset of back pain. Preoperative psychological assessment has been used to exclude patients with marked psychological impairments that predict a poor surgical outcome from spine surgery.

Idiopathic The cause of LBP occasionally remains unclear. Some patients have had multiple operations for disk disease. The original indications for surgery may have been questionable, with back pain only, no definite neurologic signs, or a minor disk bulge noted on CT or MRI. Scoring systems based on neurologic signs, psychological factors, physiologic studies, and imaging studies have been devised to minimize the likelihood of unsuccessful surgery.

GLOBAL CONSIDERATIONS

While many of the history and examination features described in this chapter apply to all patients, information regarding the global epidemiology and prevalence of LBP is limited. The Global Burden of Diseases Study 2019 reported that LBP represented the #1 cause overall for total years lived with disability (YLD), and #9 overall as a cause of disability-related life years (DALYs). These numbers increased substantially from 1990 estimates, and with the aging of the population worldwide, the numbers of individuals suffering from LBP are expected to increase further in the future. Although rankings for LBP generally were higher in developed regions, a high burden exists in every part of the world. An area of uncertainty is the degree to which regional differences exist in terms of the specific etiologies of LBP and how these are managed. For example, the most common cause of arachnoiditis in developing countries is a prior spinal infection, but in developed countries the most frequent cause is multiple lumbar spine surgeries.

TREATMENT

Back Pain

Management is considered separately for acute and chronic low back pain syndromes without radiculopathy, and for back pain with radiculopathy.

ACUTE LOW BACK PAIN WITHOUT RADICULOPATHY

This is defined as pain of <12 weeks duration. Full recovery can be expected in >85% of adults with ALBP without leg pain. Most have purely "mechanical" symptoms (i.e., pain that is aggravated by motion and relieved by rest).

The initial assessment is focused on excluding serious causes of spine pathology that require urgent intervention, including infection, cancer, or trauma. Risk factors for a serious cause of ALBP are shown in Table 17-1. Laboratory and imaging studies are unnecessary if risk factors are absent. CT, MRI, or plain spine films are rarely indicated in the first month of symptoms unless a spine fracture, tumor, or infection is suspected.

The prognosis of ALBP is generally excellent; however, episodes tend to recur, and as many as two-thirds of patients will experience a second episode within 1 year. Most patients do not seek medical care and improve on their own. Even among those seen in primary care, two-thirds report substantial improvement after 7 weeks. This high likelihood of spontaneous improvement can mislead clinicians and patients about the efficacy of treatment interventions, highlighting the importance of rigorous prospective trials. Many treatments commonly used in the past are now known to be ineffective, including bed rest and lumbar traction.

Clinicians should reassure and educate patients that improvement is very likely and instruct them in self-care. Satisfaction and the likelihood of follow-up increase when patients are educated about prognosis, evidence-based treatments, appropriate activity modifications, and strategies to prevent future exacerbations. Counseling patients about the risks of overtreatment is another important part of the discussion. Patients who report that they did not receive an adequate explanation for their symptoms are likely to request further diagnostic tests.

In general, bed rest should be avoided for relief of severe symptoms or limited to a day or two at most. Several randomized trials suggest that bed rest does not hasten the pace of recovery. In general, early resumption of normal daily physical activity should be encouraged, avoiding only strenuous manual labor. Advantages of early ambulation for ALBP also include maintenance of cardiovascular conditioning; improved bone, cartilage, and muscle strength; and increased endorphin levels. Specific back exercises or early vigorous exercise have not shown benefits for acute back pain. Empiric use of heating pads or blankets is sometimes helpful.

NSAIDs and Acetaminophen Evidence-based guidelines recommend over-the-counter medicines such as NSAIDs and acetaminophen as first-line options for treatment of ALBP. In otherwise healthy patients, a trial of NSAIDs can be followed by acetaminophen for time-limited periods. In theory, the anti-inflammatory effects of NSAIDs might provide an advantage over acetaminophen to suppress inflammation that accompanies many causes of ALBP, but in practice there is no clinical evidence to support the superiority of NSAIDs. The risk of renal and gastrointestinal toxicity with NSAIDs is increased in patients with preexisting medical comorbidities (e.g., renal insufficiency, cirrhosis, prior gastrointestinal hemorrhage, use of anticoagulants or glucocorticoids, heart failure). Some patients elect to take acetaminophen and an NSAID together in hopes of a more rapid benefit.

Muscle Relaxants Skeletal muscle relaxants, such as cyclobenzaprine or methocarbamol, may be useful, but sedation is a common side effect. Limiting the use of muscle relaxants to nighttime only may be an option for patients with back pain that interferes with sleep.

Opioids There is no good evidence to support the use of opioid analgesics or tramadol as first-line therapy for ALBP. Their use is best reserved for patients who cannot tolerate acetaminophen or NSAIDs and for those with severe refractory pain. Also, the duration of opioid treatment for ALBP should be strictly limited to 3–7 days. As with muscle relaxants, these drugs are often sedating, so it may be useful to prescribe them at nighttime only. Side effects of short-term opioid use include nausea, constipation, and pruritus; risks of long-term opioid use include hypersensitivity to pain, hypogonadism, and dependency. Falls, fractures, driving accidents, and fecal impaction are other risks. The clinical efficacy of opioids for chronic pain beyond 16 weeks of use is unproven.

Mounting evidence of morbidity from long-term opioid therapy (including overdose, dependency, addiction, falls, fractures, accident risk, and sexual dysfunction) has prompted efforts to reduce its use for chronic pain, including back pain **(Chap. 13)**. When used, safety may be improved with automated notices for high doses, early refills, prescriptions from multiple pharmacies, overlapping opioid and benzodiazepine prescriptions, and in the United States by state-based prescription drug monitoring programs (PDMPs). A recent study indicated that most patients with opioid use disorder presenting to emergency departments had no prescriptions recorded in the PDMP, reflecting other methods used to obtain opioids. Greater access to alternative treatments for chronic pain, such as tailored exercise programs and cognitive behavioral therapy (CBT), may also reduce opioid prescribing.

Other Approaches There is no evidence to support use of oral or injected glucocorticoids, antiepileptics, antidepressants, or therapies for neuropathic pain such as gabapentin or herbal therapies. Commonly used nonpharmacologic treatments for ALBP are also of unproven benefit, including spinal manipulation, physical therapy, massage, acupuncture, laser therapy, therapeutic ultrasound, corsets, transcutaneous electrical nerve stimulation (TENS), special mattresses, or lumbar traction. Although important for chronic pain, use of back exercises for ALBP are generally not supported by clinical evidence. There is no convincing evidence regarding the value of ice or heat applications for ABLP; however, many patients report temporary symptomatic relief from ice or frozen gel packs just before sleep, and heat may produce a short-term reduction in pain after the first week. Patients often report improved satisfaction with the care that they receive when they actively participate in the selection of symptomatic approaches.

CHRONIC LOW BACK PAIN WITHOUT RADICULOPATHY

Back pain is considered chronic when the symptoms last >12 weeks; it accounts for 50% of total back pain costs. Risk factors include obesity, female gender, older age, prior history of back pain, restricted spinal mobility, pain radiating into a leg, high levels of psychological distress, poor self-rated health, minimal physical activity, smoking, job dissatisfaction, and widespread pain. In general, the same treatments that are recommended for ALBP can be useful for patients with CLBP. In this setting, however, the benefit of opioid therapy or muscle relaxants is less clear. In general, improved activity tolerance is the primary goal, while pain relief is secondary.

Some observers have raised concerns that CLBP may often be overtreated. For CLBP without radiculopathy, multiple guidelines explicitly recommend against use of SSRIs, any type of injection, TENS, lumbar supports, traction, radiofrequency facet joint denervation, intradiskal electrothermal therapy, or intradiskal radiofrequency thermocoagulation. On the other hand, exercise therapy and treatment of depression appear to be useful and underused.

Exercise Programs Evidence supports the use of exercise therapy to alleviate pain symptoms and improve function. Exercise can be one of the mainstays of treatment for CLBP. Effective regimens have generally included a combination of core-strengthening exercises, stretching, and gradually increasing aerobic exercise. A program of supervised exercise can improve compliance. Supervised intensive

physical exercise or "work hardening" regimens have been effective in returning some patients to work, improving walking distance, and reducing pain. In addition, some forms of yoga have been evaluated in randomized trials and may be helpful for patients who are interested.

Intensive multidisciplinary rehabilitation programs can include daily or frequent physical therapy, exercise, CBT, a workplace evaluation, and other interventions. For patients who have not responded to other approaches, such programs appear to offer some benefit. Systematic reviews, however, suggest that the evidence and benefits are limited.

Nonopioid Medications Medications for CLBP may include short courses of NSAIDs or acetaminophen. Duloxetine is approved for the treatment of CLBP (60 mg daily) and may also treat coincident depression. Tricyclic antidepressants can provide modest pain relief for some patients without evidence of depression. Depression is common among patients with chronic pain and should be appropriately treated.

Cognitive Behavioral Therapy CBT is based on evidence that psychological and social factors, as well as somatic pathology, are important in the genesis of chronic pain and disability; CBT focuses on efforts to identify and modify patients' thinking about their condition. In one randomized trial, CBT reduced disability and pain in patients with CLBP. Such behavioral treatments appear to provide benefits similar in magnitude to exercise therapy.

Complementary Medicine Back pain is the most frequent reason for seeking complementary and alternative treatments. Spinal manipulation or massage therapy may provide short-term relief, but long-term benefit is unproven. Biofeedback has not been studied rigorously. There is no convincing evidence that either TENS, laser therapy, or ultrasound are effective in treating CLBP. Rigorous trials of acupuncture suggest that true acupuncture is not superior to sham acupuncture, but that both may offer an advantage over routine care. Whether this is due entirely to placebo effects provided even by sham acupuncture is uncertain.

Injections and Other Interventions Various injections, including epidural glucocorticoid injections, facet joint injections, and trigger point injections, have been used for treating CLBP. However, in the absence of radiculopathy, there is no clear evidence that these approaches are sustainably effective.

Injection studies are sometimes used diagnostically to help determine the anatomic source of back pain. Pain relief following a glucocorticoid and anesthetic injection into a facet or medial branch block are used as evidence that the facet joint is the pain source; however, the possibility that the response was a placebo effect or due to systemic absorption of the glucocorticoids is difficult to exclude.

Another category of intervention for CLBP is electrothermal and radiofrequency therapy. Intradiskal therapy has been proposed using energy to thermocoagulate and destroy nerves in the intervertebral disk, using specially designed catheters or electrodes. Current evidence does not support the use of discography to identify a specific disk as the pain source, or the use of intradiskal electrothermal or radiofrequency therapy for CLBP.

Radiofrequency denervation is sometimes used to destroy nerves that are thought to mediate pain, and this technique has been used for facet joint pain (with the target nerve being the medial branch of the primary dorsal ramus), for back pain thought to arise from the intervertebral disk (ramus communicans), and radicular back pain (dorsal root ganglia). These interventional therapies have not been studied in sufficient detail to draw firm conclusions regarding their value for CLBP.

Surgery Surgical intervention for CLBP without radiculopathy has been evaluated in a number of randomized trials. The case for fusion surgery for CLBP without radiculopathy is weak. While some studies have shown modest benefit, there has been no benefit when compared to an active medical treatment arm, often including highly structured, rigorous rehabilitation combined with CBT. The use of bone matrix protein (BMP) instead of iliac crest graft for the fusion was shown to increase hospital costs and length of stay but not improve clinical outcomes.

Guidelines suggest that referral for an opinion on spinal fusion can be considered for patients who have completed an optimal nonsurgical treatment program (including combined physical and psychological treatment) and who have persistent severe back pain for which they would consider surgery. The high cost, wide geographic variations, and rapidly increasing rates of spinal fusion surgery have prompted scrutiny regarding the lack of standardization of appropriate indications. Some insurance carriers have begun to limit coverage for the most controversial indications, such as LBP without radiculopathy.

Lumbar disk replacement with prosthetic disks is US Food and Drug Administration–approved for uncomplicated patients needing single-level surgery at the L3-S1 levels. The disks are generally designed as metal plates with a polyethylene cushion sandwiched in between. The trials that led to approval of these devices were not blinded. When compared to spinal fusion, the artificial disks were "not inferior." Long-term follow-up is needed to determine device failure rates over time. Serious complications are somewhat more likely with the artificial disk. This treatment remains controversial for CLBP.

LOW BACK PAIN WITH RADICULOPATHY

A common cause of back pain with radiculopathy is a herniated disk affecting the nerve root and producing back pain with radiation down the leg. The term *sciatica* is used when the leg pain radiates posteriorly in a sciatic or L5/S1 distribution. The prognosis for acute low back and leg pain with radiculopathy due to disk herniation is generally favorable, with most patients showing substantial improvement over months. Serial imaging studies suggest spontaneous regression of the herniated portion of the disk in two-thirds of patients over 6 months. Nonetheless, several important treatment options provide symptomatic relief while the healing process unfolds.

Resumption of normal activity is recommended. Randomized trial evidence suggests that bed rest is ineffective for treating sciatica as well as back pain alone. Acetaminophen and NSAIDs are useful for pain relief, although severe pain may require short courses (3–7 days) of opioid analgesics. Opioids are superior for acute pain relief in the emergency department.

Epidural glucocorticoid injections have a role in providing symptom relief for acute lumbar radiculopathy due to a herniated disk, but do not reduce the use of subsequent surgical intervention. A brief course of high-dose oral glucocorticoids (methylprednisolone dose pack) for 3 days followed by a rapid taper over 4 more days can be helpful for some patients with acute disk-related radiculopathy, although this specific regimen has not been studied rigorously.

Diagnostic nerve root blocks have been advocated to determine if pain originates from a specific nerve root. However, improvement may result even when the nerve root is not responsible for the pain; this may occur as a placebo effect, from a pain-generating lesion located distally along the peripheral nerve, or from effects of systemic absorption.

Urgent surgery is recommended for patients who have evidence of CES or spinal cord compression, generally manifesting as combinations of bowel or bladder dysfunction, diminished sensation in a saddle distribution, a sensory level on the trunk, and bilateral leg weakness or spasticity. Surgical intervention is also indicated for patients with progressive motor weakness due to nerve root injury demonstrated on clinical examination or EMG.

Surgery is also an important option for patients who have disabling radicular pain despite optimal conservative treatment. Because patients with a herniated disk and sciatica generally experience rapid improvement over weeks, most experts do not recommend considering surgery unless the patient has failed to respond to a minimum of 6–8 weeks of nonsurgical management. For patients who have not improved, randomized trials show that surgery results in more rapid pain relief than nonsurgical treatment. However, after

2 years of follow-up, patients appear to have similar pain relief and functional improvement with or without surgery. Thus, both treatment approaches are reasonable, and patient preferences and needs (e.g., rapid return to employment) strongly influence decision-making. Some patients will want the fastest possible relief and find surgical risks acceptable. Others will be more risk-averse and more tolerant of symptoms and will choose watchful waiting, especially if they understand that improvement is likely in the end.

The usual surgical procedure is a partial hemilaminectomy with excision of the prolapsed disk (diskectomy). Minimally invasive techniques have gained in popularity in recent years, but some evidence suggests they may be less effective than standard surgical techniques, with more residual back pain, leg pain, and higher rates of rehospitalization. Fusion of the involved lumbar segments should be considered only if significant spinal instability is present (i.e., degenerative spondylolisthesis). The costs associated with lumbar interbody fusion have increased dramatically in recent years. There are no large prospective, randomized trials comparing fusion to other types of surgical intervention. In one study, patients with persistent LBP despite an initial diskectomy fared no better with spine fusion than with a conservative regimen of cognitive intervention and exercise. Artificial disks, as discussed above, are used in Europe; their utility remains controversial in the United States.

PAIN IN THE NECK AND SHOULDER

Neck pain, which usually arises from diseases of the cervical spine and soft tissues of the neck, is common, typically precipitated by movement, and may be accompanied by focal tenderness and limitation of motion. Many of the earlier comments made regarding causes of LBP also apply to disorders of the cervical spine. The text below will emphasize differences. Pain arising from the brachial plexus, shoulder, or peripheral nerves can be confused with cervical spine disease **(Table 17-4)**, but the history and examination usually identify a more distal origin for the pain. When the site of nerve tissue injury is unclear, EMG studies can localize the lesion. Cervical spine trauma, disk disease, or spondylosis with intervertebral foraminal narrowing may be asymptomatic or painful and can produce a myelopathy, radiculopathy, or both. The same risk factors for serious causes of LBP also apply to neck pain with the additional feature that neurologic signs of myelopathy (incontinence, sensory level, spastic legs) may also occur. Lhermitte's sign, an electrical shock down the spine with neck flexion, suggests involvement of the cervical spinal cord.

TRAUMA TO THE CERVICAL SPINE

Trauma (fractures, subluxation) places the spinal cord at risk for compression. Motor vehicle accidents, violent crimes, or falls account for 87% of cervical spinal cord injuries **(Chap. 442)**. Immediate immobilization of the neck is essential to minimize further spinal cord injury from movement of unstable cervical spine segments. A CT scan is the diagnostic procedure of choice for detection of acute fractures following severe trauma; plain x-rays are used for lesser degrees of trauma or in settings where CT is unavailable. When traumatic injury to the vertebral arteries or cervical spinal cord is suspected, visualization by MRI with magnetic resonance angiography is preferred.

The decision to obtain imaging should be based on the clinical context of the injury. The National Emergency X-Radiography Utilization Study (NEXUS) low-risk criteria established that normally alert patients without palpation tenderness in the midline; intoxication; neurologic deficits; or painful distracting injuries were very unlikely to have sustained a clinically significant traumatic injury to the cervical spine. The Canadian C-spine rule recommends that imaging should be obtained following neck region trauma if the patient is >65 years old or has limb paresthesias or if there was a dangerous mechanism for the injury (e.g., bicycle collision with tree or parked car, fall from height >3 ft or five stairs, diving accident). These guidelines are helpful but must be tailored to individual circumstances; for example, patients with advanced osteoporosis, glucocorticoid use, or cancer may warrant imaging after even mild trauma.

Whiplash injury is due to rapid flexion and extension of the neck, usually from automobile accidents. The likely mechanism involves injury to the facet joints. This diagnosis should not be applied to patients with fractures, disk herniation, head injury, focal neurologic findings, or altered consciousness. Up to 50% of persons reporting whiplash injury acutely have persistent neck pain 1 year later. When personal compensation for pain and suffering was removed from the Australian health care system, the prognosis for recovery at 1 year improved. Imaging of the cervical spine is not cost-effective acutely but is useful to detect disk herniations when symptoms persist for >6 weeks following the injury. Severe initial symptoms have been associated with a poor long-term outcome.

CERVICAL DISK DISEASE

Degenerative cervical disk disease is very common and usually asymptomatic. Herniation of a lower cervical disk is a common cause of pain or tingling in the neck, shoulder, arm, or hand. Neck pain, stiffness, and a range of motion limited by pain are the usual manifestations.

TABLE 17-4 Cervical Radiculopathy: Neurologic Features

CERVICAL NERVE ROOT	EXAMINATION FINDINGS			PAIN DISTRIBUTION
	REFLEX	SENSORY	MOTOR	
C5	Biceps	Lateral deltoid	Rhomboids[a] (elbow extends backward with hand on hip) Infraspinatus[a] (arm rotates externally with elbow flexed at the side) Deltoid[a] (arm raised laterally 30°–45° from the side)	Lateral arm, medial scapula
C6	Biceps	Palmar thumb/index finger Dorsal hand/lateral forearm	Biceps[a] (arm flexed at the elbow in supination) Pronator teres (forearm pronated)	Lateral forearm, thumb/index fingers
C7	Triceps	Middle finger Dorsal forearm	Triceps[a] (forearm extension, flexed at elbow) Wrist/finger extensors[a]	Posterior arm, dorsal forearm, dorsal hand
C8	Finger flexors	Palmar surface of little finger Medial hand and forearm	Abductor pollicis brevis (abduction of thumb) First dorsal interosseous (abduction of index finger) Abductor digiti minimi (abduction of little finger)	Fourth and fifth fingers, medial hand and forearm
T1	Finger flexors	Axilla, medial arm, anteromedial forearm	Abductor pollicis brevis (abduction of thumb) First dorsal interosseous (abduction of index finger) Abductor digiti minimi (abduction of little finger)	Medial arm, axilla

[a]These muscles receive the majority of innervation from this root.

Herniated cervical disks are responsible for ~25% of cervical radiculopathies. Extension and lateral rotation of the neck narrow the ipsilateral intervertebral foramen and may reproduce radicular symptoms (Spurling's sign). In young adults, acute nerve root compression from a ruptured cervical disk is often due to trauma. Cervical disk herniations are usually posterolateral near the lateral recess. Typical patterns of reflex, sensory, and motor changes that accompany cervical nerve root lesions are summarized in Table 17-4. Although the classic patterns are clinically helpful, there are numerous exceptions because (1) there is overlap in sensory function between adjacent nerve roots, (2) symptoms and signs may be evident in only part of the injured nerve root territory, and (3) the location of pain is the most variable of the clinical features.

CERVICAL SPONDYLOSIS

Osteoarthritis of the cervical spine may produce neck pain that radiates into the back of the head, shoulders, or arms, or may be the source of headaches in the posterior occipital region (supplied by the C2-C4 nerve roots). Osteophytes, disk protrusions, or hypertrophic facet or uncovertebral joints may alone or in combination compress one or several nerve roots at the intervertebral foramina; these causes together account for 75% of cervical radiculopathies. The roots most commonly affected are C7 and C6. Narrowing of the spinal canal by osteophytes, ossification of the posterior longitudinal ligament (OPLL), or a large central disk may compress the cervical spinal cord and produce signs of myelopathy alone or radiculopathy with myelopathy (myeloradiculopathy). When little or no neck pain accompanies cervical cord involvement, other diagnoses to be considered include amyotrophic lateral sclerosis **(Chap. 437)**, multiple sclerosis **(Chap. 444)**, spinal cord tumors, or syringomyelia **(Chap. 442)**. Cervical spondylotic myelopathy should be considered even when the patient presents with symptoms or spinal cord signs in the legs only. MRI is the study of choice to define soft tissues in the cervical region including the spinal cord, whereas plain CT is optimal to identify bone pathology including foraminal, lateral recess, OPLL, or spinal canal stenosis. In spondylotic myelopathy, focal enhancement by MRI, sometimes in a characteristic "pancake pattern," may be present at the site of maximal cord compression.

There is no evidence to support prophylactic surgery for asymptomatic cervical spinal stenosis unaccompanied by myelopathic signs or abnormal spinal cord findings on MRI, except in the setting of *dynamic instability* (see spondylolisthesis above). If the patient has postural neck pain, a prior history of whiplash or other spine/head injury, a Lhermitte sign, or preexisting listhesis at the stenotic segment on cervical MRI or CT, then cervical spine flexion-extension x-rays or MRI are indicated to look for dynamic instability. Surgical intervention is not recommended for patients with listhesis alone, unaccompanied by dynamic instability.

OTHER CAUSES OF NECK PAIN

Rheumatoid arthritis (RA) **(Chap. 358)** of the cervical facet joints produces neck pain, stiffness, and limitation of motion. Synovitis of the atlantoaxial joint (C1-C2; Fig. 17-2) may damage the transverse ligament of the atlas, producing forward displacement of the atlas on the axis (atlantoaxial subluxation). Radiologic evidence of atlantoaxial subluxation occurs in up to 30% of patients with RA and plain x-ray films of the neck should be routinely performed preoperatively to assess the risk of neck hyperextension in patients requiring intubation. The degree of subluxation correlates with the severity of erosive disease. When subluxation is present, careful assessment is important to identify early signs of myelopathy that could be a harbinger of life-threatening spinal cord compression. Surgery should be considered when myelopathy or spinal instability is present. *Ankylosing spondylitis* is another cause of neck pain and less commonly atlantoaxial subluxation.

Acute *herpes zoster* can present as acute posterior occipital or neck pain prior to the outbreak of vesicles. *Neoplasms* metastatic to the cervical spine, *infections* (osteomyelitis and epidural abscess), and *metabolic bone diseases* may be the cause of neck pain, as discussed above. Neck pain may also be referred from the heart with coronary artery ischemia (cervical angina syndrome). Rheumatologic disease should be considered if the neck pain is accompanied by shoulder or hip girdle pain.

THORACIC OUTLET SYNDROMES

The thoracic outlet contains the first rib, the subclavian artery and vein, the brachial plexus, the clavicle, and the lung apex. Injury to these structures may result in postural or movement-induced pain around the shoulder and supraclavicular region, classified as follows.

True neurogenic thoracic outlet syndrome (*TOS*) is an uncommon disorder resulting from compression of the lower trunk of the brachial plexus or ventral rami of the C8 or T1 nerve roots, caused most often by an anomalous band of cartilaginous tissue connecting an elongate transverse process at C7 with the first rib. Pain is mild or may be absent. Signs include weakness and wasting of intrinsic muscles of the hand and diminished sensation on the palmar aspect of the fifth digit. An anteroposterior cervical spine x-ray will show an elongate C7 transverse process (an anatomic marker for the anomalous cartilaginous band), and EMG and NCSs confirm the diagnosis. Treatment consists of surgical resection of the anomalous band. The weakness and wasting of intrinsic hand muscles typically do not improve, but surgery halts the insidious progression of weakness.

Arterial TOS results from compression of the subclavian artery by a cervical rib, resulting in poststenotic dilatation of the artery and in some cases secondary thrombus formation. Blood pressure is reduced in the affected limb, and signs of emboli may be present in the hand. Neurologic signs are absent. Ultrasound can confirm the diagnosis noninvasively. Treatment is with thrombolysis or anticoagulation (with or without embolectomy) and surgical excision of the cervical rib compressing the subclavian artery.

Venous TOS is due to subclavian vein thrombosis resulting in swelling of the arm and pain. The vein may be compressed by a cervical rib or anomalous scalene muscle. Venography is the diagnostic test of choice.

Disputed TOS accounts for 95% of patients diagnosed with TOS; chronic arm and shoulder pain are prominent and of unclear cause. The lack of sensitive and specific findings on physical examination or specific markers for this condition results in diagnostic uncertainty. The role of surgery in disputed TOS is controversial. Major depression, chronic symptoms, work-related injury, and diffuse arm symptoms predict poor surgical outcomes. Multidisciplinary pain management is a conservative approach, although treatment is often unsuccessful.

BRACHIAL PLEXUS AND NERVES

Pain from injury to the brachial plexus or peripheral nerves of the arm can occasionally mimic referred pain of cervical spine origin, including cervical radiculopathy, but the pain typically begins distal to the posterior neck region in the shoulder girdle or upper arm. Neoplastic infiltration of the lower trunk of the brachial plexus may produce shoulder or supraclavicular pain radiating down the arm, numbness of the fourth and fifth fingers or medial forearm, and weakness of intrinsic hand muscles innervated by the lower trunk and medial cord of the brachial plexus. Delayed radiation injury may produce weakness in the upper arm or numbness of the lateral forearm or arm due to involvement of the upper trunk and lateral cord of the plexus. Pain is less common and less severe than with neoplastic infiltration. A Pancoast tumor of the lung **(Chap. 78)** is another cause and should be considered, especially when a concurrent Horner's syndrome is present. *Acute brachial neuritis* is often confused with radiculopathy; the acute onset of severe shoulder or scapular pain is followed typically over days by weakness of the proximal arm and shoulder girdle muscles innervated by the upper brachial plexus. The onset may be preceded by an infection, vaccination, or minor surgical procedure. The long thoracic nerve may be affected, resulting in a winged scapula. Brachial neuritis may also present as an isolated paralysis of the diaphragm with or without involvement of other nerves of the upper limb. Recovery may take up to 3 years, and full functional recovery can be expected in the majority of patients.

Occasional cases of carpal tunnel syndrome produce pain and paresthesias extending into the forearm, arm, and shoulder resembling a C5 or C6 root lesion. Lesions of the radial or ulnar nerve can also mimic radiculopathy, at C7 or C8, respectively. EMG and NCSs can accurately localize lesions to the nerve roots, brachial plexus, or peripheral nerves.

For further discussion of peripheral nerve disorders, see Chap. 446.

SHOULDER

Pain arising from the shoulder can on occasion mimic pain from the spine. If symptoms and signs of radiculopathy are absent, then the differential diagnosis includes mechanical shoulder pain (bicipital tendonitis, frozen shoulder, bursitis, rotator cuff tear, dislocation, adhesive capsulitis, or rotator cuff impingement under the acromion) and referred pain (subdiaphragmatic irritation, angina, Pancoast tumor). Mechanical pain is often worse at night, associated with local shoulder tenderness and aggravated by passive abduction, internal rotation, or extension of the arm. Demonstrating normal passive full range of motion of the arm at the shoulder without worsening the usual pain can help exclude mechanical shoulder pathology as a cause of neck region pain. Pain from shoulder disease may radiate into the arm or hand, but focal neurologic signs (sensory, motor, or reflex changes) are absent.

GLOBAL CONSIDERATIONS

Many of the considerations described above for LBP also apply to neck pain. The Global Burden of Diseases Study 2019 reported that neck pain ranked second only to back pain as a cause of total years lived with disability (YLD). In general, neck pain rankings were also higher in developed regions of the world.

TREATMENT

Neck Pain Without Radiculopathy

The evidence regarding treatment for neck pain is less comprehensive than that for LBP, but the approach is remarkably similar in many respects. As with LBP, spontaneous improvement is the norm for acute neck pain. The usual goals of therapy are to promote a rapid return to normal function and provide pain relief while healing proceeds.

Acute neck pain is often treated with NSAIDs, acetaminophen, cold packs, or heat, alone or in combination while awaiting recovery. Patients should be specifically educated regarding the favorable natural history of acute neck pain to avoid unrealistic fear and inappropriate requests for imaging and other tests. For patients kept awake by symptoms, cyclobenzaprine (5–10 mg) at night can help relieve muscle spasm and promote drowsiness. For patients with neck pain unassociated with trauma, supervised exercise with or without mobilization appears to be effective. Exercises often include shoulder rolls and neck stretches. The evidence in support of nonsurgical treatments for whiplash-associated disorders is generally of limited quality and neither supports nor refutes the common treatments used for symptom relief. Gentle mobilization of the cervical spine combined with exercise programs may be beneficial. Evidence is insufficient to recommend the use of cervical traction, TENS, ultrasound, trigger point injections, botulinum toxin injections, tricyclic antidepressants, and SSRIs for acute or chronic neck pain. Some patients obtain modest pain relief using a soft neck collar; there is little risk or cost. Massage can produce temporary pain relief.

For patients with chronic neck pain, supervised exercise programs can provide symptom relief and improve function. Acupuncture provided short-term benefit for some patients when compared to a sham procedure and is an option. Spinal manipulation alone has not been shown to be effective and carries a risk for injury. Surgical treatment for chronic neck pain without radiculopathy or spine instability is not recommended.

Neck Pain With Radiculopathy

The natural history of acute neck pain with radiculopathy due to disk disease is favorable, and many patients will improve without specific therapy. Although there are no randomized trials of NSAIDs for neck pain, a course of NSAIDs, acetaminophen, or both, with or without muscle relaxants, and avoidance of activities that trigger symptoms are reasonable as initial therapy. Gentle supervised exercise and avoidance of inactivity are reasonable as well. A short course of high-dose oral glucocorticoids with a rapid taper, or epidural steroids administered under imaging guidance can be effective for acute or subacute disk-related cervical radicular pain, but have not been subjected to rigorous trials. The risk of injection-related complications is higher in the neck than the low back; vertebral artery dissection, dural puncture, spinal cord injury, and embolism in the vertebral arteries have all been reported. Opioid analgesics can be used in the emergency department and for short courses as an outpatient. Soft cervical collars can be modestly helpful by limiting spontaneous and reflex neck movements that exacerbate pain; hard collars are in general poorly tolerated.

If cervical radiculopathy is due to bony compression from cervical spondylosis with foraminal narrowing, periodic follow-up to assess for progression is indicated and consideration of surgical decompression is reasonable. Surgical treatment can produce rapid pain relief, although it is unclear if long-term functional outcomes are improved over nonsurgical therapy. Indications for cervical disk surgery include a progressive motor deficit due to nerve root compression, functionally limiting pain that fails to respond to conservative management, or spinal cord compression. In other circumstances, clinical improvement over time regardless of therapeutic intervention is common.

Surgical treatments include anterior cervical diskectomy alone, laminectomy with diskectomy, or diskectomy with fusion. The risk of subsequent radiculopathy or myelopathy at cervical segments adjacent to a fusion is ~3% per year and 26% per decade. Although this risk is sometimes portrayed as a late complication of surgery, it may also reflect the natural history of degenerative cervical disk disease.

Section 2 Alterations in Body Temperature

18 Fever

Neeraj K. Surana, Charles A. Dinarello, Reuven Porat

Body temperature is controlled by the hypothalamus. Neurons in both the preoptic anterior hypothalamus and the posterior hypothalamus receive two kinds of signals: one from peripheral nerves that transmit information from warmth/cold receptors in the skin and the other from the temperature of the blood bathing the region. These two types of signals are integrated by the thermoregulatory center of the hypothalamus to maintain normal temperature. In a neutral temperature environment, the human metabolic rate produces more heat than is necessary to maintain the core body temperature in the range of 36.5–37.5°C (97.7–99.5°F).

A normal body temperature is ordinarily maintained despite environmental variations because the hypothalamic thermoregulatory center balances the excess heat production derived from metabolic activity in muscle and the liver with heat dissipation from the skin and lungs. According to a study of >35,000 individuals ≥18 years of age seen in routine medical visits, the mean oral temperature is 36.6°C (95% confidence interval, 35.7–37.3°C). In light of this study, *a temperature of >37.7°C (>99.9°F), which represents the 99th percentile for healthy individuals, defines a fever.* Importantly, higher ambient temperatures are linked to higher baseline body temperatures. Additionally, body temperatures have diurnal and seasonal variation, with low levels at 8 A.M. and during summer and higher levels at 4 P.M. and during winter. Baseline temperatures are also affected by age (lower by 0.02°C for every 10-year increase in age), demographics (African-American women have temperatures 0.052°C higher than white men), and comorbid conditions (cancer is associated with 0.02°C higher temperatures; hypothyroidism is linked to temperatures lower by 0.01°C). After controlling for age, sex, race, vital signs, and comorbidities, an increase in baseline temperature of 0.15°C (or 1 standard deviation) intriguingly translates into a 0.52% absolute increase in 1-year mortality.

Rectal temperatures are generally 0.4°C (0.7°F) higher than oral readings. The lower oral readings are probably attributable to mouth breathing, which is a factor in patients with respiratory infections and rapid breathing. Lower-esophageal temperatures closely reflect core temperature. Tympanic membrane thermometers measure radiant heat from the tympanic membrane and nearby ear canal and display that absolute value (*unadjusted mode*) or a value automatically calculated from the absolute reading on the basis of nomograms relating the radiant temperature measured to actual core temperatures obtained in clinical studies (*adjusted mode*). These measurements, although convenient, may be more variable than directly determined oral or rectal values. Studies in adults show that readings are lower with unadjusted-mode than with adjusted-mode tympanic membrane thermometers and that unadjusted-mode tympanic membrane values are 0.8°C (1.6°F) lower than rectal temperatures.

In women who menstruate, the A.M. temperature is generally lower during the 2 weeks before ovulation; it then rises by ~0.6°C (1°F) with ovulation and stays at that level until menses occur. During the luteal phase, the amplitude of the circadian rhythm remains the same.

FEVER VERSUS HYPERTHERMIA

Fever is an elevation of body temperature that exceeds the normal daily variation and occurs *in conjunction with an increase in the hypothalamic set point* (e.g., from 37°C to 39°C). This shift of the set point from "normothermic" to febrile levels very much resembles the resetting of the home thermostat to a higher level in order to raise the ambient temperature in a room. Once the hypothalamic set point is raised, neurons in the vasomotor center are activated and vasoconstriction commences. The individual first notices vasoconstriction in the hands and feet. Shunting of blood away from the periphery to the internal organs essentially decreases heat loss from the skin, and the person feels cold. For most fevers, body temperature increases by 1–2°C. Shivering, which increases heat production from the muscles, may begin at this time; however, shivering is not required if mechanisms of heat conservation raise blood temperature sufficiently. Nonshivering heat production from the liver also contributes to increasing core temperature. Behavioral adjustments (e.g., putting on more clothing or bedding) help raise body temperature by decreasing heat loss.

The processes of heat conservation (vasoconstriction) and heat production (shivering and increased nonshivering thermogenesis) continue until the temperature of the blood bathing the hypothalamic neurons matches the new "thermostat setting." Once that point is reached, the hypothalamus maintains the temperature at the febrile level by the same mechanisms of heat balance that function in the afebrile state. When the hypothalamic set point is again reset downward (in response to either a reduction in the concentration of pyrogens or the use of antipyretics), the processes of heat loss through vasodilation and sweating are initiated. Loss of heat by sweating and vasodilation continues until the blood temperature at the hypothalamic level matches the lower setting. Behavioral changes (e.g., removal of clothing) facilitate heat loss.

A fever of >41.5°C (>106.7°F) is called *hyperpyrexia*. This extraordinarily high fever can develop in patients with severe infections but most commonly occurs in patients with central nervous system (CNS) hemorrhages. In the preantibiotic era, fever due to a variety of infectious diseases rarely exceeded 106°F, and there has been speculation that this natural "thermal ceiling" is mediated by neuropeptides functioning as central antipyretics.

In rare cases, the hypothalamic set point is elevated as a result of local trauma, hemorrhage, tumor, or intrinsic hypothalamic malfunction. The term *hypothalamic fever* is sometimes used to describe elevated temperature caused by abnormal hypothalamic function. However, most patients with hypothalamic damage have *sub*normal, not *supra*normal, body temperatures.

Although most patients with elevated body temperature have fever, there are circumstances in which elevated temperature represents not fever but *hyperthermia* (*heat stroke*). Hyperthermia is characterized by an uncontrolled increase in body temperature that exceeds the body's ability to lose heat. The setting of the hypothalamic thermoregulatory center is unchanged. In contrast to fever in infections, hyperthermia does not involve pyrogenic molecules. Exogenous heat exposure and endogenous heat production are two mechanisms by which hyperthermia can result in dangerously high internal temperatures. Excessive heat production can easily cause hyperthermia despite physiologic and behavioral control of body temperature. For example, work or exercise in hot environments can produce heat faster than peripheral mechanisms can lose it. **For a detailed discussion of hyperthermia, see Chap. 465.**

It is important to distinguish between fever and hyperthermia since hyperthermia can be rapidly fatal and characteristically does not respond to antipyretics. In an emergency situation, however, making this distinction can be difficult. For example, in systemic sepsis, fever (hyperpyrexia) can be rapid in onset, and temperatures can exceed 40.5°C (104.9°F). Hyperthermia is often diagnosed on the basis of the events immediately preceding the elevation of core temperature—e.g., heat exposure or treatment with drugs that interfere with thermoregulation. In patients with heat stroke syndromes and in those taking drugs that block sweating, the skin is hot but dry, whereas in fever, the skin can be cold as a consequence of vasoconstriction. Antipyretics do not reduce the elevated temperature in hyperthermia, whereas in fever—and even in hyperpyrexia—adequate doses of either aspirin or acetaminophen usually result in some decrease in body temperature.

PATHOGENESIS OF FEVER

PYROGENS

The term *pyrogen* (Greek *pyro*, "fire") is used to describe any substance that causes fever. *Exogenous* pyrogens are derived from outside the patient; most are microbial products, microbial toxins, or whole microorganisms (including viruses). The classic example of an exogenous pyrogen is the lipopolysaccharide (endotoxin) produced by all gram-negative bacteria. Pyrogenic products of gram-positive organisms include the enterotoxins of *Staphylococcus aureus* and the groups A and B streptococcal toxins, also called *superantigens*. One staphylococcal toxin of clinical importance is that associated with isolates of *S. aureus* from patients with toxic shock syndrome. These products of staphylococci and streptococci cause fever in experimental animals when injected intravenously at concentrations of 1–10 μg/kg. Endotoxin is a highly pyrogenic molecule in humans: when injected intravenously into volunteers, a dose of 2–3 ng/kg produces fever, leukocytosis, acute-phase proteins, and generalized symptoms of malaise.

PYROGENIC CYTOKINES

Cytokines are small proteins (molecular mass, 10,000–20,000 Da) that regulate immune, inflammatory, and hematopoietic processes. For example, the elevated leukocytosis seen in several infections with an absolute neutrophilia is attributable to the cytokines interleukin (IL) 1 and IL-6. Some cytokines also cause fever; formerly referred to as *endogenous pyrogens*, they are now called *pyrogenic cytokines*. The pyrogenic cytokines include IL-1, IL-6, tumor necrosis factor (TNF), and ciliary neurotropic factor, a member of the IL-6 family. Fever is a prominent side effect of interferon α therapy. Each pyrogenic cytokine is encoded by a separate gene, and each has been shown to cause fever in laboratory animals and in humans. When injected into humans at low doses (10–100 ng/kg), IL-1 and TNF produce fever; in contrast, for IL-6, a dose of 1–10 μg/kg is required for fever production.

A wide spectrum of bacterial and fungal products induce the synthesis and release of pyrogenic cytokines. However, fever can be a manifestation of disease in the absence of microbial infection. For example, inflammatory processes such as pericarditis, trauma, stroke, and routine immunizations induce the production of IL-1, TNF, and/or IL-6; individually or in combination, these cytokines trigger the hypothalamus to raise the set point to febrile levels.

ELEVATION OF THE HYPOTHALAMIC SET POINT BY CYTOKINES

During fever, levels of prostaglandin E_2 (PGE_2) are elevated in hypothalamic tissue and the third cerebral ventricle. The concentrations of PGE_2 are highest near the circumventricular vascular organs (organum vasculosum of lamina terminalis)—networks of enlarged capillaries surrounding the hypothalamic regulatory centers. Destruction of these organs reduces the ability of pyrogens to produce fever. Most studies in animals have failed to show, however, that pyrogenic cytokines pass from the circulation into the brain itself. Thus, it appears that both exogenous pyrogens and pyrogenic cytokines interact with the endothelium of these capillaries and that this interaction is the first step in initiating fever—i.e., in raising the set point to febrile levels.

The key events in the production of fever are illustrated in Fig. 18-1. Myeloid and endothelial cells are the primary cell types that produce pyrogenic cytokines. Pyrogenic cytokines such as IL-1, IL-6, and TNF are released from these cells and enter the systemic circulation. Although these circulating cytokines lead to fever by inducing the synthesis of PGE_2, they also induce PGE_2 in peripheral tissues. The increase in PGE_2 in the periphery accounts for the nonspecific myalgias and arthralgias that often accompany fever. It is thought that some systemic PGE_2 escapes destruction by the lung and gains access to the hypothalamus via the internal carotid. However, it is the elevation of PGE_2 in the brain that starts the process of raising the hypothalamic set point for core temperature.

There are four receptors for PGE_2, and each signals the cell in different ways. Of the four receptors, the third (EP-3) is essential for fever: when the gene for this receptor is deleted in mice, no fever follows the injection of IL-1 or endotoxin. Deletion of the other PGE_2 receptor genes leaves the fever mechanism intact. Although PGE_2 is essential for fever, it is not a neurotransmitter. Rather, the release of PGE_2 from the brain side of the hypothalamic endothelium triggers the PGE_2 receptor on glial cells, and this stimulation results in the rapid release of cyclic adenosine 5′-monophosphate (cAMP), which is a neurotransmitter. As shown in Fig. 18-1, the release of cAMP from glial cells activates neuronal endings from the thermoregulatory center that extend into the area. The elevation of cAMP is thought to account for changes in the hypothalamic set point either directly or indirectly (by inducing the release of neurotransmitters). Distinct receptors for microbial products are located on the hypothalamic endothelium. These receptors are called *Toll-like receptors* and are similar in many ways to IL-1 receptors. IL-1 receptors and Toll-like receptors share the same signal-transducing mechanism. Thus, the direct activation of Toll-like receptors or IL-1 receptors results in PGE_2 production and fever.

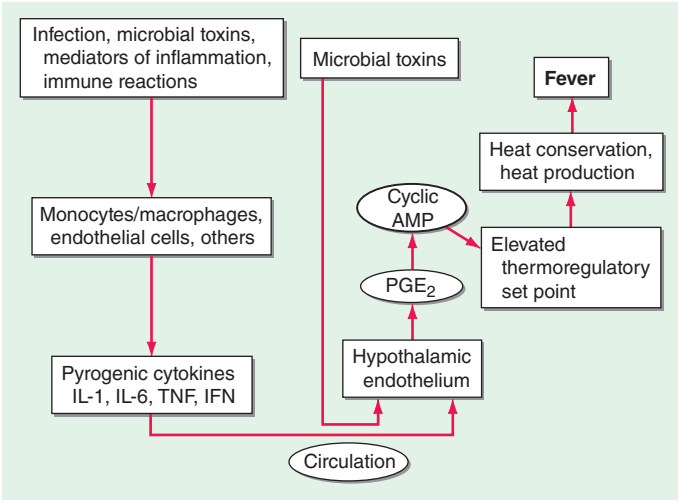

FIGURE 18-1 Chronology of events required for the induction of fever. AMP, adenosine 5′-monophosphate; IFN, interferon; IL, interleukin; PGE_2, prostaglandin E_2; TNF, tumor necrosis factor.

PRODUCTION OF CYTOKINES IN THE CNS

Cytokines produced in the brain may account for the hyperpyrexia of CNS hemorrhage, trauma, or infection. Viral infections of the CNS induce microglial and possibly neuronal production of IL-1, TNF, and IL-6. In experimental animals, the concentration of a cytokine required to cause fever is several orders of magnitude lower with direct injection into the brain substance or brain ventricles than with systemic injection. Therefore, cytokines produced in the CNS can raise the hypothalamic set point, bypassing the circumventricular organs. CNS cytokines likely account for the hyperpyrexia of CNS hemorrhage, trauma, or infection.

APPROACH TO THE PATIENT

Fever

HISTORY AND PHYSICAL EXAMINATION

There are a range of disease processes that present with fever as a cardinal manifestation, and a thorough history can help distinguish between these broad categories (Table 18-1). The chronology of events preceding fever, including exposure to other symptomatic individuals or to vectors of disease, should be ascertained. Electronic devices for measuring oral, tympanic membrane, or rectal temperatures are reliable, but the same site should be used consistently to monitor a febrile disease. Moreover, physicians should be aware that newborns, elderly patients, patients with chronic hepatic or renal failure, and patients taking glucocorticoids or being treated with an anticytokine may have active disease in the absence of fever because of a blunted febrile response.

TABLE 18-1 Disease Categories That Present with Fever as a Cardinal Sign

Infectious diseases
Autoimmune and noninfectious inflammatory disorders
Cancer
Medication related (e.g., vaccines, drug fever)
Endocrine disorders (e.g., hyperthyroidism)
Intrinsic hypothalamic malfunction

LABORATORY TESTS

The workup should include a complete blood count; a differential count should be performed manually or with an instrument sensitive to the identification of juvenile or band forms, toxic granulations, and Döhle bodies, which are suggestive of bacterial infection. Neutropenia may be present with some viral infections.

Measurement of circulating cytokines in patients with fever is not helpful since levels of cytokines such as IL-1 and TNF in the circulation often are below the detection limit of the assay or do not coincide with fever. However, in patients with low-grade fevers or with suspected occult disease, the most valuable measurements are the C-reactive protein (CRP) level and the erythrocyte sedimentation rate. These markers of inflammatory processes are particularly helpful in detecting occult disease. Measurement of circulating IL-6, which induces CRP, can be useful. However, whereas IL-6 levels may vary during a febrile disease, CRP levels remain elevated. Acute-phase reactants are discussed in **Chap. 304**.

FEVER IN PATIENTS RECEIVING ANTICYTOKINE THERAPY

Patients receiving long-term treatment with anticytokine-based regimens are at increased risk of infection because of lowered host defenses. For example, latent *Mycobacterium tuberculosis* infection can disseminate in patients receiving anti-TNF therapy. With the increasing use of anticytokines to reduce the activity of IL-1, IL-6, IL-12, IL-17, or TNF in patients with Crohn's disease, rheumatoid arthritis, or psoriasis, the possibility that these therapies blunt the febrile response should be kept in mind.

The blocking of cytokine activity has the distinct clinical drawback of lowering the level of host defenses against both routine bacterial and opportunistic infections such as *M. tuberculosis* and fungal infections. The use of monoclonal antibodies to reduce IL-17 in psoriasis increases the risk of systemic candidiasis.

In nearly all reported cases of infection associated with anticytokine therapy, fever is among the presenting signs. However, the extent to which the febrile response is blunted in these patients remains unknown. Therefore, low-grade fever in patients receiving anticytokine therapies is of considerable concern. The physician should conduct an early and rigorous diagnostic evaluation in these cases. The febrile response is also blunted in patients receiving chronic glucocorticoid therapy or anti-inflammatory agents such as nonsteroidal anti-inflammatory drugs (NSAIDs).

TREATMENT

Fever

THE DECISION TO TREAT FEVER

In deciding whether to treat fever, it is important to remember that fever itself is not an illness: it is an ordinary response to a perturbation of normal host physiology. Most fevers are associated with self-limited infections, such as common viral diseases. The use of antipyretics is not contraindicated in these infections: no significant clinical evidence indicates either that antipyretics delay the resolution of viral or bacterial infections or that fever facilitates recovery from infection or acts as an adjuvant to the immune system. In short, treatment of fever and its symptoms with routine antipyretics does no harm and does not slow the resolution of common viral and bacterial infections.

However, in bacterial infections, the withholding of antipyretic therapy can be helpful in evaluating the effectiveness of a particular antibiotic, especially in the absence of positive cultures of the infecting organism, and the routine use of antipyretics can mask an inadequately treated bacterial infection. Withholding antipyretics in some cases may facilitate the diagnosis of an unusual febrile disease. Temperature–pulse dissociation (*relative bradycardia*) occurs in typhoid fever, brucellosis, leptospirosis, some drug-induced fevers, and factitious fever. As stated earlier, in newborns, elderly patients, patients with chronic liver or kidney failure, and patients taking glucocorticoids, fever may not be present despite infection. Hypothermia can develop in patients with septic shock.

Some infections have characteristic patterns in which febrile episodes are separated by intervals of normal temperature. For example, *Plasmodium vivax* causes fever every third day, whereas fever occurs every fourth day with *Plasmodium malariae*. Another relapsing fever is related to *Borrelia* infection, with days of fever followed by a several-day afebrile period and then a relapse into additional days of fever. In the Pel-Ebstein pattern, fever lasting 3–10 days is followed by afebrile periods of 3–10 days; this pattern can be classic for Hodgkin's disease and other lymphomas. In cyclic neutropenia, fevers occur every 21 days and accompany the neutropenia. There are also a number of periodic fever syndromes (e.g., familial Mediterranean fever, TNF receptor–associated periodic syndrome [TRAPS]) that differ in their periodicity, duration of attack, constellation of clinical features, genetic causes, and therapies **(Chap. 369)**. Understanding these clinical differences can help tailor diagnostic testing to confirm the diagnosis and guide therapy.

ANTICYTOKINE THERAPY TO REDUCE FEVER IN AUTOIMMUNE AND AUTOINFLAMMATORY DISEASES

Recurrent fever is documented at some point in most autoimmune diseases and many autoinflammatory diseases, which include the periodic fever syndromes as well as disorders of inflammasomes (e.g., NLRP3, pyrin) and other components of the innate immune system **(Chap. 349)**. Although fever can be a manifestation of autoimmune diseases, recurrent fevers are characteristic of autoinflammatory diseases, including uncommon diseases such as adult and juvenile Still's disease, familial Mediterranean fever, and hyper-IgD syndrome but also common diseases such as idiopathic pericarditis and gout. In addition to recurrent fevers, neutrophilia and serosal inflammation characterize autoinflammatory diseases. The fevers associated with many of these illnesses are dramatically reduced by blocking of IL-1 activity with anakinra or canakinumab. Anticytokines therefore reduce fever in autoimmune and autoinflammatory diseases. Although fevers in autoinflammatory diseases are mediated by IL-1β, patients also respond to antipyretics.

MECHANISMS OF ANTIPYRETIC AGENTS

The reduction of fever by lowering of the elevated hypothalamic set point is a direct function of reduction of the PGE_2 level in the thermoregulatory center. The synthesis of PGE_2 depends on the constitutively expressed enzyme cyclooxygenase. The substrate for cyclooxygenase is arachidonic acid released from the cell membrane, and this release is the rate-limiting step in the synthesis of PGE_2. Therefore, inhibitors of cyclooxygenase are potent antipyretics. The antipyretic potency of various drugs is directly correlated with the inhibition of brain cyclooxygenase. Acetaminophen is a poor cyclooxygenase inhibitor in peripheral tissue and lacks noteworthy anti-inflammatory activity; in the brain, however, acetaminophen is oxidized by the P450 cytochrome system, and the oxidized form inhibits cyclooxygenase activity. Moreover, in the brain, the inhibition of another enzyme, COX-3, by acetaminophen may account for the antipyretic effect of this agent. However, COX-3 is not found outside the CNS.

Oral aspirin and acetaminophen are equally effective in reducing fever in humans. NSAIDs such as ibuprofen and specific inhibitors of COX-2 also are excellent antipyretics. Chronic, high-dose

therapy with antipyretics such as aspirin or any NSAID does not reduce normal core body temperature. Thus, PGE_2 appears to play no role in normal thermoregulation.

As effective antipyretics, glucocorticoids act at two levels. First, similar to the cyclooxygenase inhibitors, glucocorticoids reduce PGE_2 synthesis by inhibiting the activity of phospholipase A_2, which is needed to release arachidonic acid from the cell membrane. Second, glucocorticoids block the transcription of the mRNA for the pyrogenic cytokines. Limited experimental evidence indicates that ibuprofen and COX-2 inhibitors reduce IL-1-induced IL-6 production and may contribute to the antipyretic activity of NSAIDs.

REGIMENS FOR THE TREATMENT OF FEVER

The objectives in treating fever are first to reduce the elevated hypothalamic set point and second to facilitate heat loss. Reducing fever with antipyretics also reduces systemic symptoms of headache, myalgias, and arthralgias.

Oral aspirin and NSAIDs effectively reduce fever but can adversely affect platelets and the gastrointestinal tract. Therefore, acetaminophen is preferred as an antipyretic. In children, acetaminophen or oral ibuprofen must be used because aspirin increases the risk of Reye's syndrome. If the patient cannot take oral antipyretics, parenteral preparations of NSAIDs and rectal suppositories of various antipyretics can be used.

Treatment of fever in some patients is highly recommended. Fever increases the demand for oxygen (i.e., for every increase of 1°C over 37°C, there is a 13% increase in oxygen consumption) and can aggravate the condition of patients with preexisting impairment of cardiac, pulmonary, or CNS function. Children with a history of febrile or nonfebrile seizure should be aggressively treated to reduce fever. However, it is unclear what triggers the febrile seizure, and there is no correlation between absolute temperature elevation and onset of a febrile seizure in susceptible children.

In hyperpyrexia, the use of cooling blankets facilitates the reduction of temperature; however, cooling blankets should not be used without oral antipyretics. In hyperpyretic patients with CNS disease or trauma (CNS bleeding), reducing core temperature mitigates the detrimental effects of high temperature on the brain.

For a discussion of treatment for hyperthermia, see Chap. 465.

19 Fever and Rash

Elaine T. Kaye, Kenneth M. Kaye

The acutely ill patient with fever and rash often presents a diagnostic challenge for physicians, yet the distinctive appearance of an eruption in concert with a clinical syndrome can facilitate a prompt diagnosis and the institution of life-saving therapy or critical infection-control interventions. **Representative images of many of the rashes discussed in this chapter are included in Chap. A1.**

APPROACH TO THE PATIENT

Fever and Rash

A thorough history of patients with fever and rash includes the following relevant information: immune status, medications taken within the previous month, specific travel history, immunization status, exposure to domestic pets and other animals, history of animal (including arthropod) bites, recent dietary exposures, existence of cardiac abnormalities, presence of prosthetic material, recent exposure to ill individuals, and sexual exposures. The history should also include the site of onset of the rash and its direction and rate of spread.

PHYSICAL EXAMINATION

A thorough physical examination entails close attention to the rash, with an assessment and precise definition of its salient features. First, it is critical to determine what *type* of lesions make up the eruption. *Macules* are flat lesions defined by an area of changed color (i.e., a blanchable erythema). *Papules* are raised, solid lesions <5 mm in diameter; *plaques* are lesions >5 mm in diameter with a flat, plateau-like surface; and *nodules* are lesions >5 mm in diameter with a more rounded configuration. *Wheals* (urticaria, hives) are papules or plaques that are pale pink and may appear annular (ringlike) as they enlarge; classic (nonvasculitic) wheals are transient, lasting only 24 h in any defined area. *Vesicles* (<5 mm) and *bullae* (>5 mm) are circumscribed, elevated lesions containing fluid. *Pustules* are raised lesions containing purulent exudate; vesicular processes such as varicella or herpes simplex may evolve to pustules. *Nonpalpable purpura* is a flat lesion that is due to bleeding into the skin. If <3 mm in diameter, the purpuric lesions are termed *petechiae*; if >3 mm, they are termed *ecchymoses*. *Palpable purpura* is a raised lesion that is due to inflammation of the vessel wall (vasculitis) with subsequent hemorrhage. An *ulcer* is a defect in the skin extending at least into the upper layer of the dermis, and an *eschar* (tâche noire) is a necrotic lesion covered with a black crust.

Other pertinent features of rashes include their *configuration* (i.e., annular or target), the *arrangement* of their lesions, and their *distribution* (i.e., central or peripheral).

For further discussion, see Chaps. 56, 58, 122, and 129.

CLASSIFICATION OF RASH

This chapter reviews rashes that reflect systemic disease, but it does not include localized skin eruptions (i.e., cellulitis, impetigo) that may also be associated with fever **(Chap. 129)**. The chapter is not intended to be all-inclusive, but it covers the most important and most common diseases associated with fever and rash. Rashes are classified herein on the basis of lesion morphology and distribution. For practical purposes, this classification system is based on the most typical disease presentations. However, morphology may vary as rashes evolve, and the presentation of diseases with rashes is subject to many variations **(Chap. 58)**. For instance, the classic petechial rash of Rocky Mountain spotted fever **(Chap. 187)** may initially consist of blanchable erythematous macules distributed peripherally; at times, however, the rash associated with this disease may not be predominantly acral, or no rash may develop at all.

Diseases with fever and rash may be classified by type of eruption: centrally distributed maculopapular, peripheral, confluent desquamative erythematous, vesiculobullous, urticaria-like, nodular, purpuric, ulcerated, or with eschars. Diseases are listed by these categories in **Table 19-1**, and many are highlighted in the text. However, for a more detailed discussion of each disease associated with a rash, the reader is referred to the chapter dealing with that specific disease. **(Reference chapters are cited in the text and listed in Table 19-1.)**

CENTRALLY DISTRIBUTED MACULOPAPULAR ERUPTIONS

Centrally distributed rashes, in which lesions are primarily truncal, are the most common type of eruption. The rash of *rubeola* (measles) starts

TABLE 19-1 Diseases Associated with Fever and Rash

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Centrally Distributed Maculopapular Eruptions					
Acute meningococcemia[a]	—	—	—	—	155
Drug reaction with eosinophilia and systemic symptoms (DRESS); also termed drug-induced hypersensitivity syndrome (DIHS)[b]; Chikungunya[c]; COVID-19[c]	—	—	—	—	60
Rubeola (measles, first disease) (Fig. 19-1, Fig. A1-2, Fig. A1-3)	Paramyxovirus	Discrete lesions that become confluent as rash spreads from hairline downward, usually sparing palms and soles; lasts ≥3 days; Koplik's spots	Nonimmune individuals	Cough, conjunctivitis, coryza, severe prostration	205
Rubella (German measles, third disease) (Fig. A1-4)	Togavirus	Spreads from hairline downward, clearing as it spreads; Forchheimer spots	Nonimmune individuals	Adenopathy, arthritis	206
Erythema infectiosum (fifth disease) (Fig. A1-1)	Human parvovirus B19	Bright-red "slapped-cheeks" appearance followed by lacy reticular rash that waxes and wanes over 3 weeks; rarely, papular-purpuric "gloves-and-socks" syndrome on hands and feet	Most common among children 3–12 years old; occurs in winter and spring	Mild fever; arthritis in adults; rash following resolution of fever	197
Exanthem subitum (roseola, sixth disease) (Fig. A1-5)	Human herpesvirus 6 or, less commonly, the closely related human herpesvirus 7	Diffuse maculopapular eruption over trunk and neck; resolves within 2 days	Usually affects children <3 years old	Rash following resolution of fever; similar to Boston exanthem (echovirus 16); febrile seizures may occur	195
Primary HIV infection (Fig. A1-6)	HIV	Nonspecific diffuse macules and papules most commonly on upper thorax, face, collar region; less commonly, urticarial or vesicular lesions; oral or genital ulcers	Individuals recently infected with HIV	Pharyngitis, adenopathy, arthralgias	202
Infectious mononucleosis	Epstein-Barr virus	Diffuse maculopapular eruption (5% of cases; 30–90% if ampicillin is given); urticaria, petechiae in some cases; periorbital edema (50%); palatal petechiae (25%)	Adolescents, young adults	Hepatosplenomegaly, pharyngitis, cervical lymphadenopathy, atypical lymphocytosis, heterophile antibody	194
Other viral exanthems	Echoviruses 2, 4, 9, 11, 16, 19, 25; coxsackieviruses A9, B1, B5; etc.	Wide range of skin findings that may mimic rubella or measles	Affect children more commonly than adults	Nonspecific viral syndromes	204
Exanthematous drug-induced eruption (Fig. A1-7)	Drugs (antibiotics, anticonvulsants, diuretics, etc.)	Intensely pruritic, bright-red macules and papules, symmetric on trunk and extremities; may become confluent	Occurs 2–3 days after exposure in previously sensitized individuals; otherwise, after 2–3 weeks (but can occur anytime, even shortly after drug is discontinued)	Variable findings: fever and eosinophilia	60
Epidemic typhus	*Rickettsia prowazekii*	Maculopapular eruption appearing in axillae, spreading to trunk and later to extremities; usually spares face, palms, soles; evolves from blanchable macules to confluent eruption with petechiae; rash evanescent in recrudescent typhus (Brill-Zinsser disease)	Exposure to body lice; occurrence of recrudescent typhus as relapse after 30–50 years	Headache, myalgias; mortality rates 10–40% if untreated; milder clinical presentation in recrudescent form	187
Endemic (murine) typhus	*Rickettsia typhi*	Maculopapular eruption, usually sparing palms, soles	Exposure to rat or cat fleas	Headache, myalgias	187
Scrub typhus	*Orientia tsutsugamushi*	Diffuse macular rash starting on trunk; eschar at site of mite bite	Endemic in South Pacific, Australia, Asia; transmitted by mites	Headache, myalgias, regional adenopathy; mortality rates up to 30% if untreated	187
Rickettsial spotted fevers (Fig. 19-8)	*Rickettsia conorii* (boutonneuse fever), *Rickettsia australis* (North Queensland tick typhus), *Rickettsia sibirica* (Siberian tick typhus), *Rickettsia africae* (African tick-bite fever), and others	Eschar common at bite site; maculopapular (rarely, vesicular and petechial) eruption on proximal extremities, spreading to trunk and face	Exposure to ticks; *R. conorii* in Mediterranean region, India, Africa; *R. australis* in Australia; *R. sibirica* in Siberia, Mongolia; *R. africae* in Africa, Caribbean	Headache, myalgias, regional adenopathy	187

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Human monocytotropic ehrlichiosis[d]	*Ehrlichia chaffeensis*	Maculopapular eruption (40% of cases), involves trunk and extremities; may be petechial	Tick-borne; most common in U.S. Southeast, southern Midwest, and mid-Atlantic regions	Headache, myalgias, leukopenia	187
Leptospirosis	*Leptospira interrogans* and other *Leptospira* species	Maculopapular eruption; conjunctivitis; scleral hemorrhage in some cases	Exposure to water contaminated with animal urine	Myalgias; aseptic meningitis; *fulminant form*: icterohemorrhagic fever (Weil's disease)	184
Lyme disease **(Fig. A1-8)**	*Borrelia burgdorferi* (sole cause in U.S.), *Borrelia afzelii, Borrelia garinii*	Papule expanding to erythematous annular lesion with central clearing (erythema migrans; average diameter, 15 cm), sometimes with concentric rings, sometimes with indurated or vesicular center; multiple secondary erythema migrans lesions in some cases	Bite of *Ixodes* tick vector	Headache, myalgias, chills, photophobia occurring acutely; CNS disease, myocardial disease, arthritis weeks to months later in some cases	186
Southern tick-associated rash illness (STARI, Master's disease)	Unknown (possibly *Borrelia lonestari* or other *Borrelia* spirochetes)	Similar to erythema migrans of Lyme disease with several differences, including: multiple secondary lesions less likely; lesions tending to be smaller (average diameter, ~8 cm); central clearing more likely	Bite of tick vector *Amblyomma americanum* (Lone Star tick); often found in regions where Lyme disease is uncommon, including southern United States	Compared with Lyme disease: fewer constitutional symptoms, tick bite more likely to be recalled; other Lyme disease sequelae lacking	186
Typhoid fever **(Fig. A1-9)**	*Salmonella typhi*	Transient, blanchable erythematous macules and papules, 2–4 mm, usually on trunk (rose spots)	Ingestion of contaminated food or water (rare in U.S.)	Variable abdominal pain and diarrhea; headache, myalgias, hepatosplenomegaly	165
Dengue fever[e] **(Fig. A1-53)**	Dengue virus (4 serotypes; flaviviruses)	Rash in 50% of cases; initially diffuse flushing; midway through illness, onset of maculopapular rash, which begins on trunk and spreads centrifugally to extremities and face; pruritus, hyperesthesia in some cases; after defervescence, petechiae on extremities may occur	Occurs in tropics and subtropics; transmitted by mosquito	Headache; musculoskeletal pain ("breakbone fever"); leukopenia; occasionally biphasic ("saddleback") fever	209
Rat-bite fever (sodoku)	*Spirillum minus*	Eschar at bite site; then blotchy violaceous or red-brown rash involving trunk and extremities	Rat bite; primarily found in Asia; rare in U.S.	Regional adenopathy; recurrent fevers if untreated	141
Relapsing fever	*Borrelia* species	Central rash at end of febrile episode; petechiae in some cases	Exposure to ticks or body lice	Recurrent fever, headache, myalgias, hepatosplenomegaly	185
Erythema marginatum (rheumatic fever)	Group A *Streptococcus*	Erythematous annular papules and plaques occurring as polycyclic lesions in waves over trunk, proximal extremities; evolving and resolving within hours	Patients with rheumatic fever	Pharyngitis preceding polyarthritis, carditis, subcutaneous nodules, chorea	388
Systemic lupus erythematosus (SLE) **(Fig. A1-10, Fig. A1-11, Fig. A1-12)**	Autoimmune disease	Macular and papular erythema, often in sun-exposed areas; discoid lupus lesions (local atrophy, scale, pigmentary changes); periungual telangiectasis; malar rash; vasculitis sometimes causing urticaria, palpable purpura; oral erosions in some cases	Most common in young to middle-aged women; flares precipitated by sun exposure	Arthritis; cardiac, pulmonary, renal, hematologic, and vasculitic disease	359
Still's disease **(Fig. A1-13)**	Autoimmune disease	Transient 2- to 5-mm erythematous papules appearing at height of fever on trunk, proximal extremities; lesions evanescent	Children and young adults	High spiking fever, polyarthritis, splenomegaly; erythrocyte sedimentation rate >100 mm/h	—
African trypanosomiasis **(Fig. A1-47)**	*Trypanosoma brucei rhodesiense/gambiense*	Blotchy or annular erythematous macular and papular rash (trypanid), primarily on trunk; pruritus; chancre at site of tsetse fly bite may precede rash by several weeks	Tsetse fly bite in eastern (*T. brucei rhodesiense*) or western (*T. brucei gambiense*) Africa	Hemolymphatic disease followed by meningoencephalitis; Winterbottom's sign (posterior cervical lymphadenopathy) *(T. brucei gambiense)*	227
Arcanobacterial pharyngitis	*Arcanobacterium (Corynebacterium) haemolyticum*	Diffuse, erythematous, maculopapular eruption involving trunk and proximal extremities; may desquamate	Children and young adults	Exudative pharyngitis, lymphadenopathy	150

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
West Nile virus infection	West Nile virus	Maculopapular eruption involving the trunk, extremities, and head or neck; rash in 20–50% of cases	Mosquito bite; rarely, blood transfusion or transplanted organ	Headache, weakness, malaise, myalgia, neuroinvasive disease (encephalitis, meningitis, flaccid paralysis)	209
Zika virus infection (Fig. A1-51)	Zika virus	Pruritic macular and papular erythema; rash may begin on trunk and descend to lower body; conjunctival injection; palatal petechiae may occur	Mosquito bite; sexual transmission or blood transfusion less common	Arthralgia (especially of small joints), myalgia, lymphadenopathy, headache, low-grade fever; illness in pregnancy may cause severe birth defects, including microcephaly; neurologic complications, including Guillain-Barré, may occur	209
Peripheral Eruptions					
Chronic meningococcemia, disseminated gonococcal infection,[a] human parvovirus B19 infection,[f] MIRM[g]	—	—	—	—	155, 156, 197
Rocky Mountain spotted fever (Fig. 19-2, Fig. A1-16)	*Rickettsia rickettsii*	Rash beginning on wrists and ankles and spreading centripetally; appears on palms and soles later in disease; lesion evolution from blanchable macules to petechiae	Tick vector; widespread but more common in southeastern and southwest-central U.S.	Headache, myalgias, abdominal pain; mortality rates up to 40% if untreated	187
Secondary syphilis (Figs. A1-18, Fig. A1-19, Fig. A1-20, Fig. A1-21)	*Treponema pallidum*	Coincident primary chancre in 10% of cases; copper-colored, scaly papular eruption, diffuse but prominent on palms and soles; rash never vesicular in adults; condyloma latum, mucous patches, and alopecia in some cases	Sexually transmitted	Fever, constitutional symptoms	182
Chikungunya fever (Fig. A1-54)	Chikungunya virus	Maculopapular eruption; typically occurs on trunk, but also occurs on extremities and face	*Aedes aegypti* and *A. albopictus* mosquito bites; tropical and subtropical regions	Severe polyarticular, migratory arthralgias, especially involving small joints (e.g., hands, wrists, ankles)	209
Hand-foot-and-mouth disease (Fig. A1-22)	Coxsackievirus A16 and enterovirus 71 most common causes; coxsackievirus A6 associated with atypical syndrome	Tender vesicles, erosions in mouth; 0.25-cm papules on hands and feet with rim of erythema evolving into tender vesicles; shedding of nails (onychomadesis) can occur 1–2 months after acute illness; coxsackievirus A6 lesions may also be maculopapular, petechial, purpuric, or erosive; atypical form often extends to perioral area, extremities, trunk, buttocks, genitals, and areas affected by eczema (eczema coxsackium)	Summer and fall; primarily children <10 years old; multiple family members; coxsackievirus A6 infection also occurs in young adults	Transient fever; enterovirus 71 can be associated with brain stem encephalitis, flaccid paralysis resembling polio, or aseptic meningitis	204
Erythema multiforme (EM) (Fig. A1-24)	Infection, drugs, idiopathic causes	Target lesions (central erythema surrounded by area of clearing and another rim of erythema) up to 2 cm; symmetric on knees, elbows, palms, soles; spreads centripetally; papular, sometimes vesicular; when extensive and involving mucous membranes, termed *EM major*	Herpes simplex virus or *Mycoplasma pneumoniae* infection; drug intake (i.e., sulfa, phenytoin, penicillin)	50% of patients <20 years old; fever more common in most severe form, EM major, which can be confused with Stevens-Johnson syndrome (but EM major lacks prominent skin sloughing)	—[h]
Rat-bite fever (Haverhill fever)	*Streptobacillus moniliformis*	Maculopapular eruption over palms, soles, and extremities; tends to be more severe at joints; eruption sometimes becoming generalized; may be purpuric; may desquamate	Rat bite, ingestion of contaminated food	Myalgias; arthritis (50%); fever recurrence in some cases	141

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Bacterial endocarditis **(Fig. A1-23)**	*Streptococcus*, *Staphylococcus*, etc.	*Subacute course* (e.g., viridans streptococci): Osler's nodes (tender pink nodules on finger or toe pads); petechiae on skin and mucosa; splinter hemorrhages. *Acute course* (e.g., *Staphylococcus aureus*): Janeway lesions (painless erythematous or hemorrhagic macules, usually on palms and soles)	Abnormal heart valve (e.g., viridans streptococci), intravenous drug use	New or changing heart murmur	**128**
COVID-19 **(Fig. A1-57)**	SARS-CoV-2	*Mild or asymptomatic COVID-19:* Pernio (macules, papules, or plaques that are tender, erythematous/violaceous; acral, feet more common than hands); *Moderate/severe COVID-19:* vesicles, urticaria, maculopapular erythema; often pruritic; occur on trunk, extremities; *Severe COVID-19:* Retiform purpura (net-like, purple patches/ plaques often with necrosis); lesions often asymptomatic; occur on extremities, buttocks; *Multisystem inflammatory syndrome in children (MIS-C):* findings *similar to Kawasaki disease*	Infection with SARS-CoV-2; MIS-C in older children/adolescents	Ranging from asymptomatic to mild/ moderate with loss of taste/smell, pharyngitis, cough, fever, to severe with dyspnea, ARDS; complications include thrombosis, especially with retiform purpura; lesions may be delayed compared to other COVID-19 symptoms; MIS-C occurs ~2-6 weeks following acute (often asymptomatic) infection	
Confluent Desquamative Erythemas					
Scarlet fever (second disease) **(Fig. A1-25)**	Group A *Streptococcus* (pyrogenic exotoxins A, B, C)	Diffuse blanchable erythema beginning on face and spreading to trunk and extremities; circumoral pallor; "sandpaper" texture to skin; accentuation of linear erythema in skin folds (Pastia's lines); enanthem of white evolving into red "strawberry" tongue; desquamation in second week	Most common among children 2–10 years old; usually follows group A streptococcal pharyngitis	Fever, pharyngitis, headache	**148**
Kawasaki disease **(Fig. A1-29)**	Idiopathic	Rash similar to scarlet fever (scarlatiniform) or EM; fissuring of lips, strawberry tongue; conjunctivitis; edema of hands, feet; desquamation later in disease	Children <8 years old	Cervical adenopathy, pharyngitis, coronary artery vasculitis	**58, 363**
Streptococcal toxic shock syndrome	Group A *Streptococcus* (associated with pyrogenic exotoxin A and/ or B or certain M types)	When present, rash often scarlatiniform	May occur in setting of severe group A streptococcal infections (e.g., necrotizing fasciitis, bacteremia, pneumonia)	Multiorgan failure, hypotension; mortality rate 30%	**148**
Staphylococcal toxic shock syndrome	*S. aureus* (toxic shock syndrome toxin 1, enterotoxins B and others)	Diffuse erythema involving palms; pronounced erythema of mucosal surfaces; conjunctivitis; desquamation 7–10 days into illness	Colonization with toxin-producing *S. aureus*	Fever >39°C (>102°F), hypotension, multiorgan dysfunction	**147**
Staphylococcal scalded-skin syndrome **(Fig. 19-3, Fig. A1-28)**	*S. aureus*, phage group II	Diffuse tender erythema, often with bullae and desquamation; Nikolsky's sign	Colonization with toxin-producing *S. aureus*; occurs in children <10 years old (termed *Ritter's disease* in neonates) or adults with renal dysfunction	Irritability; nasal or conjunctival secretions	**147**
Exfoliative erythroderma syndrome **(Fig. A1-27)**	Underlying psoriasis, eczema, drug eruption, mycosis fungoides	Diffuse erythema (often scaling) interspersed with lesions of underlying condition	Usually occurs in adults over age 50; more common among men	Fever, chills (i.e., difficulty with thermoregulation); lymphadenopathy	**58, 60**
DRESS (drug-induced hypersensitivity syndrome [DIHS]) **(Fig. A1-48)**	Aromatic anticonvulsants; other drugs, including sulfonamides, minocycline	Maculopapular eruption (mimicking exanthematous drug rash), sometimes progressing to exfoliative erythroderma; profound edema, especially facial; pustules may occur	Individuals genetically unable to detoxify arene oxides (anticonvulsant metabolites), patients with slow *N*-acetylating capacity (sulfonamides)	Lymphadenopathy, multiorgan failure (especially hepatic), eosinophilia, atypical lymphocytes; mimics sepsis	**60**
Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) **(Fig. A1-26)**	Drugs (80% of cases; often allopurinol, anticonvulsants, antibiotics), infection, idiopathic factors	Erythematous and purpuric macules, sometimes targetoid, or diffuse erythema progressing to bullae, with sloughing and necrosis of entire epidermis; Nikolsky's sign; involves mucosal surfaces; TEN (>30% epidermal necrosis) is maximal form; SJS involves <10% of epidermis; SJS/TEN overlap involves 10–30% of epidermis	Uncommon among children; more common among patients with HIV infection, systemic lupus erythematosus, certain HLA types, or slow acetylators	Dehydration, sepsis sometimes resulting from lack of normal skin integrity; mortality rates up to 30%	**60**

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Vesiculobullous or Pustular Eruptions					
Hand-foot-and-mouth syndrome[c]; staphylococcal scalded-skin syndrome[b]; TEN[b]; DRESS[b]; COVID-19[c]	—	—	—	—	—[h]
Varicella (chickenpox) **(Fig. 19-4, Fig. A1-30)**	Varicella-zoster virus (VZV)	Macules (2–3 mm) evolving into papules, then vesicles (sometimes umbilicated), on an erythematous base ("dewdrops on a rose petal"); pustules then forming and crusting; lesions appearing in crops; may involve scalp, mouth; intensely pruritic	Usually affects children; 10% of adults susceptible; most common in late winter and spring; incidence down by 90% in U.S. as a result of varicella vaccination	Malaise; generally mild disease in healthy children; more severe disease with complications in adults and immunocompromised children	**193**
Pseudomonas "hot-tub" folliculitis **(Fig. A1-55)**	*Pseudomonas aeruginosa*	Pruritic erythematous follicular, papular, vesicular, or pustular lesions that may involve axillae, buttocks, abdomen, and especially areas occluded by bathing suits; can manifest as tender isolated nodules on palmar or plantar surfaces (the latter designated "*Pseudomonas* hot-foot syndrome")	Bathers in hot tubs or swimming pools; occurs in outbreaks	Earache, sore eyes and/or throat; fever may be absent; generally self-limited	**164**
Variola (smallpox) **(Fig. A1-50)**	Variola major virus	Red macules on tongue and palate evolving to papules and vesicles; skin macules evolving to papules, then vesicles, then pustules over 1 week, with subsequent lesion crusting; lesions initially appearing on face and spreading centrifugally from trunk to extremities; differs from varicella in that (1) skin lesions in any given area are at same stage of development and (2) there is a prominent distribution of lesions on face and extremities (including palms, soles)	Nonimmune individuals exposed to smallpox	Prodrome of fever, headache, backache, myalgias; vomiting in 50% of cases	**S3**
Primary herpes simplex virus (HSV) infection	HSV	Erythema rapidly followed by hallmark painful *grouped vesicles* that may evolve into pustules that ulcerate, especially on mucosal surfaces; lesions at site of inoculation: commonly gingivostomatitis for HSV-1 and genital lesions for HSV-2; recurrent disease milder (e.g., herpes labialis does not involve oral mucosa)	Primary infection most common among children and young adults for HSV-1 and among sexually active young adults for HSV-2; no fever in recurrent infection	Regional lymphadenopathy	**192**
Disseminated herpesvirus infection **(Fig. A1-31)**	VZV or HSV	Generalized vesicles that can evolve to pustules and ulcerations; individual lesions similar for VZV and HSV. *Zoster cutaneous dissemination*: >25 lesions extending outside involved dermatome. *HSV*: extensive, progressive mucocutaneous lesions that may occur in absence of dissemination, sometimes disseminate in eczematous skin (eczema herpeticum); HSV visceral dissemination may occur with only localized mucocutaneous disease; in disseminated neonatal disease, skin lesions diagnostically helpful when present, but rash absent in a substantial minority of cases	Patients with immunosuppression, eczema; neonates	Visceral organ involvement (e.g., liver, lungs) in some cases; neonatal disease particularly severe	**138, 192, 193**
Rickettsialpox **(Fig. A1-33)**	*Rickettsia akari*	Eschar found at site of mite bite; generalized rash involving face, trunk, extremities; may involve palms and soles; <100 papules and plaques (2–10 mm); centers of papules develop vesicles or pustules	Seen in urban settings; transmitted by mouse mites	Headache, myalgias, regional adenopathy; mild disease	**187**
Acute generalized exanthematous pustulosis **(Fig. A1-49)**	Drugs (mostly anticonvulsants or antimicrobials); also viral	Tiny, sterile, nonfollicular pustules on erythematous, edematous skin; begins on face and in body folds, then becomes generalized	Appears 2–21 days after start of drug therapy, depending on whether patient has been sensitized	Acute fever, pruritus, leukocytosis	**60**

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Disseminated *Vibrio vulnificus* infection	*V. vulnificus*	Erythematous lesions evolving into hemorrhagic bullae and then into necrotic ulcers	Patients with cirrhosis, diabetes, renal failure; exposure by ingestion of contaminated saltwater, seafood	Hypotension; mortality rate 50%	168
Ecthyma gangrenosum (Fig. A1-34)	*P. aeruginosa*, other gram-negative rods, fungi	Indurated plaque evolving into hemorrhagic bulla or pustule that sloughs, resulting in eschar formation; erythematous halo; most common in axillary, groin, perianal regions	Usually affects neutropenic patients; occurs in up to 28% of individuals with *Pseudomonas* bacteremia	Clinical signs of sepsis	164
Mycoplasma-induced rash and mucositis (MIRM)	*Mycoplasma pneumoniae*	Severe mucositis of at least two sites (e.g., oropharynx, ocular, genital) with nearly universal hemorrhagic crusting of lips; sparse, vesiculobullous, or atypical targetoid rash over <10% of body; lesions typically on extremities but can be truncal; rash sometimes absent (MIRM sine rash)	More common in males; usually children (mean age 11–12 years old)	Evidence *of M. pneumoniae* infection (typically pneumonia); good prognosis; distinct from SJS/TEN; rarely *Chlamydophila pneumoniae* can cause similar syndrome	
Urticaria-Like Eruptions					
COVID-19[c]					
Urticarial vasculitis (Fig. 19-5, Fig. A1-35)	Serum sickness, often due to infection (including acute hepatitis B, enteroviral, parasitic), drugs; connective tissue disease	Erythematous, edematous "urticaria-like" plaques, pruritic or burning; unlike urticaria: typical lesion duration >24 h (up to 5 days) and lack of complete lesion blanching with compression due to hemorrhage	Patients with serum sickness (including acute hepatitis B), connective tissue disease	Fever variable; arthralgias/arthritis	363[h]
Nodular Eruptions					
Disseminated infection (Fig. 19-6, Fig. A1-36, Fig. A1-37, Fig. A1-38)	Fungal infections (e.g., candidiasis, histoplasmosis, cryptococcosis, sporotrichosis, coccidioidomycosis); mycobacteria	Subcutaneous nodules (up to 3 cm); fluctuance, draining common with mycobacteria; necrotic nodules (extremities, periorbital or nasal regions) common with *Aspergillus, Mucor*	Immunocompromised hosts (e.g., bone marrow transplant recipients, patients undergoing chemotherapy, HIV-infected patients)	Features vary with organism	—[h]
Erythema nodosum (septal panniculitis) (Fig. A1-39)	Infections (e.g., streptococcal, fungal, mycobacterial, yersinial); drugs (e.g., sulfas, penicillins, oral contraceptives); sarcoidosis; idiopathic causes	Large, violaceous, nonulcerative, subcutaneous nodules; exquisitely tender; usually on lower legs but also on upper extremities	More common among females 15–30 years old	Arthralgias (50%); features vary with associated condition	—[h]
Sweet syndrome (acute febrile neutrophilic dermatosis) (Fig. A1-40)	*Yersinia* infection; upper respiratory infection; inflammatory bowel disease; pregnancy; malignancy (usually hematologic); drugs (G-CSF)	Tender red or blue edematous nodules giving impression of vesiculation; usually on face, neck, upper extremities; when on lower extremities, may mimic erythema nodosum	More common among women and among persons 30–60 years old; 20% of cases associated with malignancy (men and women equally affected in this group)	Headache, arthralgias, leukocytosis	58
Bacillary angiomatosis	*Bartonella henselae, B. quintana*	Many forms, including erythematous, smooth vascular nodules; friable, exophytic lesions; erythematous plaques (may be dry, scaly); subcutaneous nodules (may be erythematous)	Immunosuppressed individuals, especially those with advanced HIV infection	Peliosis of liver and spleen in some cases; lesions sometimes involving multiple organs; bacteremia	172
Purpuric Eruptions					
Rocky Mountain spotted fever, rat-bite fever, endocarditis[c]; epidemic typhus[f]; dengue fever[e,f]; human parvovirus B19 infection[f]; COVID-19[c]	—	—	—	—	—[h]
Acute meningococcemia	*Neisseria meningitidis*	Initially pink maculopapular lesions evolving into petechiae; petechiae rapidly becoming numerous, sometimes enlarging and becoming vesicular; trunk, extremities most commonly involved; may appear on face, hands, feet; may include purpura fulminans (see below) reflecting DIC	Most common among children, individuals with asplenia or terminal complement component deficiency (C5–C8)	Hypotension, meningitis (sometimes preceded by upper respiratory infection)	155

(*Continued*)

TABLE 19-1 Diseases Associated with Fever and Rash (Continued)

DISEASE	ETIOLOGY	DESCRIPTION	GROUP AFFECTED/ EPIDEMIOLOGIC FACTORS	CLINICAL SYNDROME	CHAPTER
Purpura fulminans **(Fig. 19-7, Fig. A1-41)**	Severe DIC	Large ecchymoses with sharply irregular shapes evolving into hemorrhagic bullae and then into black necrotic lesions	Individuals with sepsis (e.g., involving *N. meningitidis*), malignancy, or massive trauma; asplenic patients at high risk for sepsis	Hypotension	**155, 304**
Chronic meningococcemia **(Fig. A1-42)**	*N. meningitidis*	Variety of recurrent eruptions, including pink maculopapular; nodular (usually on lower extremities); petechial (sometimes developing vesicular centers); purpuric areas with pale blue-gray centers	Individuals with complement deficiencies	Fevers, sometimes intermittent; arthritis, myalgias, headache	**155**
Disseminated gonococcal infection **(Fig. A1-43)**	*Neisseria gonorrhoeae*	Papules (1–5 mm) evolving over 1–2 days into hemorrhagic pustules with gray necrotic centers; hemorrhagic bullae occurring rarely; lesions (usually <40) distributed peripherally near joints (more commonly on upper extremities)	Sexually active individuals (more often females), some with complement deficiency	Low-grade fever, tenosynovitis, arthritis	**156**
Enteroviral petechial rash	Usually echovirus 9 or coxsackievirus A9	Disseminated petechial lesions (may also be maculopapular, vesicular, or urticarial)	Often occurs in outbreaks	Pharyngitis, headache; aseptic meningitis with echovirus 9	**204**
Viral hemorrhagic fever	Arenaviruses, bunyaviruses, filoviruses (including Ebola), flaviviruses (including dengue)	Petechial rash	Residence in or travel to endemic areas, other virus exposure	Triad of fever, shock, hemorrhage from mucosa or gastrointestinal tract	**209, 210**
Thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome	Idiopathic, bloody diarrhea caused by Shiga toxin–generating bacteria (e.g., *Escherichia coli* O157:H7), deficiency in ADAMTS13 (cleaves von Willebrand factor), drugs (e.g., quinine, chemotherapy, immunosuppression)	Petechiae	Individuals with *E. coli* O157:H7 gastroenteritis (especially children), cancer chemotherapy, HIV infection, autoimmune diseases, pregnant/postpartum women, those with ADAMTS13 deficiency	Fever (not always present), microangiopathic hemolytic anemia, thrombocytopenia, renal dysfunction, neurologic dysfunction; coagulation studies normal	**58, 100, 115, 161, 166**
Cutaneous small-vessel vasculitis (leukocytoclastic vasculitis) **(Fig. A1-44)**	Infections (including group A streptococcal infection, hepatitis B or C), drugs, idiopathic factors	Palpable purpuric lesions appearing in crops on legs or other dependent areas; may become vesicular or ulcerative	Occurs in a wide spectrum of diseases, including connective tissue disease, cryoglobulinemia, malignancy, Henoch-Schönlein purpura (HSP); more common among children	Fever (not always present), malaise, arthralgias, myalgias; systemic vasculitis in some cases; renal, joint, and gastrointestinal involvement common in HSP	**58**
Eruptions with Ulcers and/or Eschars					
Scrub typhus, rickettsial spotted fevers, rat-bite fever, African trypanosomiasis[f]; rickettsialpox, ecthyma gangrenosum[g]	—	—	—	—	—[h]
Tularemia **(Fig. A1-45, Fig. A1-46)**	*Francisella tularensis*	Ulceroglandular form: erythematous, tender papule evolves into necrotic, tender ulcer with raised borders; in 35% of cases, eruptions (maculopapular, vesiculopapular, acneiform, or urticarial; erythema nodosum; or EM) may occur	Exposure to ticks, biting flies, infected animals	Fever, headache, lymphadenopathy	**170**
Anthrax **(Fig. A1-52)**	*Bacillus anthracis*	Pruritic papule enlarging and evolving into a 1- by 3-cm painless ulcer surrounded by vesicles and then developing a central eschar with edema; residual scar	Exposure to infected animals or animal products, other exposure to anthrax spores	Lymphadenopathy, headache	**S3**

[a]See "Purpuric Eruptions." [b]See "Confluent Desquamative Erythemas." [c]See "Peripheral Eruptions." [d]Rash is rare in human granulocytotropic ehrlichiosis or anaplasmosis (caused by *Anaplasma phagocytophilum*; most common in the upper midwestern and northeastern United States). [e]See "Viral hemorrhagic fever" under "Purpuric Eruptions" for dengue hemorrhagic fever/dengue shock syndrome. [f]See "Centrally Distributed Maculopapular Eruptions." [g]See "Vesiculobullous or Pustular Eruptions." [h]See etiology-specific chapters.

Abbreviations: CNS, central nervous system; DIC, disseminated intravascular coagulation; G-CSF, granulocyte colony-stimulating factor; HLA, human leukocyte antigen.

FIGURE 19-1 Centrally distributed, maculopapular eruption on the trunk in a patient with measles. *(From EJ Mayeaux Jr et al: Measles, in Usatine RP et al [eds]: Color Atlas and Synopsis of Family Medicine, 3rd ed. New York, McGraw-Hill, 2019, p. 797, Figure 132-2. Reproduced with permission from Richard P. Usatine, MD.)*

at the hairline 2–3 days into the illness and moves down the body, typically sparing the palms and soles **(Fig. 19-1; see also Fig. A1-3) (Chap. 205)**. It begins as discrete erythematous lesions, which become confluent as the rash spreads. Koplik's spots (1- to 2-mm white or bluish lesions with an erythematous halo on the buccal mucosa) **(Fig. A1-2)** are pathognomonic for measles and are generally seen during the first 2 days of symptoms. They should not be confused with Fordyce's spots (ectopic sebaceous glands), which have no erythematous halos and are found in the mouth of healthy individuals. Koplik's spots may briefly overlap with the measles exanthem.

Rubella (German measles) **(Fig. A1-4)** also spreads from the hairline downward; unlike that of measles, however, the rash of rubella tends to clear from originally affected areas as it migrates, and it may be pruritic **(Chap. 206)**. Forchheimer spots (palatal petechiae) may develop but are nonspecific because they also develop in *infectious mononucleosis* **(Chap. 194)**, *scarlet fever* **(Chap. 148)**, and *Zika virus infection* **(Chap. 209) (Fig. A1-51D)**. Postauricular and suboccipital adenopathy and arthritis are common among adults with rubella. Exposure of pregnant women to ill individuals should be avoided, as rubella causes severe congenital abnormalities. Numerous strains of *enteroviruses* **(Chap. 204)**, primarily echoviruses and coxsackieviruses, cause nonspecific syndromes of fever and eruptions that may mimic rubella or measles. Patients with *infectious mononucleosis* caused by Epstein-Barr virus **(Chap. 194)** or with *primary HIV infection* **(Fig. A1-6; see also Chapter 202)** may exhibit pharyngitis, lymphadenopathy, and a nonspecific maculopapular exanthem.

The rash of *erythema infectiosum* (fifth disease), which is caused by human parvovirus B19, primarily affects children 3–12 years old; it develops after fever has resolved as a bright blanchable erythema on the cheeks ("slapped cheeks") **(Fig. A1-1A)** with perioral pallor **(Chap. 197)**. A more diffuse rash (often pruritic) appears the next day on the trunk and extremities and then rapidly develops into a lacy reticular eruption **(Fig. A1-1B)** that may wax and wane (especially with temperature change) over 3 weeks. Adults with fifth disease often have arthritis, and fetal hydrops can develop in association with this condition in pregnant women.

Exanthem subitum (roseola) is caused by human herpesvirus 6, or less commonly by the closely related human herpesvirus 7, and is most common among children <3 years of age **(Chap. 195)**. As in erythema infectiosum, the rash usually appears after fever has subsided. It consists of 2- to 3-mm rose-pink macules and papules that coalesce only rarely, occur initially on the trunk **(Fig. A1-5)** and sometimes on the extremities (sparing the face), and fade within 2 days.

Although drug reactions have many manifestations, including urticaria, exanthematous *drug-induced eruptions* **(Chap. 60) (Fig. A1-7)** are most common and are often difficult to distinguish from viral exanthems. Eruptions elicited by drugs are usually more intensely erythematous and pruritic than viral exanthems, but this distinction is not reliable. A history of new medications and an absence of prostration may help to distinguish a drug-related rash from an eruption of another etiology. Rashes may persist for up to 2 weeks after administration of the offending agent is discontinued. Certain populations are more prone than others to drug rashes. Of HIV-infected patients, 50–60% develop a rash in response to sulfa drugs; 30–90% of patients with mononucleosis due to Epstein-Barr virus develop a rash when given ampicillin.

Rickettsial illnesses **(Chap. 187)** should be considered in the evaluation of individuals with centrally distributed maculopapular eruptions. The usual setting for *epidemic typhus* is a site of war or natural disaster in which people are exposed to body lice. Endemic typhus or *leptospirosis* (the latter caused by a spirochete) **(Chap. 184)** may be seen in urban environments where rodents proliferate. Outside the United States, other rickettsial diseases cause a spotted-fever syndrome and should be considered in residents of or travelers to endemic areas. Similarly, *typhoid fever*, a nonrickettsial disease caused by *Salmonella typhi* **(Chap. 165) (Fig. A1-9)**, is usually acquired during travel outside the United States. *Dengue fever* **(Fig. A1-53)**, caused by a mosquito-transmitted flavivirus, occurs in tropical and subtropical regions of the world **(Chap. 209)**.

Some centrally distributed maculopapular eruptions have distinctive features. Erythema migrans **(Fig. A1-8)**, the rash of *Lyme disease* **(Chap. 186)**, typically manifests as single or multiple annular lesions. Untreated erythema migrans lesions usually fade within a month but may persist for more than a year. *Southern tick-associated rash illness* (STARI) **(Chap. 186)** has an erythema migrans–like rash, but is less severe than Lyme disease and often occurs in regions where Lyme is not endemic. Erythema marginatum, the rash of *acute rheumatic fever* **(Chap. 359)**, has a distinctive pattern of enlarging and shifting transient annular lesions.

Collagen vascular diseases may cause fever and rash. Patients with *systemic lupus erythematosus* **(Chap. 356)** typically develop a sharply defined, erythematous eruption in a butterfly distribution on the cheeks (malar rash) **(Fig. A1-10)** as well as many other skin manifestations **(Figs. A1-11, A1-12)**. *Still's disease* presents as an evanescent, salmon-colored rash on the trunk and proximal extremities that coincides with fever spikes **(Fig. A1-13)**.

Hemophagocytic lymphohistiocytosis may be familial or triggered by infection, autoimmunity, or neoplasia. Cutaneous manifestations are protean and can present as an erythematous maculopapular eruption, pyoderma gangrenosum, purpura, panniculitis, or Stevens Johnson syndrome.

Zika virus is a mosquito-transmitted flavivirus that is associated with severe birth defects **(Chap. 209)**. Zika is widespread among tropical and subtropical regions of the world. The eruption of Zika virus infection **(Fig. A1-51A, A1-51B)** is typically pruritic and often accompanied by conjunctival injection **(Fig. A1-51C)**.

PERIPHERAL ERUPTIONS

These rashes are alike in that they are most prominent peripherally or begin in peripheral (acral) areas before spreading centripetally. Early diagnosis and therapy are critical in *Rocky Mountain spotted fever* **(Chap. 187)** because of its grave prognosis if untreated. Lesions **(Fig. 19-2; see also Fig. A1-16)** evolve from macular to petechial, start on the wrists and ankles, spread centripetally, and appear on the palms and soles only later in the disease. The rash of *secondary syphilis* **(Chap. 182)**, which may be generalized **(Fig. A1-18)** but is prominent on the palms and soles **(Fig. A1-19)**, should be considered in the differential diagnosis of pityriasis rosea, especially in sexually active patients. *Chikungunya fever* **(Chap. 209)**, which is transmitted by mosquito bite

FIGURE 19-2 Peripheral eruption on the wrist and palm exhibiting erythematous macules in the process of evolving into petechial lesions in a patient with Rocky Mountain spotted fever. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 562, Figure 25-50; with permission.)*

in tropical and subtropical regions, is associated with a maculopapular eruption **(Fig. A1-54)** and severe polyarticular small-joint arthralgias. *Hand-foot-and-mouth disease* **(Chap. 204)**, most commonly caused by coxsackievirus A16 or enterovirus 71, is distinguished by tender vesicles distributed on the hands and feet and in the mouth **(Fig. A1-22)**; coxsackievirus A6 causes an atypical syndrome with more extensive lesions. The classic target lesions of *erythema multiforme* **(Fig. A1-24)** appear symmetrically on the elbows, knees, palms, soles, and face. In severe cases, these lesions spread diffusely and involve mucosal surfaces. Lesions may develop on the hands and feet in *endocarditis* **(Fig. A1-23) (Chap. 128)**. Pernio, tender violaceous lesions that are acral **(Fig. A1-57)**, occur most commonly on the feet, in asymptomatic or mild COVID-19. Vesicles, urticaria, or maculopapular eruptions, often pruritic, may occur on the trunk and extremities in moderate or severe disease, while retiform purpura occurs on the extremities and buttocks in severe COVID-19.

CONFLUENT DESQUAMATIVE ERYTHEMAS

These eruptions consist of diffuse erythema frequently followed by desquamation. The eruptions caused by group A *Streptococcus* or *Staphylococcus aureus* are toxin-mediated. *Scarlet fever* **(Chap. 148) (Fig. A1-25)** usually follows pharyngitis; patients have a facial flush, a "strawberry" tongue, and accentuated petechiae in body folds (Pastia's lines). *Kawasaki disease* **(Fig. A1-29) (Chaps. 58 and 363)** presents in the pediatric population as fissuring of the lips, a strawberry tongue, conjunctivitis, adenopathy, and sometimes cardiac abnormalities. *Streptococcal toxic shock syndrome* **(Chap. 148)** manifests with hypotension, multiorgan failure, and, often, a severe group A streptococcal infection (e.g., necrotizing fasciitis). *Staphylococcal toxic shock syndrome* **(Chap. 147)** also presents with hypotension and multiorgan failure, but usually only *S. aureus* colonization—not a severe *S. aureus* infection—is documented. *Staphylococcal scalded-skin syndrome* **(Fig. A1-28) (Chap. 147)** is seen primarily in children and in immunocompromised adults. Generalized erythema is often evident during the prodrome of fever and malaise; profound tenderness of the skin is distinctive. In the exfoliative stage, the skin can be induced to form bullae with light lateral pressure (Nikolsky's sign) **(Fig. 19-3)**. In a mild form, a scarlatiniform eruption mimics scarlet fever, but the patient does not exhibit a strawberry tongue or circumoral pallor. In contrast to the staphylococcal scalded-skin syndrome, in which the cleavage plane is superficial in the epidermis, *toxic epidermal necrolysis* **(Chap. 60)**, a maximal variant of *Stevens-Johnson syndrome*, involves sloughing of the entire epidermis **(Fig. A1-26)**, resulting in severe disease. *Exfoliative erythroderma syndrome* **(Chaps. 58 and 60)** is a serious reaction associated with systemic toxicity that is often due to eczema, psoriasis **(Fig. A1-27)**, a drug reaction, or mycosis fungoides. *Drug rash with eosinophilia and systemic symptoms (DRESS)*, often due to antiepileptic and antibiotic agents **(Chap. 60)**, initially appears similar to an exanthematous drug reaction **(Fig. A1-48)** but may progress to exfoliative erythroderma; it is accompanied by multiorgan failure and has an associated mortality rate of ~10%.

VESICULOBULLOUS OR PUSTULAR ERUPTIONS

Varicella **(Chap. 193)** is highly contagious, often occurring in winter or spring, and is characterized by pruritic lesions that, within a given region of the body, are in different stages of development at any point in time **(Fig. 19-4; see also Fig. A1-30)**. In immunocompromised hosts, varicella vesicles may lack the characteristic erythematous base or may appear hemorrhagic. Lesions of *Pseudomonas "hot-tub" folliculitis* **(Chap. 164)** are also pruritic and may appear similar to those of varicella **(Fig. A1-55)**. However, hot-tub folliculitis generally occurs in outbreaks after bathing in hot tubs or swimming pools, and lesions occur in regions occluded by bathing suits. Lesions of *variola (smallpox)* **(Chap. S3)** also appear similar to those of varicella but are

FIGURE 19-3 Confluent desquamative erythema in a patient with Staphylococcal scalded-skin syndrome. Nikolsky sign evident as shearing of epidermis due to gentle, lateral pressure. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 554, Figure 25-42; with permission.)*

FIGURE 19-4 Vesicular and pustular lesions on the chest in a patient with varicella. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 695, Figure 27-48; with permission.)*

all at the same stage of development in a given region of the body **(Figs. A1-50B, A1-50C)**. Variola lesions are most prominent on the face **(Fig. A1-50A)** and extremities, while varicella lesions are most prominent on the trunk. *Herpes simplex virus infection* **(Chap. 192)** is characterized by hallmark grouped vesicles on an erythematous base. Primary herpes infection is accompanied by fever and toxicity, while recurrent disease is milder. *Rickettsialpox* **(Chap. 187)** is often documented in urban settings and is characterized by vesicles followed by pustules **(Figs. A1-33B, A1-33C)**. It can be distinguished from varicella by an eschar at the site of the mouse-mite bite **(Fig. A1-33A)** and the papule/plaque base of each vesicle. *Acute generalized exanthematous pustulosis* **(Fig. A1-49)** should be considered in individuals who are acutely febrile and are taking new medications, especially anticonvulsant or antimicrobial agents **(Chap. 60)**. Disseminated *Vibrio vulnificus* infection **(Chap. 168)** or *ecthyma gangrenosum* due to *Pseudomonas aeruginosa* **(Fig. A1-34)** **(Chap. 164)** should be considered in immunosuppressed individuals with sepsis and hemorrhagic bullae. In children, *Mycoplasma pneumoniae*–induced rash and mucositis (MIRM) **(Fig. A1-56)** is characterized by a sparse, often vesiculobullous eruption with prominent oral, ocular, or urogenital mucositis.

URTICARIA-LIKE ERUPTIONS

Individuals with classic urticaria ("hives") **(Fig. 19-5; see also Fig. A1-35)** usually have a hypersensitivity reaction without associated fever. In the presence of fever, urticaria-like eruptions are most often due to *urticarial vasculitis* **(Chap. 363)**. Unlike individual lesions of classic urticaria, which last up to 24 h, these lesions may last 3–5 days. Etiologies include serum sickness (often induced by drugs such as penicillins, sulfas, salicylates, or barbiturates), connective-tissue disease (e.g., systemic lupus erythematosus or Sjögren's syndrome), and infection (e.g., with hepatitis B virus, enteroviruses, or parasites). Malignancy, especially lymphoma, may be associated with fever and chronic urticaria **(Chap. 58)**.

FIGURE 19-5 Urticarial eruption. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 299, Figure 14-2; with permission.)*

NODULAR ERUPTIONS

In immunocompromised hosts, nodular lesions often represent disseminated infection. Patients with disseminated *candidiasis* **(Fig. A1-37)** (often due to *Candida tropicalis*) may have a triad of fever, myalgias, and eruptive nodules **(Chap. 216)**. Disseminated *cryptococcosis* lesions **(Fig. 19-6; see also Fig. A1-36)** **(Chap. 215)** may resemble molluscum contagiosum **(Chap. 196)**. Necrosis of nodules should raise the suspicion of *aspergillosis* **(Fig. A1-38)** **(Chap. 217)** or *mucormycosis*

FIGURE 19-6 Nodular eruption on the face due to disseminated Cryptococcus in a patient with HIV infection. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 641, Figure 26-57. Used with permission from Loïc Vallant, MD.)*

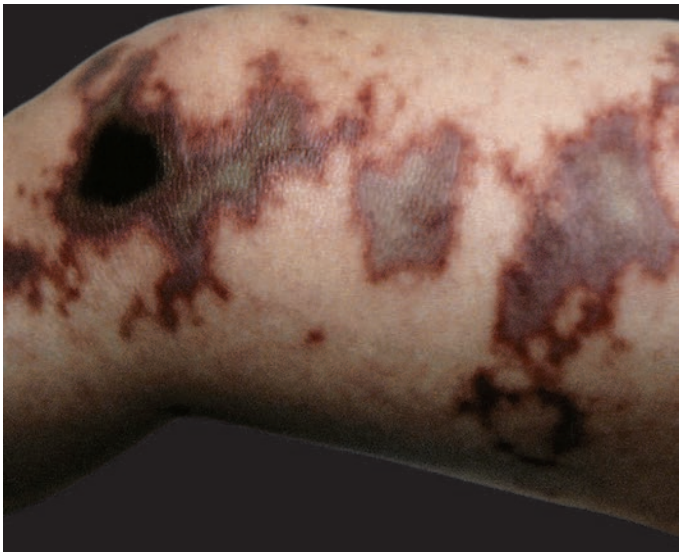

FIGURE 19-7 Purpura fulminans in a patient with acute meningococcemia. *(From K Wolff et al [eds]: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 8th ed. New York, McGraw-Hill, 2017, p. 568, Figure 25-59; with permission.)*

(Chap. 218). *Erythema nodosum* presents with exquisitely tender nodules on the lower extremities **(Fig. A1-39)**. *Sweet syndrome* **(Chap. 58)** should be considered in individuals with multiple nodules and plaques, often so edematous **(Fig. A1-40)** that they give the appearance of vesicles or bullae. Sweet syndrome may occur in individuals with infection, inflammatory bowel disease, or malignancy and can also be induced by drugs.

PURPURIC ERUPTIONS

Acute meningococcemia **(Chap. 155)** classically presents in children as a petechial eruption, but initial lesions may appear as blanchable macules or urticaria. Rocky Mountain spotted fever should be considered in the differential diagnosis of acute meningococcemia. *Echovirus 9 infection* **(Chap. 204)** may mimic acute meningococcemia; patients should be treated as if they have bacterial sepsis because prompt differentiation of these conditions may be impossible. Large ecchymotic areas of *purpura fulminans* **(Fig. 19-7; see also Fig. A1-41) (Chaps. 155 and 304)** reflect severe underlying disseminated intravascular coagulation, which may be due to infectious or noninfectious causes. The lesions of *chronic meningococcemia* **(Fig. A1-42) (Chap. 155)** may have a variety of morphologies, including petechial. Purpuric nodules may develop on the legs and resemble erythema nodosum but lack its exquisite tenderness. Lesions of *disseminated gonococcemia* **(Chap. 156)** are distinctive, sparse, countable hemorrhagic pustules **(Fig. A1-43)**, usually located near joints. The lesions of chronic meningococcemia and those of gonococcemia may be indistinguishable in terms of appearance and distribution. *Viral hemorrhagic fever* **(Chaps. 209 and 210)** should be considered in patients with an appropriate travel history and a petechial rash. *Thrombotic thrombocytopenic purpura* **(Chaps. 58, 100, and 115)** and *hemolytic-uremic syndrome* **(Chaps. 115, 161, and 166)** are closely related and are noninfectious causes of fever and petechiae. *Cutaneous small-vessel vasculitis* (*leukocytoclastic vasculitis*) typically manifests as palpable purpura **(Fig. A1-44)** and has a wide variety of causes **(Chap. 58)**.

ERUPTIONS WITH ULCERS OR ESCHARS

The presence of an ulcer or eschar **(Fig. 19-8)** in the setting of a more widespread eruption can provide an important diagnostic clue. For example, an eschar may suggest the diagnosis of *scrub typhus* or *rickettsialpox* **(Fig. A1-33A) (Chap. 187)** in the appropriate setting. In other illnesses (e.g., anthrax) **(Fig. A1-52) (Chap. S3)**, an ulcer or eschar may be the only skin manifestation.

20 Fever of Unknown Origin

Chantal P. Bleeker-Rovers,
Catharina M. Mulders-Manders,
Jos W. M. van der Meer

DEFINITION

Clinicians commonly refer to any febrile illness without an initially obvious etiology as *fever of unknown origin* (FUO). Most febrile illnesses either resolve before a diagnosis can be made or develop distinguishing characteristics that lead to a diagnosis. The term *FUO* should be reserved for prolonged febrile illnesses without an established etiology despite intensive evaluation and diagnostic testing. This chapter focuses on FUO in the adult patient.

FUO was originally defined by Petersdorf and Beeson in 1961 as an illness of >3 weeks' duration with fever of ≥38.3°C (≥101°F) on two occasions and an uncertain diagnosis despite 1 week of inpatient evaluation. Nowadays, most patients with FUO are hospitalized only if their clinical condition requires it, and not for diagnostic purposes alone; thus the in-hospital evaluation requirement has been eliminated from the definition. The definition of FUO has been further modified by the exclusion of immunocompromised patients, whose workup requires an entirely different diagnostic and therapeutic approach. For optimal comparison of patients with FUO in different geographic areas, it has been proposed that the quantitative criterion (diagnosis uncertain after 1 week of evaluation) be changed to a qualitative criterion that requires the performance of a specific list of investigations. Accordingly, FUO is now defined as follows:

1. Fever ≥38.3°C (≥101°F) on at least two occasions
2. Illness duration of ≥3 weeks
3. No known immunocompromised state
4. Diagnosis that remains uncertain after a thorough history-taking, physical examination, and the following obligatory investigations: determination of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level; platelet count; leukocyte count and differential; measurement of levels of hemoglobin, electrolytes, creatinine, total protein, alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, creatine kinase, ferritin, antinuclear antibodies, and rheumatoid factor; protein electrophoresis; urinalysis; blood cultures (n = 3); urine culture; chest x-ray; abdominal ultrasonography; and tuberculin skin test (TST) or interferon γ release assay (IGRA).

Closely related to FUO is *inflammation of unknown origin (IUO)*, which has the same definition as FUO, except for the body temperature criterion: IUO is defined as the presence of elevated inflammatory parameters (CRP or ESR) on multiple occasions for a period of at least 3 weeks in an immunocompetent patient with normal body temperature, for which a final explanation is lacking despite history-taking, physical examination, and the obligatory tests listed above. It has been shown that the causes and workup for IUO are the same as for FUO. Therefore, for convenience, the term FUO will refer to both FUO and IUO within the remainder of this chapter.

ETIOLOGY AND EPIDEMIOLOGY

Table 20-1 summarizes the findings of large studies on FUO conducted over the past 20 years.

The range of FUO etiologies has evolved since its first definition as a result of changes in the spectrum of diseases causing FUO, the widespread use of antibiotics, and especially the availability of new diagnostic techniques. The proportion of cases caused by intraabdominal abscesses and tumors, for example, has decreased because of earlier detection by CT and ultrasound. In addition, infective endocarditis is a less frequent cause because blood culture and echocardiographic techniques have improved. Conversely, some diagnoses such as acute HIV infection were unknown six decades ago.

Roughly comparable to 60 years ago, in non-Western cohorts infections remain the most common cause of FUO. Up to half of all infections in patients with FUO outside Western nations are caused by *Mycobacterium tuberculosis*, which is a less common cause in Western Europe and probably also in the United States. Recent data from the latter, however, have not been reported. In Western cohorts, noninfectious inflammatory diseases (NIIDs), including autoimmune, autoinflammatory, and granulomatous diseases, as well as vasculitides, form the most common cause of FUO. More than one-third of Western patients with FUO have a diagnosis that falls within the category of NIIDs. The number of FUO patients diagnosed with NIIDs probably will not decrease in the near future, as fever may precede more typical manifestations or laboratory evidence of these diseases by months. Moreover, many NIIDs can be diagnosed only after prolonged observation and exclusion of other diseases.

In Western cohorts, FUO remains unexplained in more than one-third of patients. This is much higher than 60 years ago. This difference can be explained by the fact that in patients with fever a diagnosis is often established before 3 weeks have elapsed because these patients tend to seek medical advice earlier, and because better diagnostic techniques, such as CT, MRI, and positron emission tomography (PET)/CT, are now available. Therefore, only the cases that are most difficult to diagnose continue to meet the criteria for FUO. Furthermore, most patients who have FUO without a diagnosis currently do well. A less aggressive diagnostic approach may be used in clinically stable patients once diseases with immediate therapeutic or prognostic consequences have been ruled out. In patients with recurrent fever (defined as repeated episodes of fever

interspersed with fever-free intervals of at least 2 weeks and apparent remission of the underlying disease), the chance of attaining an etiologic diagnosis is <50%.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for FUO is extensive. It is important to remember that FUO is far more often caused by an atypical presentation of a rather common disease than by a very rare disease. **Table 20-2** presents an overview of possible causes of FUO. Atypical presentations of endocarditis, diverticulitis, vertebral osteomyelitis, and extrapulmonary tuberculosis are the more common infectious disease diagnoses. Q fever and Whipple's disease (*Tropheryma whipplei* infection) are quite rare but should always be kept in mind as a cause of FUO since the presenting symptoms can be nonspecific. Serologic testing for Q fever, which results from exposure to animals or animal products, should be performed by immunofluorescence assay (IFA) when the patient lives in a rural area or has a history of heart valve disease, an aortic aneurysm, or a vascular prosthesis. In patients with unexplained symptoms localized to the central nervous system, gastrointestinal tract, or joints, polymerase chain reaction testing for *Tropheryma whipplei* should be performed. Travel to or (former) residence in tropical countries or the American Southwest should lead to consideration

TABLE 20-2 All Reported Causes of Fever of Unknown Origin (FUO)[a]

Infections	
Bacterial, nonspecific	Abdominal abscess, adnexitis, apical granuloma, appendicitis, cholangitis, cholecystitis, diverticulitis, endocarditis, endometritis, epidural abscess, infected joint prosthesis, infected vascular catheter, infected vascular prosthesis, infectious arthritis, infective myonecrosis, intracranial abscess, liver abscess, lung abscess, malakoplakia, mastoiditis, mediastinitis, mycotic aneurysm, osteomyelitis, pelvic inflammatory disease, prostatitis, pyelonephritis, pylephlebitis, renal abscess, septic phlebitis, sinusitis, spondylodiscitis, xanthogranulomatous urinary tract infection
Bacterial, specific	Actinomycosis, atypical mycobacterial infection, bartonellosis, brucellosis, *Campylobacter* infection, *Chlamydia pneumoniae* infection, chronic meningococcemia, ehrlichiosis, gonococcemia, legionellosis, leptospirosis, listeriosis, louse-borne relapsing fever (*Borrelia recurrentis*), Lyme disease, melioidosis (*Pseudomonas pseudomallei*), *Mycoplasma* infection, nocardiosis, psittacosis, Q fever (*Coxiella burnetii),* rickettsiosis, *Spirillum minor* infection, *Streptobacillus moniliformis* infection, syphilis, tick-borne relapsing fever (*Borrelia duttonii*), tuberculosis, tularemia, typhoid fever and other salmonelloses, Whipple's disease (*Tropheryma whipplei*), yersiniosis
Fungal	Aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, *Malassezia furfur* infection, paracoccidioidomycosis, *Pneumocystis jirovecii* pneumonia, sporotrichosis, zygomycosis
Parasitic	Amebiasis, babesiosis, echinococcosis, fascioliasis, malaria, schistosomiasis, strongyloidiasis, toxocariasis, toxoplasmosis, trichinellosis, trypanosomiasis, visceral leishmaniasis
Viral	Colorado tick fever, coxsackievirus infection, cytomegalovirus infection, dengue, Epstein-Barr virus infection, hantavirus infection, hepatitis (A, B, C, D, E), herpes simplex, HIV infection, human herpesvirus 6 infection, parvovirus infection, West Nile virus infection
Noninfectious Inflammatory Diseases	
Systemic rheumatic and autoimmune diseases	Ankylosing spondylitis, antiphospholipid syndrome, autoimmune hemolytic anemia, autoimmune hepatitis, Behçet's disease, cryoglobulinemia, dermatomyositis, Felty syndrome, gout, mixed connective-tissue disease, polymyositis, pseudogout, reactive arthritis, relapsing polychondritis, rheumatic fever, rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus, Vogt-Koyanagi-Harada syndrome
Vasculitis	Allergic vasculitis, eosinophilic granulomatosis with polyangiitis, giant cell vasculitis/polymyalgia rheumatica, granulomatosis with polyangiitis, hypersensitivity vasculitis, Kawasaki disease, polyarteritis nodosa, Takayasu arteritis, urticarial vasculitis
Granulomatous diseases	Idiopathic granulomatous hepatitis, sarcoidosis
Autoinflammatory syndromes	Adult-onset Still's disease, Blau syndrome, CAPS[b] (cryopyrin-associated periodic syndromes), Crohn's disease, DIRA (deficiency of the interleukin 1 receptor antagonist), familial Mediterranean fever, hemophagocytic syndrome, hyper-IgD syndrome (HIDS, also known as mevalonate kinase deficiency), juvenile idiopathic arthritis, PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum, and acne), PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, adenitis), recurrent idiopathic pericarditis, SAPHO (synovitis, acne, pustulosis, hyperostosis, osteomyelitis), Schnitzler syndrome, TRAPS (tumor necrosis factor receptor–associated periodic syndrome)
Neoplasms	
Hematologic malignancies	Amyloidosis, angioimmunoblastic lymphoma, Castleman's disease, Hodgkin's disease, hypereosinophilic syndrome, leukemia, lymphomatoid granulomatosis, malignant histiocytosis, multiple myeloma, myelodysplastic syndrome, myelofibrosis, non-Hodgkin's lymphoma, plasmacytoma, systemic mastocytosis, vaso-occlusive crisis in sickle cell disease
Solid tumors	Most solid tumors and metastases can cause fever. Those most commonly causing FUO are breast, colon, hepatocellular, lung, pancreatic, and renal cell carcinomas.
Benign tumors	Angiomyolipoma, cavernous hemangioma of the liver, craniopharyngioma, necrosis of dermoid tumor in Gardner's syndrome
Miscellaneous Causes	
	ADEM (acute disseminated encephalomyelitis), adrenal insufficiency, aneurysms, anomalous thoracic duct, aortic dissection, aortic-enteral fistula, aseptic meningitis (Mollaret's syndrome), atrial myxoma, brewer's yeast ingestion, Caroli disease, cholesterol emboli, cirrhosis, complex partial status epilepticus, cyclic neutropenia, drug fever, Erdheim-Chester disease, extrinsic allergic alveolitis, Fabry's disease, factitious disease, fire-eater's lung, fraudulent fever, Gaucher disease, Hamman-Rich syndrome (acute interstitial pneumonia), Hashimoto's encephalopathy, hematoma, hypersensitivity pneumonitis, hypertriglyceridemia, hypothalamic hypopituitarism, idiopathic normal-pressure hydrocephalus, inflammatory pseudotumor, Kikuchi's disease, linear IgA dermatosis, mesenteric fibromatosis, metal fume fever, milk protein allergy, myotonic dystrophy, nonbacterial osteitis, organic dust toxic syndrome, panniculitis, POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes), polymer fume fever, post–cardiac injury syndrome, primary biliary cirrhosis, primary hyperparathyroidism, pulmonary embolism, pyoderma gangrenosum, retroperitoneal fibrosis, Rosai-Dorfman disease, sclerosing mesenteritis, silicone embolization, subacute thyroiditis (de Quervain's), Sweet syndrome (acute febrile neutrophilic dermatosis), thrombosis, tubulointerstitial nephritis and uveitis syndrome (TINU), ulcerative colitis
Thermoregulatory Disorders	
Central	Brain tumor, cerebrovascular accident, encephalitis, hypothalamic dysfunction
Peripheral	Anhidrotic ectodermal dysplasia, exercise-induced hyperthermia, hyperthyroidism, pheochromocytoma

[a]This table includes all causes of FUO that have been described in the literature. [b]CAPS includes chronic infantile neurologic cutaneous and articular syndrome (CINCA, also known as neonatal-onset multisystem inflammatory disease, or NOMID), familial cold autoinflammatory syndrome (FCAS), and Muckle-Wells syndrome.

of infectious diseases such as malaria, leishmaniasis, histoplasmosis, or coccidioidomycosis. Fever with signs of endocarditis and negative blood culture results poses a special problem. Culture-negative endocarditis **(Chap. 128)** may be due to difficult-to-culture bacteria such as nutritionally variant bacteria, HACEK organisms (including *Haemophilus parainfluenzae*, *H. paraphrophilus*, *Aggregatibacter actinomycetemcomitans*, *A. aphrophilus*, *A. paraphrophilus*, *Cardiobacterium hominis*, *C. valvarum*, *Eikenella corrodens*, and *Kingella kingae*; discussed below), *Coxiella burnetii*, *T. whipplei*, and *Bartonella* species. Marantic endocarditis is a sterile thrombotic disease that occurs as a paraneoplastic phenomenon, especially with adenocarcinomas. Sterile endocarditis is also seen in the context of systemic lupus erythematosus and antiphospholipid syndrome.

Of the NIIDs, adult-onset Still's disease, large-vessel vasculitis, polymyalgia rheumatica, systemic lupus erythematodus (SLE), and sarcoidosis are rather common diagnoses in patients with FUO. The hereditary autoinflammatory syndromes are very rare (with the exception of familial Mediterranean fever in specific geographic regions) and usually present in young patients. Schnitzler syndrome, which can present at any age, is uncommon but can often be diagnosed easily in a patient with FUO who presents with urticaria, bone pain, and monoclonal gammopathy.

Although most tumors can present with fever, malignant lymphoma is by far the most common diagnosis of FUO among the neoplasms. Sometimes the fever even precedes lymphadenopathy detectable by physical examination.

Apart from drug-induced fever and exercise-induced hyperthermia, none of the miscellaneous causes of fever is found very frequently in patients with FUO. Virtually all drugs can cause fever, even after long-term use. *Drug-induced fever*, including DRESS (drug reaction with eosinophilia and systemic symptoms; **Fig. A1-48**), is often accompanied by eosinophilia and also by lymphadenopathy, which can be extensive. More common causes of drug-induced fever are allopurinol, carbamazepine, lamotrigine, phenytoin, sulfasalazine, furosemide, antimicrobial drugs (especially sulfonamides, minocycline, vancomycin, β-lactam antibiotics, and isoniazid), some cardiovascular drugs (e.g., quinidine), and some antiretroviral drugs (e.g., nevirapine). *Exercise-induced hyperthermia* **(Chaps. 18 and 465)** is characterized by an elevated body temperature that is associated with moderate to strenuous exercise lasting from half an hour up to several hours without an increase in CRP level or ESR. Unlike patients with fever, these patients typically sweat during the temperature elevation. *Factitious fever* (fever artificially induced by the patient—for example, by IV injection of contaminated water) should be considered in all patients but is more common among young women in health-care professions. In *fraudulent fever*, the patient is normothermic but manipulates the thermometer. Simultaneous measurements at different body sites (rectum, ear, mouth) should rapidly identify this diagnosis. Another clue to fraudulent fever is dissociation between pulse rate and temperature.

Previous studies of FUO have shown that a cause is more likely to be found in elderly patients than in younger age groups. In many cases, FUO in the elderly results from an atypical manifestation of a common disease, among which giant cell arteritis and polymyalgia rheumatica are most frequently involved. Tuberculosis is the most common infectious disease associated with FUO in elderly patients, occurring much more often than in younger patients. As many of these diseases are treatable, it is well worth pursuing the cause of fever in elderly patients.

APPROACH TO THE PATIENT

Fever of Unknown Origin

FIRST-STAGE DIAGNOSTIC TESTS

Figure 20-1 shows a structured approach to patients presenting with FUO. The most important step in the diagnostic workup is the search for potentially diagnostic clues (PDCs) through complete and repeated history-taking and physical examination and the obligatory investigations listed above and in the figure. *PDCs* are defined as all localizing signs, symptoms, and abnormalities potentially pointing toward a diagnosis. Although PDCs are often misleading, only with their help can a concise list of probable diagnoses be made. The history should include information about the fever pattern (continuous or recurrent) and duration, previous medical history, present and recent drug use, family history, sexual history, country of origin, recent and remote travel, unusual environmental exposures associated with travel or hobbies, and animal contacts. A complete physical examination should be performed, with special attention to the eyes, lymph nodes, temporal arteries, liver, spleen, sites of previous surgery, entire skin surface, and mucous membranes. Before further diagnostic tests are initiated, antibiotic and glucocorticoid treatment, which can mask many diseases, should be stopped. For example, blood and other cultures are not reliable when samples are obtained during antibiotic treatment, and the size of enlarged lymph nodes usually decreases during glucocorticoid treatment, regardless of the cause of lymphadenopathy. Despite the high percentage of false-positive ultrasounds and the relatively low sensitivity of chest x-rays, the performance of these simple, low-cost diagnostic tests remains obligatory in all patients with FUO in order to separate cases that are caused by easily diagnosed diseases from those that are not. Abdominal ultrasound is preferred to abdominal CT as an obligatory test because of relatively low cost, lack of radiation burden, and absence of side effects.

Only rarely do biochemical tests (beyond the obligatory tests needed to classify a patient's fever as FUO) lead directly to a definitive diagnosis in the absence of PDCs. The diagnostic yield of immunologic serology other than that included in the obligatory tests is relatively low. These tests more often yield false-positive rather than true-positive results and are of little use without PDCs pointing to specific immunologic disorders. Given the absence of specific symptoms in many patients and the relatively low cost of the test, investigation of cryoglobulins appears to be a valuable screening test in patients with FUO.

Multiple blood samples should be cultured in the laboratory long enough to ensure ample growth time for any fastidious organisms, such as HACEK organisms. It is critical to inform the laboratory of the intent to test for unusual organisms. Specialized media should be used when the history suggests uncommon microorganisms, such as *Histoplasma* or *Legionella*. Performing more than three blood cultures or more than one urine culture is useless in patients with FUO in the absence of PDCs (e.g., a high level of clinical suspicion of endocarditis). Repeating blood or urine cultures is useful only when previously cultured samples were collected during antibiotic treatment or within 1 week after its discontinuation. FUO with headache should prompt microbiologic examination of cerebrospinal fluid (CSF) for organisms including herpes simplex virus (especially type 2), *Cryptococcus neoformans*, and *Mycobacterium tuberculosis*. In central nervous system tuberculosis, the CSF typically has elevated protein and lowered glucose concentrations, with a mononuclear pleocytosis. CSF protein levels range from 100 to 500 mg/dL in most patients, the CSF glucose concentration is <45 mg/dL in 80% of cases, and the usual CSF cell count is between 100 and 500 cells/μL.

Microbiologic serology should not be included in the diagnostic workup of patients without PDCs for specific infections. A tuberculin skin test (TST) or interferon γ release assay (IGRA, QuantiFERON test) is included in the obligatory investigations, but it may yield false-negative results in patients with miliary tuberculosis, malnutrition, or immunosuppression. Although the IGRA is less influenced by prior vaccination with bacille Calmette-Guérin (BCG) or by infection with nontuberculous mycobacteria, its sensitivity is similar to that of the TST; a negative TST or IGRA therefore does not exclude a diagnosis of tuberculosis. Miliary tuberculosis is especially difficult to diagnose. Granulomatous disease in liver or bone marrow biopsy samples, for example, should always lead to a (re)consideration of this diagnosis. If miliary tuberculosis is suspected, liver biopsy for acid-fast smear, culture, and polymerase chain reaction probably still has the highest diagnostic yield;

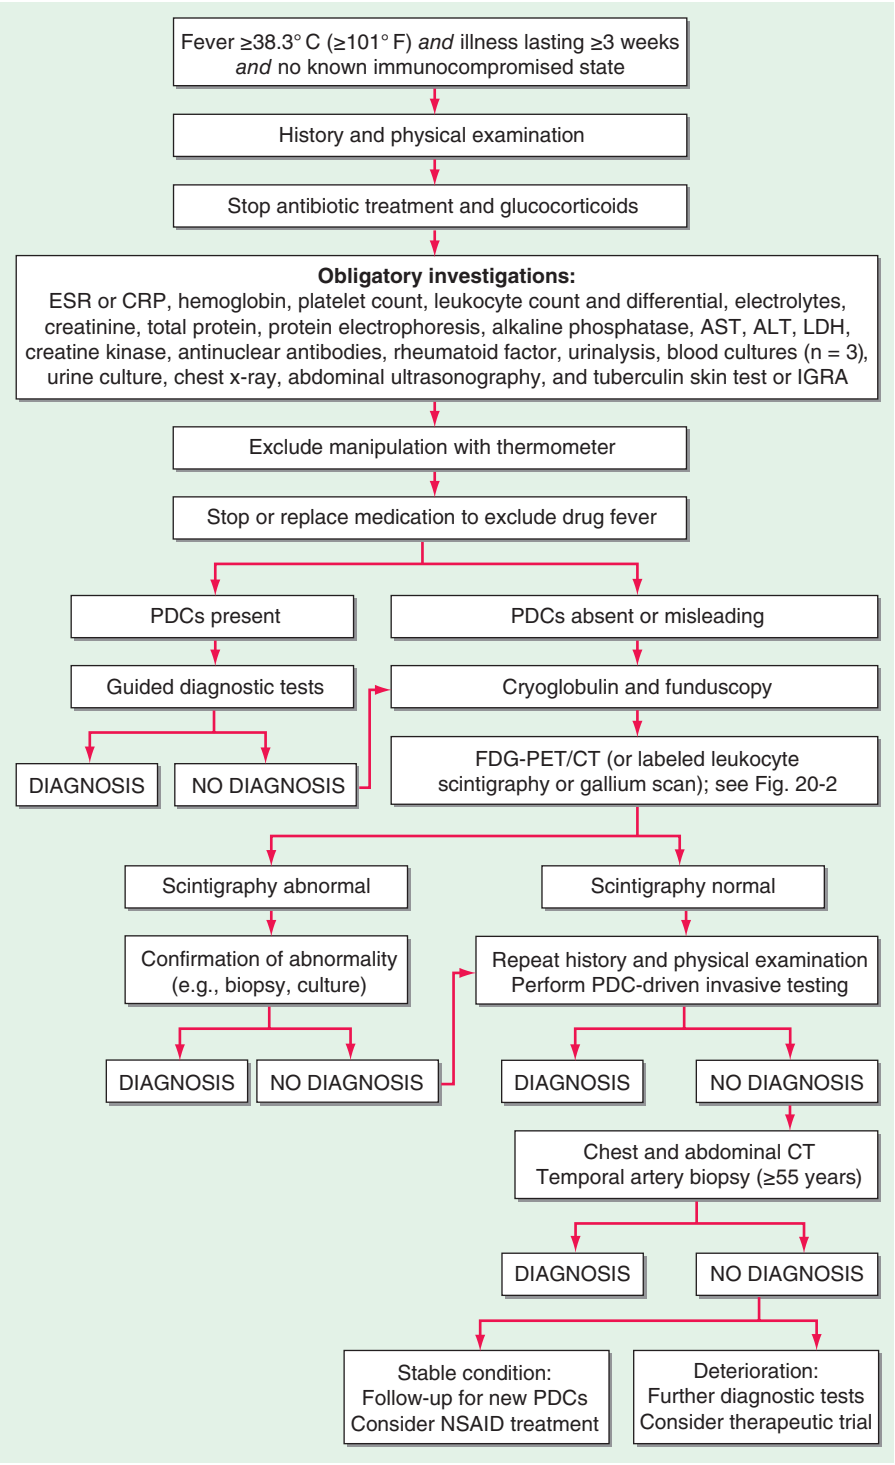

FIGURE 20-1 Structured approach to patients with FUO. ALT, alanine aminotransferase; AST, aspartate aminotransferase; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; FDG-PET/CT, ^{18}F-fluorodeoxyglucose positron emission tomography combined with low-dose CT; IGRA, interferon γ release assay; LDH, lactate dehydrogenase; NSAID, nonsteroidal anti-inflammatory drug; PDCs, potentially diagnostic clues (all localizing signs, symptoms, and abnormalities potentially pointing toward a diagnosis).

however, biopsies of bone marrow, lymph nodes, or other involved organs also can be considered.

The diagnostic yield of echocardiography, sinus radiography, radiologic or endoscopic evaluation of the gastrointestinal tract, and bronchoscopy is very low in the absence of PDCs. Therefore, these tests should not be used as screening procedures.

After identification of all PDCs retrieved from the history, physical examination, and obligatory tests, a limited list of the most probable diagnoses should be made. Since most investigations are helpful only for patients who have PDCs for the diagnoses sought, further diagnostic procedures should be limited to specific investigations aimed at confirming or excluding diseases on this list. In FUO, the diagnostic pointers are numerous and diverse but may be missed on initial examination, often being detected only by a very careful examination performed subsequently. In the absence of PDCs, the history and physical examination should therefore be repeated regularly. One of the first steps should be to rule out factitious or fraudulent fever, particularly in patients without signs

of inflammation in laboratory tests. All medications, including nonprescription drugs and nutritional supplements, should be discontinued early in the evaluation to exclude drug fever. If fever persists beyond 72 h after discontinuation of the suspected drug, it is unlikely that this drug is the cause. In patients without PDCs or with only misleading PDCs, fundoscopy by an ophthalmologist may be useful in the early stage of the diagnostic workup to exclude retinal vasculitis. When the first-stage diagnostic tests do not lead to a diagnosis, ^{18}F-fluorodeoxyglucose (^{18}F-FDG) positron emission tomography combined with computed tomography (PET/CT) or, if the former is not available, radiolabeled leukocyte scintigraphy should be performed, especially when the ESR or the CRP level is elevated.

Recurrent Fever In patients with recurrent fever, the diagnostic workup should consist of thorough history-taking, physical examination, and obligatory tests. The search for PDCs should be directed toward clues matching known recurrent syndromes **(Table 20-3)**. Patients should be asked to return during a febrile episode so that the history, physical examination, and laboratory tests can be repeated during a symptomatic phase. Further diagnostic tests, such as PET/CT or scintigraphic imaging (see below), should be performed only during a febrile episode or when inflammatory parameters are abnormal because abnormalities may be absent between episodes. In patients with recurrent fever lasting >2 years, it is very unlikely that the fever is caused by infection or malignancy. Further diagnostic tests in that direction should be considered only when PDCs for infections, vasculitis syndromes, or malignancy are present or when the patient's clinical condition is deteriorating.

Fluorodeoxyglucose Positron Emission Tomography ^{18}F-FDG PET/CT has become an established imaging procedure in FUO. FDG accumulates in tissues with a high rate of glycolysis, which occurs not only in malignant cells but also in activated leukocytes and thus permits the imaging of acute and chronic inflammatory processes. Compared with conventional scintigraphy (see below), FDG-PET/CT offers the advantages of higher resolution, greater sensitivity in chronic low-grade infections, and a high degree of accuracy in the central skeleton. Furthermore, vascular uptake of FDG is increased in patients with vasculitis **(Fig. 20-2)**. The mechanisms responsible for FDG uptake do not allow differentiation among infection, sterile inflammation, and malignancy. However, since all of these disorders are causes of FUO, FDG-PET/CT can be used to guide additional diagnostic tests (e.g., targeted biopsies) that may yield the final diagnosis. It is important to realize that physiologic uptake of FDG may obscure pathologic foci in the brain, heart, bowel, kidneys, and bladder. FDG uptake in the heart, which obscures endocarditis, may be prevented by consumption of a low-carbohydrate diet before the PET investigation. In patients with fever, bone marrow uptake is frequently increased in a nonspecific way due to cytokine activation, which upregulates glucose transporters in bone marrow cells.

TABLE 20-3 All Reported Causes of Recurrent Fever[a]

Infections	
Bacterial, nonspecific	Apical granuloma, diverticulitis, prostatitis, recurrent bacteremia caused by colonic neoplasia or persistent focal infection, recurrent cellulitis, recurrent cholangitis or cholecystitis, recurrent pneumonia, recurrent sinusitis, recurrent urinary tract infection
Bacterial, specific	Bartonellosis, brucellosis, chronic gonococcemia, chronic meningococcemia, louse-borne relapsing fever (*Borrelia recurrentis*), melioidosis (*Pseudomonas pseudomallei*), Q fever (*Coxiella burnetii*), salmonellosis, *Spirillum minor* infection, *Streptobacillus moniliformis* infection, syphilis, tick-borne relapsing fever (*Borrelia duttonii*), tularemia, Whipple's disease (*Tropheryma whipplei*), yersiniosis
Fungal	Coccidioidomycosis, histoplasmosis, paracoccidioidomycosis
Parasitic	Babesiosis, malaria, toxoplasmosis, trypanosomiasis, visceral leishmaniasis
Viral	Cytomegalovirus infection, Epstein-Barr virus infection, herpes simplex
Noninfectious Inflammatory Diseases	
Systemic rheumatic and autoimmune diseases	Ankylosing spondylitis, antiphospholipid syndrome, autoimmune hemolytic anemia, autoimmune hepatitis, Behçet's disease, cryoglobulinemia, gout, polymyositis, pseudogout, reactive arthritis, relapsing polychondritis, systemic lupus erythematosus
Vasculitis	Churg-Strauss syndrome, giant cell vasculitis/polymyalgia rheumatica, hypersensitivity vasculitis, polyarteritis nodosa, urticarial vasculitis
Granulomatous diseases	Idiopathic granulomatous hepatitis, sarcoidosis
Autoinflammatory syndromes	Adult-onset Still's disease, Blau syndrome, CANDLE (chronic atypical neutrophilic dermatitis with lipodystrophy and elevated temperature syndrome), CAPS[b] (cryopyrin-associated periodic syndrome), CRMO (chronic recurrent multifocal osteomyelitis), Crohn's disease, DIRA (deficiency of the interleukin 1 receptor antagonist), familial Mediterranean fever, hemophagocytic syndrome, hyper-IgD syndrome (HIDS, also known as mevalonate kinase deficiency), juvenile idiopathic arthritis, NLRC4-activating mutations, PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum, and acne), PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, adenitis), recurrent idiopathic pericarditis, SAPHO (synovitis, acne, pustulosis, hyperostosis, osteomyelitis), SAVI (stimulator of interferon genes [STING]–associated vasculopathy with onset in infancy), Schnitzler syndrome, TRAPS (tumor necrosis factor receptor–associated periodic syndrome)
Neoplasms	
	Angioimmunoblastic lymphoma, Castleman's disease, colon carcinoma, craniopharyngioma, Hodgkin's disease, malignant histiocytosis, mesothelioma, non-Hodgkin's lymphoma
Miscellaneous Causes	
	Adrenal insufficiency, aortic-enteral fistula, aseptic meningitis (Mollaret's syndrome), atrial myxoma, brewer's yeast ingestion, cholesterol emboli, cyclic neutropenia, drug fever, extrinsic allergic alveolitis, Fabry's disease, factitious disease, fraudulent fever, Gaucher disease, hypersensitivity pneumonitis, hypertriglyceridemia, hypothalamic hypopituitarism, inflammatory pseudotumor, metal fume fever, milk protein allergy, polymer fume fever, pulmonary embolism, sclerosing mesenteritis
Thermoregulatory Disorders	
Central	Hypothalamic dysfunction
Peripheral	Anhidrotic ectodermal dysplasia, exercise-induced hyperthermia, pheochromocytoma

[a]This table includes all causes of recurrent fever that have been described in the literature. [b]CAPS includes chronic infantile neurologic cutaneous and articular syndrome (CINCA, also known as neonatal-onset multisystem inflammatory disease, or NOMID), familial cold autoinflammatory syndrome (FCAS), and Muckle-Wells syndrome.

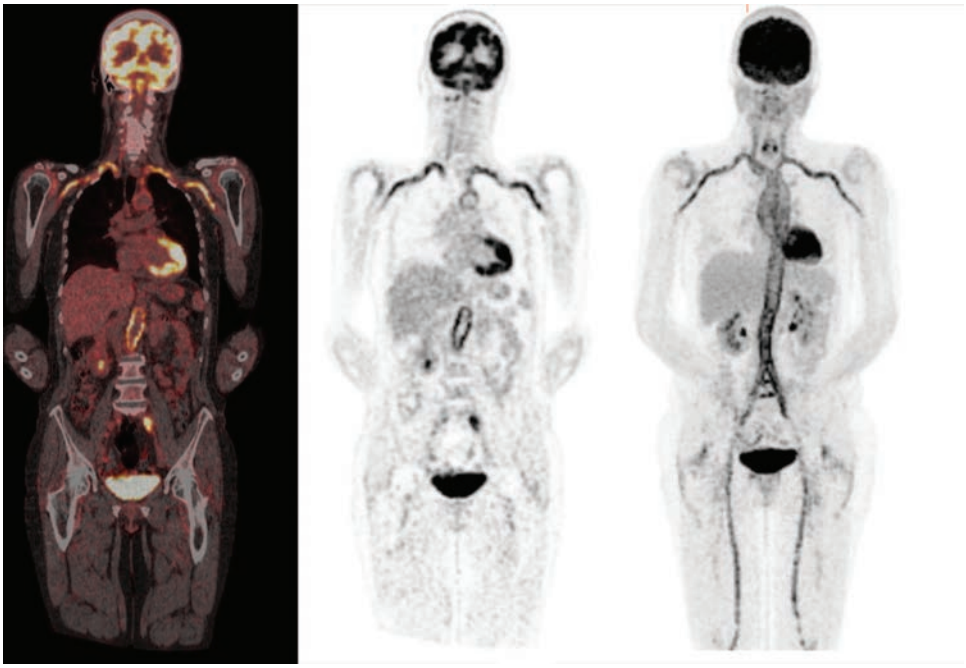

FIGURE 20-2 FDG-PET/CT in a patient with FUO. This 72-year-old woman presented with a low-grade fever and severe fatigue of almost 3 months' duration. An extensive history was taken, but the patient had no specific complaints and had not traveled recently. Her previous history was unremarkable, and she did not use any drugs. Physical examination, including palpation of the temporal arteries, yielded completely normal results. Laboratory examination showed normocytic anemia, a C-reactive protein level of 43 mg/L, an erythrocyte sedimentation rate of 87 mm/h, and mild hypoalbuminemia. Results of the other obligatory tests were all normal. Since there were no potentially diagnostic clues, FDG-PET/CT was performed. This test showed increased FDG uptake in all major arteries (carotid, jugular, and subclavian arteries; thoracic and abdominal aorta; iliac, femoral, and popliteal arteries) and in the soft tissue around the shoulders, hips, and knees—findings compatible with large-vessel vasculitis and polymyalgia rheumatica. Within 1 week after the initiation of treatment with prednisone (60 mg once daily), the patient completely recovered. After 1 month, the prednisone dose was slowly tapered.

In recent years, many cohort studies and several meta-analyses have focused on the diagnostic yield of PET and PET/CT in FUO. These studies are highly variable in terms of the selection of patients, the follow-up, and the selection of a gold-standard reference. Indirect comparisons of test performance suggested that FDG-PET/CT outperformed stand-alone FDG-PET, gallium scintigraphy, and leukocyte scintigraphy. Similarly, indirect comparisons of diagnostic yield suggested that FDG-PET/CT was more likely than alternative tests to correctly identify the cause of FUO. Meta-analyses report a high diagnostic yield for PET and PET/CT in the workup of FUO patients, with pooled sensitivity and specificity figures of ~85% and ~50%, respectively, and a total diagnostic yield of ~50% for PET/CT and ~40% for PET.

As many patients with FUO present with periodic fever, correct timing of PET/CT increases its diagnostic value. Few studies on the use of biomarkers such as elevated CRP or ESR for a contributory outcome of PET/CT have been performed. When both CRP and ESR are normal at the time of FDG-PET/CT, outcome may only be contributory when a patient does have fever at the time of the scan.

Although PET/CT and other scintigraphic techniques do not directly provide a definitive diagnosis (with the exception of some patients with, for instance, large vessel vasculitis), they often identify the anatomic location of a particular ongoing metabolic process. With the help of other techniques such as biopsy and culture, a timely diagnosis and treatment can be facilitated. Pathologic FDG uptake is quickly eradicated by treatment with glucocorticoids in many diseases, including vasculitis and lymphoma; therefore, glucocorticoid use should be stopped or postponed until after FDG-PET/CT is performed.

FDG-PET/CT is a relatively expensive procedure whose availability is still limited compared with that of CT and conventional scintigraphy. Nevertheless, FDG-PET/CT can be cost-effective in the FUO diagnostic workup if used at an early stage, helping to establish an early diagnosis, reducing days of hospitalization for diagnostic purposes, and obviating unnecessary and unhelpful tests. When FDG-PET/CT has been made under the right conditions (i.e., when elevated CRP or ESR or fever were present during the scan) but has not contributed to the final diagnosis, repeating PET/CT is probably of little value, unless new signs or symptoms appear.

Conventional scintigraphic imaging other than PET/CT

Conventional scintigraphic methods used in clinical practice are ^{67}Ga-citrate scintigraphy and ^{111}In- or ^{99m}Tc-labeled leukocyte scintigraphy. Sensitivity and specificity of conventional scintigraphic studies are lower than for PET/CT: the diagnostic yield of gallium scintigraphy ranges from 21% to 54%, and on average the location of a source of fever can correctly be localized in approximately one-third of patients. The diagnostic value of leukocyte scintigraphy ranges from 8% to 31%, and overall the cause of FUO can correctly be identified in one-fifth of patients. When PET/CT is not available, these techniques are the only alternative.

LATER-STAGE DIAGNOSTIC TESTS

In some cases, more invasive tests are appropriate. Abnormalities found with imaging often need to be confirmed by pathology and/or culture of biopsy specimens. If lymphadenopathy is found, lymph node biopsy is necessary, even when the affected lymph nodes are hard to reach or when previous biopsies were inconclusive. In the case of skin lesions, skin biopsy should be undertaken.

If no diagnosis is reached despite PET/CT and PDC-driven histologic investigations or culture, second-stage screening diagnostic tests should be considered (Fig. 20-1). In three studies, the diagnostic yield of screening chest and abdominal CT in patients with FUO was ~20%. The specificity of chest CT was ~80%, but that of abdominal CT varied between 63% and 80%. Despite the

relatively limited specificity of abdominal CT and the probably limited additional value of chest CT after normal FDG-PET/CT, chest and abdominal CT may be used as screening procedures at a later stage of the diagnostic protocol because of their noninvasive nature and high sensitivity. Bone marrow aspiration is seldom useful in the absence of PDCs for bone marrow disorders. With addition of FDG-PET/CT, which is highly sensitive in detecting lymphoma, carcinoma, and osteomyelitis, the value of bone marrow biopsy as a screening procedure is probably further reduced. Several studies have shown a high prevalence of giant cell arteritis among patients with FUO, with rates up to 17% among elderly patients. Giant cell arteritis often involves large arteries and in most cases can be diagnosed by FDG-PET/CT. However, temporal artery biopsy is still recommended for patients ≥55 years of age in a later stage of the diagnostic protocol: FDG-PET/CT will not be useful in vasculitis limited to the temporal arteries because of the small diameter of these vessels and the high levels of FDG uptake in the brain. In the past, liver biopsies were often performed as a screening procedure in patients with FUO. In each of two studies, liver biopsy as part of the later stage of a screening diagnostic protocol was helpful in only one patient. Moreover, abnormal liver tests are not predictive of a diagnostic liver biopsy in FUO. Liver biopsy is an invasive procedure that carries the possibility of complications and even death. Therefore, it should not be used for screening purposes in patients with FUO except in those with PDCs for liver disease or miliary tuberculosis.

In patients with unexplained fever after all of the above procedures, the last steps in the diagnostic workup—with only a marginal diagnostic yield—come at an extraordinarily high cost in terms of both expense and discomfort for the patient. Repetition of a thorough history-taking and physical examination and review of laboratory results and imaging studies (including those from other hospitals) are recommended. Diagnostic delay often results from a failure to recognize PDCs in the available information. In these patients with persisting FUO, waiting for new PDCs to appear probably is better than ordering more screening investigations. Only when a patient's condition deteriorates without providing new PDCs should a further diagnostic workup be performed.

SECOND OPINION IN AN EXPERT CENTER

When despite the workup described above no explanation for FUO is found, second opinion in an expert center on FUO should be considered. The single study on the value of second opinion in FUO reported that in 57.3% of patients with unexplained FUO, a diagnosis could be found in an expert center. Additionally, of all patients who remained without a diagnosis even after second opinion, 10.9% became fever-free upon empirical treatment, adding up to a beneficial outcome in 68.2% of patients.

TREATMENT

Fever of Unknown Origin

Empirical therapeutic trials with antibiotics, glucocorticoids, or antituberculous agents should be avoided in FUO except when a patient's condition is rapidly deteriorating after the aforementioned diagnostic tests have failed to provide a definite diagnosis.

ANTIBIOTICS AND ANTITUBERCULOUS THERAPY

Antibiotic or antituberculous therapy may irrevocably diminish the ability to culture fastidious bacteria or mycobacteria. However, hemodynamic instability or neutropenia is a good indication for empirical antibiotic therapy. If the TST or IGRA is positive or if granulomatous disease is present with anergy and sarcoidosis seems unlikely, a trial of therapy for tuberculosis should be started. Especially in miliary tuberculosis, it may be very difficult to obtain a rapid diagnosis. If the fever does not respond after 6 weeks of empirical antituberculous treatment, another diagnosis should be considered.

COLCHICINE, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS, AND GLUCOCORTICOIDS

Colchicine is highly effective in preventing attacks of familial Mediterranean fever (FMF) but is not always effective once an attack is well under way. When FMF is suspected, the response to colchicine is not a completely reliable diagnostic tool in the acute phase, but with colchicine treatment most patients show remarkable improvements in the frequency and severity of subsequent febrile episodes within weeks to months. Therefore, colchicine may be tried in patients with features compatible with FMF, especially when these patients originate from a high-prevalence region.

If the fever persists and the source remains elusive after completion of the later-stage investigations, supportive treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) can be helpful. The response of adult-onset Still's disease to NSAIDs is dramatic in some cases.

The effects of glucocorticoids on giant cell arteritis and polymyalgia rheumatica are equally impressive. Early empirical trials with glucocorticoids, however, decrease the chances of reaching a diagnosis for which more specific and sometimes life-saving treatment might be more appropriate, such as malignant lymphoma. The ability of NSAIDs and glucocorticoids to mask fever while permitting the spread of infection or lymphoma dictates that their use should be avoided unless infectious diseases and malignant lymphoma have been largely ruled out and inflammatory disease is probable and is likely to be debilitating or threatening.

INTERLEUKIN 1 INHIBITION

Interleukin (IL) 1 is a key cytokine in local and systemic inflammation and the febrile response. The availability of specific IL-1-targeting agents has revealed a pathologic role of IL-1-mediated inflammation in a growing list of diseases. Anakinra, a recombinant form of the naturally occurring IL-1 receptor antagonist (IL-1Ra), blocks the activity of both IL-1α and IL-1β. Anakinra is extremely effective in the treatment of many autoinflammatory syndromes, such as FMF, cryopyrin-associated periodic syndrome, tumor necrosis factor receptor–associated periodic syndrome, mevalonate kinase deficiency (hyper IgD syndrome), Schnitzler syndrome, and adult onset Still's disease. There are many other chronic inflammatory disorders in which anti-IL-1 therapy is highly effective. A therapeutic trial with anakinra can be considered in patients whose FUO has not been diagnosed after later-stage diagnostic tests. Although most chronic inflammatory conditions without a known basis can be controlled with glucocorticoids, monotherapy with IL-1 blockade can provide improved control without the metabolic, immunologic, and gastrointestinal side effects of glucocorticoid administration.

PROGNOSIS

In patients in whom FUO remains unexplained, prognosis is favorable. Two large studies on mortality in these patients have been performed. The first study included 436 patients of whom 168 remained without a diagnosis. Of these, 4 (2.4%) died during follow-up. All 4 patients died during the index admission, and in 2 of them a diagnosis was made upon autopsy (1 had intravascular lymphoma and 1 had bilateral pneumonia). The second study included 131 patients with unexplained FUO. Of these patients, 9 (6.9%) died during a median follow-up of 5 years. In 6 of these patients the cause of death was known, and in 5 of them death was considered unrelated to the febrile disease. Overall, FUO-related mortality rates have continuously declined over recent decades. The majority of fevers are caused by treatable diseases, and the risk of death related to FUO is, of course, dependent on the underlying disease.

Section 3 Nervous System Dysfunction

21 Syncope

Roy Freeman

Syncope is a transient, self-limited loss of consciousness due to acute global impairment of cerebral blood flow. The onset is rapid, duration brief, and recovery spontaneous and complete. Other causes of transient loss of consciousness need to be distinguished from syncope; these include seizures, vertebrobasilar ischemia, hypoxemia, and hypoglycemia. A syncopal prodrome (*presyncope*) is common, although loss of consciousness may occur without any warning symptoms. Typical presyncopal symptoms include lightheadedness or faintness, dizziness, weakness, fatigue, and visual and auditory disturbances. The causes of syncope can be divided into three general categories: (1) neurally mediated syncope (also called *reflex or vasovagal syncope*), (2) orthostatic hypotension, and (3) cardiac syncope.

Neurally mediated syncope comprises a heterogeneous group of functional disorders that are characterized by a transient change in the reflexes responsible for maintaining cardiovascular homeostasis. Episodic vasodilation (or loss of vasoconstrictor tone), decreased cardiac output, and bradycardia occur in varying combinations, resulting in temporary failure of blood pressure control. In contrast, in patients with orthostatic hypotension due to autonomic failure, these cardiovascular homeostatic reflexes are chronically impaired. Cardiac syncope may be due to arrhythmias or structural cardiac diseases that cause a decrease in cardiac output. The clinical features, underlying pathophysiologic mechanisms, therapeutic interventions, and prognoses differ markedly among these three causes.

EPIDEMIOLOGY AND NATURAL HISTORY

Syncope is a common presenting problem, accounting for ~3% of all emergency department (ED) visits and 1% of all hospital admissions. The annual cost for syncope-related hospitalization in the United States is ~$2.4 billion. Syncope has a lifetime cumulative incidence of up to 35% in the general population. The peak incidence in the young occurs between ages 10 and 30 years, with a median peak around 15 years. Neurally mediated syncope is the etiology in the vast majority of these cases. In older adults, there is a sharp rise in the incidence of syncope after 70 years of age.

In population-based studies, neurally mediated syncope is the most common cause of syncope. The incidence is higher in women than men. In young subjects, there is often a family history in first-degree relatives. Cardiovascular disease due to structural disease or arrhythmias is the next most common cause in most series, particularly in ED settings and in older patients. Orthostatic hypotension also increases in prevalence with age because of the reduced baroreflex responsiveness, decreased cardiac compliance, and attenuation of the vestibulosympathetic reflex associated with aging. Other contributors are reduced fluid intake and vasoactive medications, also more likely in this age group. In the elderly, orthostatic hypotension is more common in institutionalized than community-dwelling individuals, most likely explained by a greater prevalence of predisposing neurologic disorders, physiologic impairment, and vasoactive medication use among institutionalized patients.

Syncope of noncardiac and unexplained origin in younger individuals has an excellent prognosis; life expectancy is unaffected. By contrast, syncope due to a cardiac cause, either structural heart disease or a primary arrhythmic disorder, is associated with an increased risk of sudden cardiac death and mortality from other causes. Similarly, the mortality rate is increased in individuals with syncope due to orthostatic hypotension related to age and the associated comorbid conditions **(Table 21-1)**. The likelihood of hospitalization and mortality risk are higher in older adults.

TABLE 21-1 High-Risk Features Indicating Hospitalization or Intensive Evaluation of Syncope

Chest pain suggesting coronary ischemia
Features of congestive heart failure
Moderate or severe valvular disease
Moderate or severe structural cardiac disease
Electrocardiographic features of ischemia
History of ventricular arrhythmias
Prolonged QT interval (>500 ms)
Repetitive sinoatrial block or sinus pauses
Persistent sinus bradycardia
Bi- or trifascicular block or intraventricular conduction delay with QRS duration ≥120 ms
Atrial fibrillation
Nonsustained ventricular tachycardia
Family history of sudden death
Preexcitation syndromes
Brugada pattern on ECG
Palpitations at time of syncope
Syncope at rest or during exercise

PATHOPHYSIOLOGY

The upright posture imposes a unique physiologic stress upon humans; most, although not all, syncopal episodes occur from a standing position. Standing results in pooling of 500–1000 mL of blood in the lower extremities, buttocks, and splanchnic circulation. The dependent pooling leads to a decrease in venous return to the heart and reduced ventricular filling that result in diminished cardiac output and blood pressure. These hemodynamic changes provoke a compensatory reflex response, initiated by the baroreceptors in the carotid sinus and aortic arch, resulting in increased sympathetic outflow and decreased vagal nerve activity **(Fig. 21-1)**. The reflex increases peripheral resistance, venous return to the heart, and cardiac output and thus limits the fall in blood pressure. If this response fails, as is the case chronically in orthostatic hypotension and transiently in neurally mediated syncope, hypotension and cerebral hypoperfusion occur.

Syncope is a consequence of global cerebral hypoperfusion and thus represents a failure of cerebral blood flow autoregulatory mechanisms. Myogenic factors, local metabolites, and to a lesser extent autonomic neurovascular control are responsible for the autoregulation of cerebral blood flow **(Chap. 307)**. The latency of the autoregulatory response is 5–10 s. Typically, cerebral blood flow ranges from 50–60 mL/min per 100 g brain tissue and remains relatively constant over perfusion pressures ranging from 50–150 mmHg. Cessation of blood flow for 6–8 s

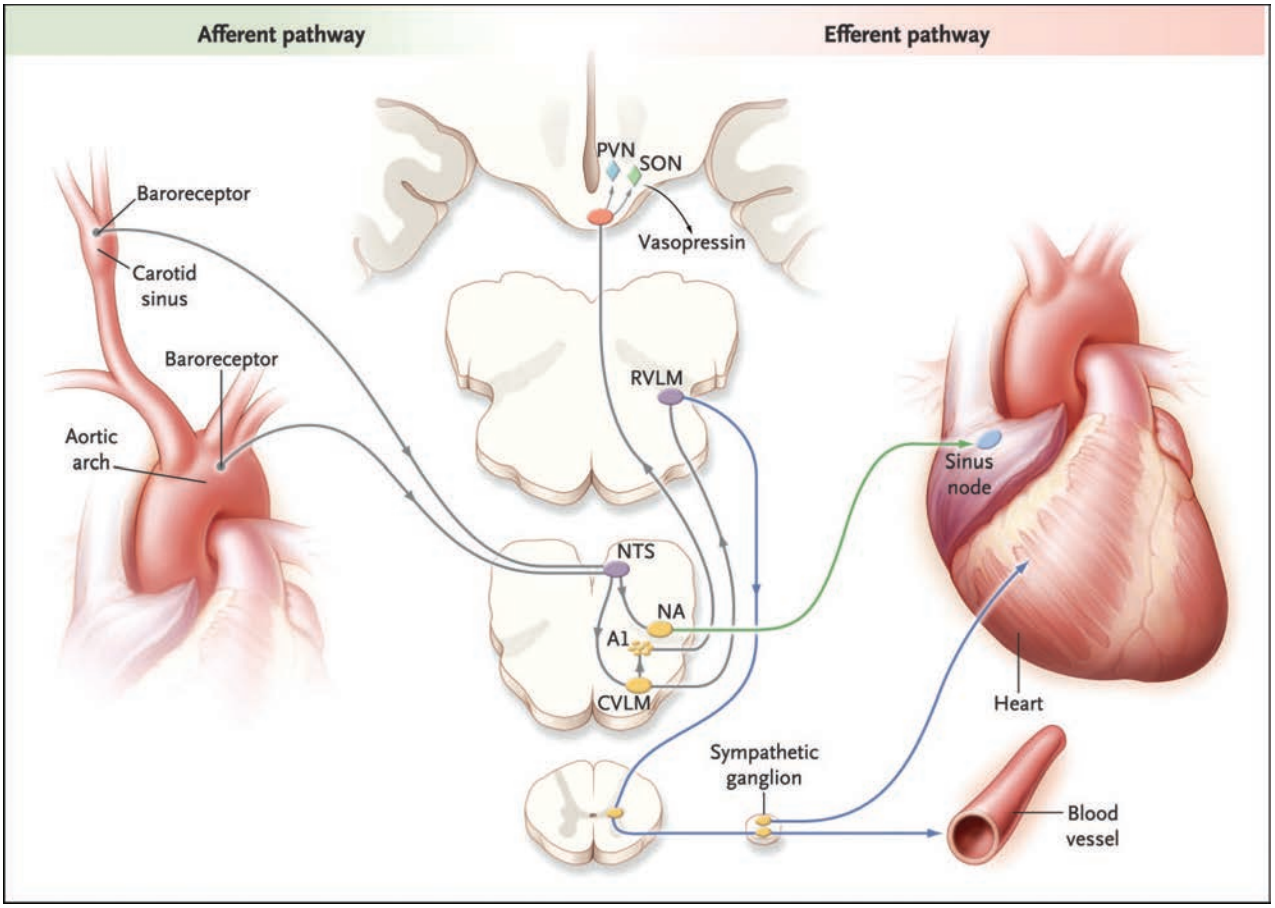

FIGURE 21-1 The baroreflex. A decrease in arterial pressure unloads the baroreceptors—the terminals of afferent fibers of the glossopharyngeal and vagus nerves—that are situated in the carotid sinus and aortic arch. This leads to a reduction in the afferent impulses that are relayed from these mechanoreceptors through the glossopharyngeal and vagus nerves to the nucleus of the tractus solitarius (NTS) in the dorsomedial medulla. The reduced baroreceptor afferent activity produces a decrease in vagal nerve input to the sinus node that is mediated via connections of the NTS to the nucleus ambiguus (NA). There is an increase in sympathetic efferent activity that is mediated by the NTS projections to the caudal ventrolateral medulla (CVLM) (an excitatory pathway) and from there to the rostral ventrolateral medulla (RVLM) (an inhibitory pathway). The activation of RVLM presympathetic neurons in response to hypotension is thus predominantly due to disinhibition. In response to a sustained fall in blood pressure, vasopressin release is mediated by projections from the A1 noradrenergic cell group in the ventrolateral medulla. This projection activates vasopressin-synthesizing neurons in the magnocellular portion of the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus. *Blue* denotes sympathetic neurons, and *green* denotes parasympathetic neurons. *(From R Freeman: Neurogenic orthostatic hypotension. N Engl J Med 358:615, 2008. Copyright © 2008 Massachusetts Medical Society. Reprinted with permission.)*

will result in loss of consciousness, while impairment of consciousness ensues when blood flow decreases to 25 mL/min per 100 g brain tissue.

From the clinical standpoint, a fall in systemic systolic blood pressure to ~50 mmHg or lower will result in syncope. A decrease in cardiac output and/or systemic vascular resistance—the determinants of blood pressure—thus underlies the pathophysiology of syncope. Common causes of impaired cardiac output include decreased effective circulating blood volume, increased thoracic pressure, massive pulmonary embolus, cardiac brady- and tachyarrhythmias, valvular heart disease, and myocardial dysfunction. Systemic vascular resistance may be decreased by central and peripheral autonomic nervous system diseases, sympatholytic medications, and transiently during neurally mediated syncope. Increased cerebral vascular resistance, most frequently due to hypocarbia induced by hyperventilation, may also contribute to the pathophysiology of syncope.

Two patterns of electroencephalographic (EEG) changes occur in syncopal subjects. The first is a "slow-flat-slow" pattern **(Fig. 21-2)** in which normal background activity is replaced with high-amplitude slow delta waves. This is followed by sudden flattening of the EEG—a cessation or attenuation of cortical activity—followed by the return of slow waves, and then normal activity. A second pattern, the "slow pattern," is characterized by increasing and decreasing slow wave activity only. The EEG flattening that occurs in the slow-flat-slow pattern is a marker of more severe cerebral hypoperfusion. Despite the presence of myoclonic movements and other motor activity during some syncopal events, EEG seizure discharges are not detected.

CLASSIFICATION

NEURALLY MEDIATED SYNCOPE

Neurally mediated (reflex; vasovagal) syncope is the final pathway of a complex central and peripheral nervous system reflex arc. There is a transient change in autonomic efferent activity with increased parasympathetic outflow, plus sympathoinhibition, resulting in bradycardia, vasodilation, and/or reduced vasoconstrictor tone (the vasodepressor response) and reduced cardiac output. The resulting fall in systemic blood pressure can then reduce cerebral blood flow to below the compensatory limits of autoregulation **(Fig. 21-3)**. In order to develop neurally mediated syncope, a functioning autonomic nervous system is necessary, in contrast to syncope resulting from autonomic failure (discussed below).

Multiple triggers of the afferent limb of the reflex arc can result in neurally mediated syncope. In some situations, these can be clearly defined, e.g., orthostatic stress and stimulus of the carotid sinus, the gastrointestinal tract, or the bladder. Often, however, the trigger is less easily recognized and the cause is multifactorial. Under these circumstances, it is likely that different afferent pathways converge on the central autonomic network within the medulla that integrates the neural impulses and mediates the vasodepressor-bradycardic response.

Classification of Neurally Mediated Syncope Neurally mediated syncope may be subdivided based on the afferent pathway and provocative trigger. Vasovagal syncope (the common faint) is provoked

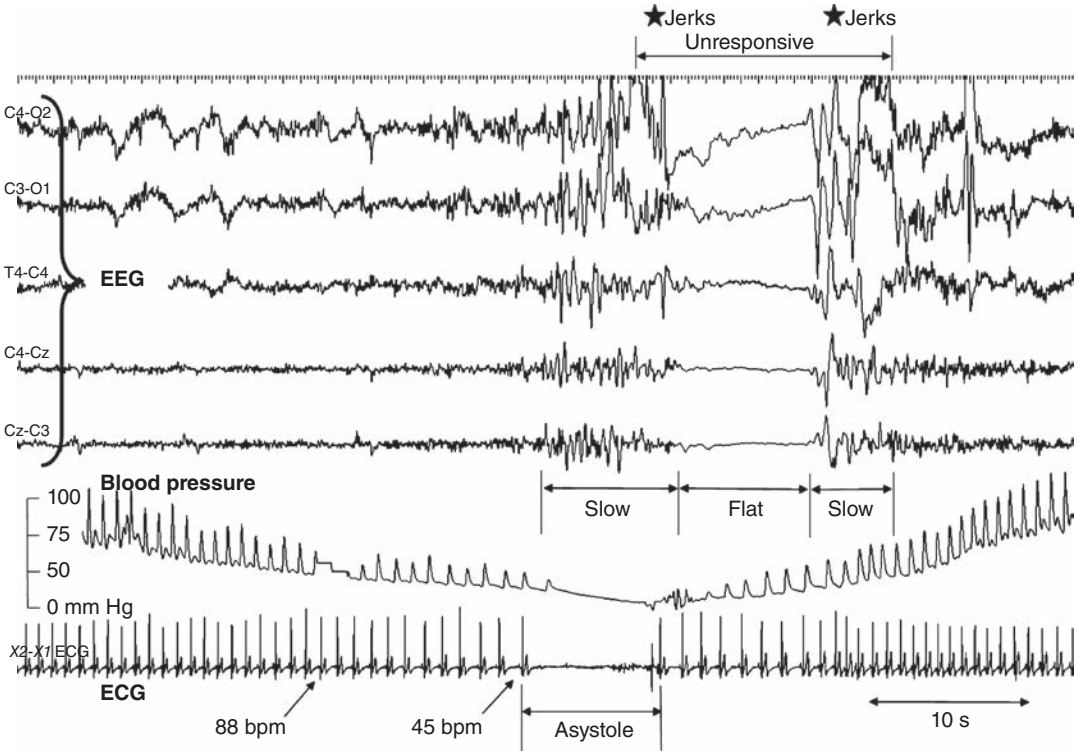

FIGURE 21-2 The electroencephalogram (EEG) in vasovagal syncope. A 1-min segment of a tilt-table test with typical vasovagal syncope demonstrating the "slow-flat-slow" EEG pattern. Finger beat-to-beat blood pressure, electrocardiogram (ECG), and selected EEG channels are shown. EEG slowing starts when systolic blood pressure drops to ~50 mmHg; heart rate is then ~45 beats/min (bpm). Asystole occurred, lasting about 8 s. The EEG flattens for a similar period, but with a delay. A transient loss of consciousness, lasting 14 s, was observed. There were muscle jerks just before and just after the flat period of the EEG. *(From W Wieling et al: Symptoms and signs of syncope: a review of the link between physiology and clinical clues. Brain 132:2630, 2009. Reprinted (and translated) by permission of Oxford University Press on behalf of the Guarantors of Brain.)*

by intense emotion, pain, and/or orthostatic stress, whereas the situational reflex syncopes have specific localized stimuli that provoke the reflex vasodilation and bradycardia that leads to syncope. The underlying mechanisms have been identified and pathophysiology delineated for most of these situational reflex syncopes. The afferent trigger may originate in the pulmonary system, gastrointestinal system, urogenital system, heart, and carotid sinus in the carotid artery **(Table 21-2)**. Hyperventilation leading to hypocarbia and cerebral vasoconstriction, and raised intrathoracic pressure that impairs venous return to the heart, play a central role in many of the situational reflex syncopes. The afferent pathway of the reflex arc differs among these disorders, but the efferent response via the vagus and sympathetic pathways is similar.

Alternately, neurally mediated syncope may be subdivided based on the predominant efferent pathway. Vasodepressor syncope describes syncope predominantly due to efferent, sympathetic, vasoconstrictor failure; cardioinhibitory syncope describes syncope predominantly associated with bradycardia or asystole due to increased vagal outflow;

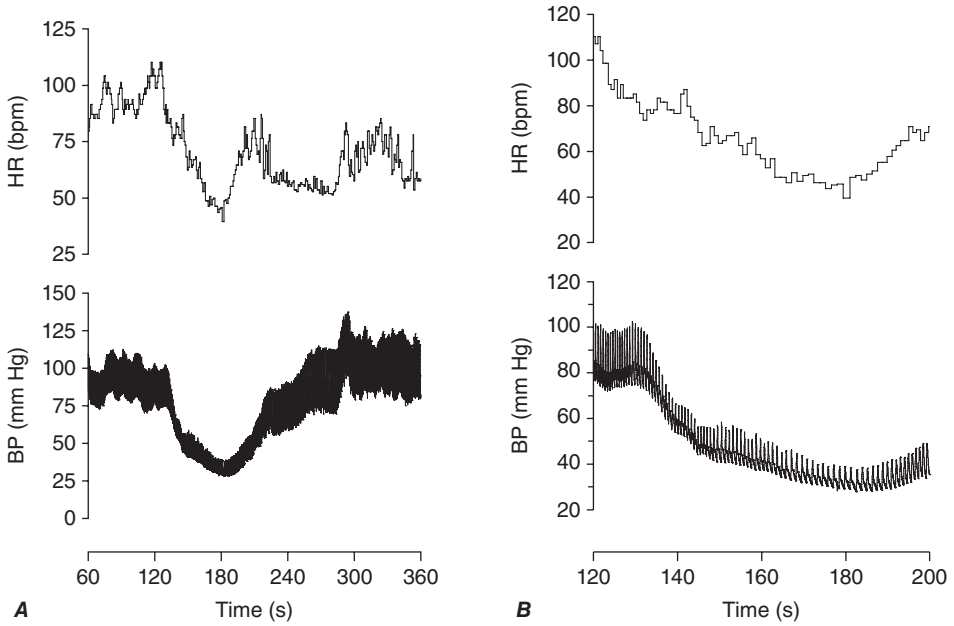

FIGURE 21-3 ***A.*** The paroxysmal hypotensive-bradycardic response that is characteristic of neurally mediated syncope. Noninvasive beat-to-beat blood pressure and heart rate are shown >5 min (from 60 to 360 s) of an upright tilt on a tilt table. ***B.*** The same tracing expanded to show 80 s of the episode (from 80 to 200 s). BP, blood pressure; bpm, beats per minute; HR, heart rate.

TABLE 21-2 Causes of Syncope

A. Neurally Mediated Syncope
Vasovagal syncope
Provoked fear, pain, anxiety, intense emotion, sight of blood, unpleasant sights and odors, orthostatic stress
Situational reflex syncope
Pulmonary
Cough syncope, wind instrument player's syncope, weightlifter's syncope, "mess trick"[a] and "fainting lark,"[b] sneeze syncope, airway instrumentation
Urogenital
Postmicturition syncope, urogenital tract instrumentation, prostatic massage
Gastrointestinal
Swallow syncope, glossopharyngeal neuralgia, esophageal stimulation, gastrointestinal tract instrumentation, rectal examination, defecation syncope
Cardiac
Bezold-Jarisch reflex, cardiac outflow obstruction
Carotid sinus
Carotid sinus sensitivity, carotid sinus massage
Ocular
Ocular pressure, ocular examination, ocular surgery
B. Orthostatic Hypotension
Primary autonomic failure due to idiopathic central and peripheral neurodegenerative diseases—the "synucleinopathies"
Lewy body diseases
Parkinson's disease
Lewy body dementia
Pure autonomic failure
Multiple system atrophy (Shy-Drager syndrome)
Secondary autonomic failure due to autonomic peripheral neuropathies
Diabetes
Hereditary amyloidosis (familial amyloid polyneuropathy)
Primary amyloidosis (AL amyloidosis; immunoglobulin light chain associated)
Hereditary sensory and autonomic neuropathies (HSAN) (especially type III—familial dysautonomia)
Idiopathic immune-mediated autonomic neuropathy
Autoimmune autonomic ganglionopathy
Sjögren's syndrome
Paraneoplastic autonomic neuropathy
HIV neuropathy
Postprandial hypotension
Iatrogenic (drug-induced)
Volume depletion
C. Cardiac Syncope
Arrhythmias
Sinus node dysfunction
Atrioventricular dysfunction
Supraventricular tachycardias
Ventricular tachycardias
Inherited channelopathies
Cardiac structural disease
Valvular disease
Myocardial ischemia
Obstructive and other cardiomyopathies
Atrial myxoma
Pericardial effusions and tamponade

[a]Hyperventilation for ~1 min, followed by sudden chest compression. [b]Hyperventilation (~20 breaths) in a squatting position, rapid rise to standing, then Valsalva maneuver.

and mixed syncope describes syncope in which there are both vagal and sympathetic reflex changes.

Features of Neurally Mediated Syncope In addition to symptoms of orthostatic intolerance such as dizziness, lightheadedness, and fatigue, premonitory features of autonomic activation may be present in patients with neurally mediated syncope. These include diaphoresis, pallor, palpitations, nausea, hyperventilation, and yawning. During the syncopal event, proximal and distal myoclonus (typically arrhythmic and multifocal) may occur, raising the possibility of a seizure. The eyes typically remain open and usually deviate upward. Pupils are usually dilated. Roving eye movements may occur. Grunting, moaning, snorting, and stertorous breathing may be present. Urinary incontinence may occur. Fecal incontinence is very rare, however. Postictal confusion is also rare, although visual and auditory hallucinations and near-death and out-of-body experiences are sometimes reported.

Although some predisposing factors and provocative stimuli are well established (for example, motionless upright posture, warm ambient temperature, intravascular volume depletion, alcohol ingestion, hypoxemia, anemia, pain, the sight of blood, venipuncture, and intense emotion), the underlying basis for the widely different thresholds for syncope among individuals exposed to the same provocative stimulus is not known. A genetic basis for neurally mediated syncope may exist; several studies have reported an increased incidence of syncope in first-degree relatives of fainters, but no gene or genetic marker has been identified, and environmental, social, and cultural factors have not been excluded by these studies.

TREATMENT

Neurally Mediated Syncope

Reassurance, education, avoidance of provocative stimuli, and plasma volume expansion with fluid and salt are the cornerstones of the management of neurally mediated syncope. Isometric counterpressure maneuvers of the limbs (tensing of the abdominal and leg muscles, handgrip and arm tensing, and leg crossing) may raise blood pressure by increasing central blood volume and cardiac output. Of these, abdominal muscle tensing is the most effective. By maintaining pressure in the autoregulatory zone, these maneuvers, which may be particularly helpful in patients with a long prodrome, avoid or delay the onset of syncope. Randomized controlled trials support this intervention.

Fludrocortisone, vasoconstricting agents, and β-adrenoreceptor antagonists are widely used by experts to treat refractory patients, although there is no consistent evidence from randomized controlled trials for any pharmacotherapy to treat neurally mediated syncope. Because vasodilation, decreased central blood volume, decreased stroke volume and cardiac output are the dominant pathophysiologic syncopal mechanisms in most patients, use of a cardiac pacemaker is rarely beneficial. A systematic review of the literature examining whether cardiac pacing reduces risk of recurrent syncope and relevant clinical outcomes in adults with neurally mediated syncope, concluded that the existing evidence does not support the use of routine cardiac pacing. Possible exceptions are (1) older patients (>40 years), with at least three prior episodes associated with asystole (of at least 3 s associated with syncope or at least 6 s associated with presyncope) documented by an implantable loop recorder; and (2) patients with prominent cardioinhibition due to carotid sinus syndrome. In these patients, dual-chamber pacing may be helpful, although this continues to be an area of uncertainty.

ORTHOSTATIC HYPOTENSION

Orthostatic hypotension, defined as a reduction in systolic blood pressure of at least 20 mmHg or diastolic blood pressure of at least 10 mmHg after 3 min of standing or head-up tilt on a tilt table, is a manifestation of sympathetic vasoconstrictor (autonomic) failure (Fig. 21-4). In many (but not all) cases, there is no compensatory

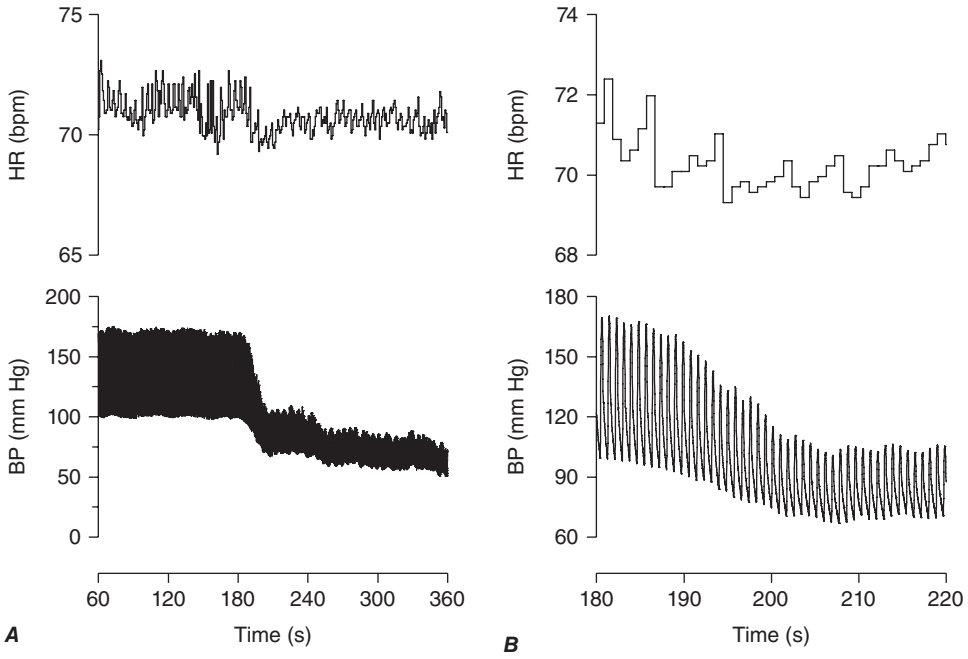

FIGURE 21-4 ***A.*** The gradual fall in blood pressure without a compensatory heart rate increase that is characteristic of orthostatic hypotension due to autonomic failure. Blood pressure and heart rate are shown >5 min (from 60 to 360 s) of an upright tilt on a tilt table. ***B.*** The same tracing expanded to show 40 s of the episode (from 180 to 220 s). BP, blood pressure; bpm, beats per minute; HR, heart rate.

increase in heart rate despite hypotension; with partial autonomic failure, heart rate may increase to some degree but is insufficient to maintain cardiac output. A variant of orthostatic hypotension is "delayed" orthostatic hypotension, which occurs beyond 3 min of standing; this may reflect a mild or early form of sympathetic adrenergic dysfunction. In some cases, orthostatic hypotension occurs within 15 s of standing (so-called initial orthostatic hypotension), a finding that may reflect a transient mismatch between cardiac output and peripheral vascular resistance and does not represent autonomic failure.

Characteristic symptoms of orthostatic hypotension include light-headedness, dizziness, and presyncope (near-faintness) occurring in response to sudden postural change. However, symptoms may be absent or nonspecific, such as generalized weakness, fatigue, cognitive slowing, leg buckling, or headache. Visual blurring may occur, likely due to retinal or occipital lobe ischemia. Neck pain, typically in the suboccipital, posterior cervical, and shoulder region (the "coat-hanger headache"), most likely due to neck muscle ischemia, may be the only symptom. Patients may report orthostatic dyspnea (thought to reflect ventilation-perfusion mismatch due to inadequate perfusion of ventilated lung apices) or angina (attributed to impaired myocardial perfusion even with normal coronary arteries). Symptoms may be exacerbated by exertion, prolonged standing, increased ambient temperature, or meals. Syncope is usually preceded by warning symptoms, but may occur suddenly, suggesting the possibility of a seizure or cardiac cause. Some patients have profound decreases in blood pressure, sometimes without symptoms but placing them at risk for falls and injuries if the autoregulatory threshold is crossed with ensuing cerebral hypoperfusion.

Supine hypertension is common in patients with orthostatic hypotension due to autonomic failure, affecting >50% of patients in some series. Orthostatic hypotension may present after initiation of therapy for hypertension, and supine hypertension may follow treatment of orthostatic hypotension. However, in other cases, the association of the two conditions is unrelated to therapy; it may in part be explained by baroreflex dysfunction in the presence of residual sympathetic outflow, particularly in patients with central autonomic degeneration.

Causes of Neurogenic Orthostatic Hypotension Causes of neurogenic orthostatic hypotension include central and peripheral autonomic nervous system dysfunction **(Chap. 440)**. Autonomic dysfunction of other organ systems (including the bladder, bowels, sexual organs, and sudomotor system) of varying severity frequently accompanies orthostatic hypotension in these disorders (Table 21-2).

The primary autonomic degenerative disorders are multiple system atrophy (Shy-Drager syndrome; **Chap. 440**), Parkinson's disease **(Chap. 435)**, dementia with Lewy bodies **(Chap. 434)**, and pure autonomic failure **(Chap. 440)**. These are often grouped together as "synucleinopathies" due to the presence of α-synuclein, a protein that aggregates predominantly in the cytoplasm of neurons in the Lewy body disorders (Parkinson's disease, dementia with Lewy bodies, and pure autonomic failure) and in the glia in multiple system atrophy.

Peripheral autonomic dysfunction may also accompany small-fiber peripheral neuropathies such as those associated with diabetes mellitus, acquired and hereditary amyloidosis, immune-mediated neuropathies, and hereditary sensory and autonomic neuropathies (HSAN; particularly HSAN type III, familial dysautonomia) **(Chaps. 446 and 447)**. Less frequently, orthostatic hypotension is associated with the peripheral neuropathies that accompany vitamin B_{12} deficiency, neurotoxin exposure, HIV and other infections, and porphyria.

Patients with autonomic failure and the elderly are susceptible to falls in blood pressure associated with meals. The magnitude of the blood pressure fall is exacerbated by large meals, meals high in carbohydrate, and alcohol intake. The mechanism of postprandial syncope is not fully elucidated.

Orthostatic hypotension is often iatrogenic. Drugs from several classes may lower peripheral resistance (e.g., α-adrenoreceptor antagonists used to treat hypertension and prostatic hypertrophy; antihypertensive agents of several classes; nitrates and other vasodilators; tricyclic agents and phenothiazines). Iatrogenic volume depletion due to diuresis and volume depletion due to medical causes (hemorrhage, vomiting, diarrhea, or decreased fluid intake) may also result in decreased effective circulatory volume, orthostatic hypotension, and syncope.

TREATMENT

Orthostatic Hypotension

The first step is to remove reversible causes—usually vasoactive medications **(see Table 440-6)**. Next, nonpharmacologic interventions should be introduced. These include patient education regarding staged moves from supine to upright; warnings about the hypotensive effects of large meals; instructions about the isometric counterpressure maneuvers that increase intravascular pressure (see above); and raising the head of the bed to reduce supine hypertension and nocturnal diuresis. Intravascular volume should be expanded by increasing dietary fluid and salt. If these nonpharmacologic measures fail, pharmacologic intervention with fludrocortisone acetate and vasoconstricting agents such as midodrine and L-dihydroxyphenylserine should be introduced. Some patients with intractable symptoms require additional therapy with supplementary agents that include pyridostigmine, atomoxetine, yohimbine, octreotide, desmopressin acetate (DDAVP), and erythropoietin **(Chap. 440)**.

CARDIAC SYNCOPE

Cardiac (or cardiovascular) syncope is caused by arrhythmias and structural heart disease. These may occur in combination because structural disease renders the heart more vulnerable to abnormal electrical activity.

Arrhythmias Bradyarrhythmias that cause syncope include those due to severe sinus node dysfunction (e.g., sinus arrest or sinoatrial block) and atrioventricular (AV) block (e.g., Mobitz type II, high-grade, and complete AV block). The bradyarrhythmias due to sinus node dysfunction are often associated with an atrial tachyarrhythmia, a disorder known as the tachycardia-bradycardia syndrome. A prolonged pause following the termination of a tachycardic episode is a frequent cause of syncope in patients with the tachycardia-bradycardia syndrome. Medications of several classes may also cause bradyarrhythmias of sufficient severity to cause syncope. Syncope due to bradycardia or asystole has been referred to as a Stokes-Adams attack.

Ventricular tachyarrhythmias frequently cause syncope. The likelihood of syncope with ventricular tachycardia is in part dependent on the ventricular rate; rates <200 beats/min are less likely to cause syncope. The compromised hemodynamic function during ventricular tachycardia is caused by ineffective ventricular contraction, reduced diastolic filling due to abbreviated filling periods, loss of AV synchrony, and concurrent myocardial ischemia.

Several disorders associated with cardiac electrophysiologic instability and arrhythmogenesis are due to mutations in ion channel subunit genes. These include the long QT syndrome, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia. The long QT syndrome is a genetically heterogeneous disorder associated with prolonged cardiac repolarization and a predisposition to ventricular arrhythmias. Syncope and sudden death in patients with long QT syndrome result from a unique polymorphic ventricular tachycardia called *torsades des pointes* that degenerates into ventricular fibrillation. The long QT syndrome has been linked to genes encoding K^+ channel α-subunits, K^+ channel β-subunits, voltage-gated Na^+ channel, and a scaffolding protein, ankyrin B (ANK2). Brugada syndrome is characterized by idiopathic ventricular fibrillation in association with right ventricular electrocardiogram (ECG) abnormalities without structural heart disease. This disorder is also genetically heterogeneous, although it is most frequently linked to mutations in the Na^+ channel α-subunit, SCN5A. Catecholaminergic polymorphic tachycardia is an inherited, genetically heterogeneous disorder associated with exercise- or stress-induced ventricular arrhythmias, syncope, or sudden death. Acquired QT interval prolongation, most commonly due to drugs, may also result in ventricular arrhythmias and syncope. **These disorders are discussed in detail in Chap. 255.**

Structural Disease Structural heart disease (e.g., valvular disease, myocardial ischemia, hypertrophic and other cardiomyopathies, cardiac masses such as atrial myxoma, and pericardial effusions) may lead to syncope by compromising cardiac output. Structural disease may also contribute to other pathophysiologic mechanisms of syncope. For example, cardiac structural disease may predispose to arrhythmogenesis; aggressive treatment of cardiac failure with diuretics and/or vasodilators may lead to orthostatic hypotension; and inappropriate reflex vasodilation may occur with structural disorders such as aortic stenosis and hypertrophic cardiomyopathy, possibly provoked by increased ventricular contractility.

TREATMENT

Cardiac Syncope

Treatment of cardiac disease depends on the underlying disorder. Therapies for arrhythmias include cardiac pacing for sinus node disease and AV block, and ablation, antiarrhythmic drugs, and cardioverter-defibrillators for atrial and ventricular tachyarrhythmias. These disorders are best managed by physicians with specialized skills in this area.

APPROACH TO THE PATIENT

Syncope

DIFFERENTIAL DIAGNOSIS

Syncope is easily diagnosed when the characteristic features are present; however, several disorders with transient real or apparent loss of consciousness may create diagnostic confusion.

Generalized and partial seizures may be confused with syncope; however, there are a number of differentiating features. Whereas tonic-clonic movements are the hallmark of a generalized seizure, myoclonic and other movements also may occur in up to 90% of syncopal episodes. Myoclonic jerks associated with syncope may be multifocal or generalized. They are typically arrhythmic and of short duration (<30 s). Mild flexor and extensor posturing also may occur. Partial or partial-complex seizures with secondary generalization are usually preceded by an aura, commonly an unpleasant smell; fear; anxiety; abdominal discomfort; or other visceral sensations. These phenomena should be differentiated from the premonitory features of syncope.

Autonomic manifestations of seizures (autonomic epilepsy) may provide a more difficult diagnostic challenge. Autonomic seizures have cardiovascular, gastrointestinal, pulmonary, urogenital, pupillary, and cutaneous manifestations that are similar to the premonitory features of syncope. Furthermore, the cardiovascular manifestations of autonomic epilepsy include clinically significant tachycardias and bradycardias that may be of sufficient magnitude to cause loss of consciousness. The presence of accompanying nonautonomic auras may help differentiate these episodes from syncope.

Loss of consciousness associated with a seizure usually lasts >5 min and is associated with prolonged postictal drowsiness and disorientation, whereas reorientation occurs almost immediately after a syncopal event. Muscle aches may occur after both syncope and seizures, although they tend to last longer and be more severe following a seizure. Seizures, unlike syncope, are rarely provoked by emotions or pain. Incontinence of urine may occur with both seizures and syncope; however, fecal incontinence occurs very rarely with syncope.

Hypoglycemia may cause transient loss of consciousness, typically in individuals with type 1 or type 2 diabetes **(Chap. 403)** treated with insulin. The clinical features associated with impending or actual hypoglycemia include tremor, palpitations, anxiety, diaphoresis, hunger, and paresthesias. These symptoms are due to autonomic activation to counter the falling blood glucose. Hunger, in particular, is not a typical premonitory feature of syncope. Hypoglycemia also impairs neuronal function, leading to fatigue, weakness, dizziness, and cognitive and behavioral symptoms. Diagnostic difficulties may occur in individuals in strict glycemic control; repeated hypoglycemia impairs the counterregulatory response and leads to a loss of the characteristic warning symptoms that are the hallmark of hypoglycemia.

Patients with cataplexy **(Chap. 31)** experience an abrupt partial or complete loss of muscular tone triggered by strong emotions, typically anger or laughter. Unlike syncope, consciousness is maintained throughout the attacks, which typically last between 30 s and 2 min. There are no premonitory symptoms. Cataplexy occurs in 60%–75% of patients with narcolepsy.

The clinical interview and interrogation of eyewitnesses usually allow differentiation of syncope from falls due to vestibular dysfunction, cerebellar disease, extrapyramidal system dysfunction, and other gait disorders. A diagnosis of syncope can be particularly challenging in patients with dementia who experience repeated falls and are unable to provide a clear history of the episodes. If the fall is accompanied by head trauma, a postconcussive syndrome, amnesia for the precipitating events, and/or a loss or alteration of consciousness, this may also contribute to diagnostic difficulty.

Apparent loss of consciousness can be a manifestation of psychiatric disorders such as generalized anxiety, panic disorders, major

depression, and somatization disorder. These possibilities should be considered in individuals who faint frequently without prodromal symptoms. Such patients are rarely injured despite numerous falls. There are no clinically significant hemodynamic changes concurrent with these episodes. In contrast, transient loss of consciousness due to vasovagal syncope precipitated by fear, stress, anxiety, and emotional distress is accompanied by hypotension, bradycardia, or both.

INITIAL EVALUATION

The goals of the initial evaluation are to determine whether the transient loss of consciousness was due to syncope; to identify the cause; and to assess risk for future episodes and serious harm (Table 21-1). The initial evaluation should include a detailed history, thorough questioning of eyewitnesses, and a complete physical and neurologic examination. Blood pressure and heart rate should be measured in the supine position and after 3 min of standing to determine whether orthostatic hypotension is present. High-risk features on history include: the new onset of chest discomfort, abdominal pain, shortness of breath or headache; syncope during exertion or while supine; sudden onset of palpitations followed by syncope; severe coronary artery or structural heart disease.

High-risk features on examination include an unexplained systolic BP of <90 mmHg; suggestion of gastrointestinal hemorrhage; persistent bradycardia (<40 beats/min); and an undiagnosed systolic murmur.

An ECG should be performed if there is suspicion of syncope due to an arrhythmia or underlying cardiac disease. Relevant electrocardiographic abnormalities include bradyarrhythmias or tachyarrhythmias, AV block, acute myocardial ischemia, old myocardial infarction, long QT_c, and bundle branch block. This initial assessment will lead to the identification of a cause of syncope in ~50% of patients and also allows stratification of patients at risk for cardiac mortality.

Laboratory Tests Baseline laboratory blood tests are rarely helpful in identifying the cause of syncope. Blood tests should be performed when specific disorders, e.g., myocardial infarction, anemia, and secondary autonomic failure, are suspected (Table 21-2).

Autonomic Nervous System Testing (Chap. 440) Autonomic testing, including tilt-table testing, can be performed in specialized centers. Autonomic testing is helpful to uncover objective evidence of autonomic failure and also to demonstrate a predisposition to neurally mediated syncope. Autonomic testing includes assessments of parasympathetic autonomic nervous system function (e.g., heart rate variability to deep respiration and a Valsalva maneuver), sympathetic cholinergic function (e.g., thermoregulatory sweat response and quantitative sudomotor axon reflex test), and sympathetic adrenergic function (e.g., blood pressure response to a Valsalva maneuver and a tilt-table test with beat-to-beat blood pressure measurement). The hemodynamic abnormalities demonstrated on the tilt-table test (Figs. 21-3 and 21-4) may be useful in distinguishing orthostatic hypotension due to autonomic failure from the hypotensive bradycardic response of neurally mediated syncope. Similarly, the tilt-table test may help identify patients with syncope due to immediate or delayed orthostatic hypotension.

Carotid sinus massage should be considered in patients with symptoms suggestive of carotid sinus syncope and in patients >40 years with recurrent syncope of unknown etiology. This test should only be carried out under continuous ECG and blood pressure monitoring and should be avoided in patients with carotid bruits, possible or known plaques, or stenosis.

Cardiac Evaluation ECG monitoring is indicated for patients with a high pretest probability of arrhythmia causing syncope. Patients should be monitored in the hospital if the likelihood of a life-threatening arrhythmia is high, e.g., patients with severe coronary artery or structural heart disease, nonsustained ventricular tachycardia, supraventricular tachycardia, paroxysmal atrial fibrillation, trifascicular heart block, prolonged QT interval, Brugada syndrome ECG pattern, syncope during exertion, syncope while seated or supine, and family history of sudden cardiac death (Table 21-1). Outpatient Holter monitoring is recommended for patients who experience frequent syncopal episodes (e.g., one or more per week), whereas loop recorders, which continually record and erase cardiac rhythm, are indicated for patients with suspected arrhythmias with low risk of sudden cardiac death. Loop recorders may be external (e.g., for evaluation of episodes that occur at a frequency of >1 per month) or implantable (e.g., if syncope occurs less frequently).

Echocardiography should be performed in patients with a history of cardiac disease or if abnormalities are found on physical examination or the ECG. Echocardiographic diagnoses that may be responsible for syncope include aortic stenosis, hypertrophic cardiomyopathy, cardiac tumors, aortic dissection, and pericardial tamponade. Echocardiography also has a role in risk stratification based on the left ventricular ejection fraction.

Treadmill exercise testing with ECG and blood pressure monitoring should be performed in patients who have experienced syncope during or shortly after exercise. Treadmill testing may help identify exercise-induced arrhythmias (e.g., tachycardia-related AV block) and exercise-induced exaggerated vasodilation.

Electrophysiologic studies are indicated in patients with structural heart disease and ECG abnormalities in whom noninvasive investigations have failed to yield a diagnosis. Electrophysiologic studies have low sensitivity and specificity and should only be performed when a high pretest probability exists. Currently, these tests are rarely performed to evaluate patients with syncope.

Psychiatric Evaluation Screening for psychiatric disorders may be appropriate in patients with recurrent unexplained syncope episodes. Tilt-table testing, with demonstration of symptoms in the absence of hemodynamic change, may be useful in reproducing syncope in patients with suspected psychogenic syncope.

22 Dizziness and Vertigo

Mark F. Walker, Robert B. Daroff

Dizziness is an imprecise symptom used to describe a variety of common sensations that include vertigo, light-headedness, faintness, and imbalance. *Vertigo* refers to a sense of spinning or other motion that may be physiological, occurring during or after a sustained head rotation, or pathological, due to vestibular dysfunction. The term *light-headedness* is classically applied to presyncopal sensations resulting from brain hypoperfusion but as used by patients has little specificity, as it may also refer to other symptoms such as disequilibrium and imbalance. A challenge to diagnosis is that patients often have difficulty distinguishing among these various symptoms, and the words they choose do not reliably indicate the underlying etiology.

There are many causes of dizziness. Vestibular dizziness (vertigo or imbalance) may be due to peripheral disorders that affect the labyrinths or vestibular nerves, or it may result from disruption of central vestibular pathways. It may be paroxysmal or due to a fixed unilateral or bilateral vestibular deficit. Acute unilateral lesions cause vertigo due to a sudden imbalance in vestibular inputs from the two labyrinths. Bilateral lesions cause imbalance and instability of vision when the head moves (*oscillopsia*) due to loss of normal vestibular reflexes.

Presyncopal dizziness occurs when cardiac dysrhythmia, orthostatic hypotension, medication effects, or another cause leads to brain hypoperfusion. Such presyncopal sensations vary in duration; they may increase in severity until loss of consciousness occurs, or they may resolve before loss of consciousness if the cerebral ischemia is corrected. Faintness and syncope, which are discussed in detail in **Chap. 21**, should always be considered when one is evaluating patients with brief episodes of dizziness or dizziness that occurs with upright posture. Other causes of dizziness include nonvestibular imbalance, gait disorders (e.g., loss of proprioception from sensory neuropathy, parkinsonism), and anxiety.

When evaluating patients with dizziness, questions to consider include the following: (1) Is it dangerous (e.g., arrhythmia, transient ischemic attack/stroke)? (2) Is it vestibular? (3) If vestibular, is it peripheral or central? A careful history and examination often provide sufficient information to answer these questions and determine whether additional studies or referral to a specialist is necessary.

APPROACH TO THE PATIENT

Dizziness

HISTORY

When a patient presents with dizziness, the first step is to delineate more precisely the nature of the symptom. In the case of vestibular disorders, the physical symptoms depend on whether the lesion is unilateral or bilateral, and whether it is acute or chronic. Vertigo, an illusion of self or environmental motion, implies an acute asymmetry of vestibular inputs from the two labyrinths or in their central pathways. Symmetric bilateral vestibular hypofunction causes imbalance but no vertigo. Because of the ambiguity in patients' descriptions of their symptoms, diagnosis based simply on symptom characteristics is typically unreliable. Thus the history should focus closely on other features, including whether this is the first attack, the duration of this and any prior episodes, provoking factors, and accompanying symptoms.

Dizziness can be divided into episodes that last for seconds, minutes, hours, or days. Common causes of brief dizziness (seconds) include benign paroxysmal positional vertigo (BPPV) and orthostatic hypotension, both of which typically are provoked by changes in head and/or body position relative to gravity. Attacks of vestibular migraine and Ménière's disease often last hours. When episodes are of intermediate duration (minutes), transient ischemic attacks of the posterior circulation should be considered, although migraine and other causes are also possible.

Symptoms that accompany vertigo may be helpful in distinguishing peripheral vestibular lesions from central causes. Unilateral hearing loss and other acute aural symptoms (ear pain, pressure, fullness, new tinnitus) typically point to a peripheral cause. Because the auditory pathways quickly become bilateral upon entering the brainstem, central lesions are unlikely to cause unilateral hearing loss unless the lesion lies near the root entry zone of the auditory nerve. Symptoms such as double vision, numbness, and limb ataxia suggest a brainstem or cerebellar lesion.

EXAMINATION

Because dizziness and imbalance can be a manifestation of a variety of neurologic disorders, the neurologic examination is important in the evaluation of these patients. Focus should be given to assessment of eye movements, vestibular function, and hearing. The range of eye movements and whether they are equal in each eye should be observed. Peripheral eye movement disorders (e.g., cranial neuropathies, eye muscle weakness) are usually disconjugate (different in the two eyes). One should check pursuit (the ability to follow a smoothly moving target) and saccades (the ability to look back and forth accurately between two targets). Poor pursuit or inaccurate (dysmetric) saccades usually indicate central pathology, often involving the cerebellum. Alignment of the two eyes can be checked with a cover test: while the patient is looking at a target, alternately cover the eyes and observe for corrective saccades. A vertical misalignment may indicate a brainstem or cerebellar lesion. Finally, one should look for spontaneous nystagmus, an involuntary back-and-forth movement of the eyes. Nystagmus is most often of the jerk type, in which a slow drift (slow phase) in one direction alternates with a rapid saccadic movement (quick phase or fast phase) in the opposite direction that resets the position of the eyes in the orbits. Except in the case of acute vestibulopathy (e.g., vestibular neuritis), if primary position nystagmus is easily seen in the light, it is probably due to a central cause. Two forms of nystagmus that are characteristic of lesions of the cerebellar pathways are vertical nystagmus with downward fast phases (downbeat nystagmus) and horizontal nystagmus that changes direction with gaze (gaze-evoked nystagmus). By contrast, peripheral lesions typically cause unidirectional horizontal nystagmus. Use of Frenzel eyeglasses (self-illuminated goggles with convex lenses that blur the patient's vision but allow the examiner to see the eyes greatly magnified) or infrared video goggles can aid in the detection of peripheral vestibular nystagmus, because they reduce the patient's ability to use visual fixation to suppress nystagmus. **Table 22-1** outlines key findings that help distinguish peripheral from central causes of vertigo.

The most useful bedside test of peripheral vestibular function is the head impulse test, in which the vestibulo-ocular reflex (VOR) is assessed with small-amplitude (~20 degrees) rapid head rotations. While the patient fixates on a target, the head is rotated quickly to the left or right. If the VOR is deficient, the rotation is followed by a catch-up saccade in the opposite direction (e.g., a leftward saccade

TABLE 22-1 Features of Peripheral and Central Vertigo

- Nystagmus from an acute peripheral lesion is unidirectional, with fast phases beating away from the ear with the lesion. Nystagmus that changes direction with gaze is due to a central lesion.
- Transient mixed vertical-torsional nystagmus occurs in benign paroxysmal positional vertigo (BPPV), but pure vertical or pure torsional nystagmus is a central sign.
- Nystagmus from a peripheral lesion may be inhibited by visual fixation, whereas central nystagmus is not suppressed.
- Absence of a head impulse sign in a patient with acute prolonged vertigo should suggest a central cause.
- Unilateral hearing loss suggests peripheral vertigo. Findings such as diplopia, dysarthria, and limb ataxia suggest a central disorder.

after a rightward rotation). The head impulse test can identify both unilateral (catch-up saccades after rotations toward the weak side) and bilateral (catch-up saccades after rotations in both directions) vestibular hypofunction.

All patients with episodic dizziness, especially if provoked by positional change, should be tested with the Dix-Hallpike maneuver. The patient begins in a sitting position with the head turned 45 degrees; holding the back of the head, the examiner then lowers the patient into a supine position with the head extended backward by about 20 degrees while watching the eyes. Posterior canal BPPV can be diagnosed confidently if transient upbeating-torsional nystagmus is seen. If no nystagmus is observed after 15–20 s, the patient is raised to the sitting position, and the procedure is repeated with the head turned to the other side. Again, Frenzel goggles may improve the sensitivity of the test.

Dynamic visual acuity is a functional test that can be useful in assessing vestibular function. Visual acuity is measured with the head still and when the head is rotated back and forth by the examiner (about 1–2 Hz). A drop in visual acuity during head motion of more than one line on a near card or Snellen chart is abnormal and indicates vestibular dysfunction.

ANCILLARY TESTING

The choice of ancillary tests should be guided by the history and examination findings. Audiometry should be performed whenever a vestibular disorder is suspected. Unilateral sensorineural hearing loss supports a peripheral disorder (e.g., vestibular schwannoma). Predominantly low-frequency hearing loss is characteristic of Ménière's disease. Videonystagmography includes recordings of spontaneous nystagmus (if present) and measurement of positional nystagmus. Caloric testing compares the responses of the two horizontal semicircular canals, while video head-impulse testing measures the integrity of each of the six semicircular canals. Vestibular evoked potentials assess otolith reflexes. The test battery often includes recording of saccades and pursuit to evaluate central ocular motor function. Neuroimaging is important if a central vestibular disorder is suspected. In addition, patients with unexplained unilateral hearing loss or vestibular hypofunction should undergo MRI of the internal auditory canals, including administration of gadolinium, to rule out a schwannoma.

DIFFERENTIAL DIAGNOSIS AND TREATMENT

Treatment of vestibular symptoms should be driven by the underlying diagnosis. Simply treating dizziness with vestibular suppressant medications is often not helpful and may make the symptoms worse and prolong recovery. The diagnostic and specific treatment approaches for the most commonly encountered vestibular disorders are discussed below.

ACUTE PROLONGED VERTIGO (VESTIBULAR NEURITIS)

An acute unilateral vestibular lesion causes constant vertigo, nausea, vomiting, oscillopsia (motion of the visual scene), and imbalance. These symptoms are due to a sudden asymmetry of inputs from the two labyrinths or in their central connections, simulating a continuous rotation of the head. Unlike BPPV, continuous vertigo persists even when the head remains still.

When a patient presents with an acute vestibular syndrome, the most important question is whether the lesion is central (e.g., a cerebellar or brainstem infarct or hemorrhage), which may be life-threatening, or peripheral, affecting the vestibular nerve or labyrinth (vestibular neuritis). Attention should be given to any symptoms or signs that point to central dysfunction (diplopia, weakness or numbness, dysarthria). The pattern of spontaneous nystagmus, if present, may be helpful (Table 22-1). If the head impulse test is normal, an acute peripheral vestibular lesion is unlikely. A central lesion cannot always be excluded with certainty based on symptoms and examination alone; thus older patients with vascular risk factors who present with an acute vestibular syndrome should be evaluated for the possibility of stroke even when there are no specific findings that indicate a central lesion.

Most patients with vestibular neuritis recover spontaneously, although chronic dizziness, motion sensitivity, and disequilibrium may persist. The role of early glucocorticoid therapy is uncertain, as studies have yielded disparate results. Antiviral medications are of no proven benefit and are not typically given unless there is evidence to suggest herpes zoster oticus (Ramsay Hunt syndrome). Vestibular suppressant medications may reduce acute symptoms but should be avoided after the first several days because they may impede central compensation and recovery. Patients should be encouraged to resume a normal level of activity as soon as possible, and directed vestibular rehabilitation therapy may accelerate improvement.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

BPPV is a common cause of recurrent vertigo. Episodes are brief (<1 min and typically 15–20 s) and are always provoked by changes in head position relative to gravity, such as lying down, rising from a supine position, and extending the head to look upward. Rolling over in bed is a common trigger that may help to distinguish BPPV from orthostatic hypotension. The attacks are caused by free-floating otoconia (calcium carbonate crystals) that have been dislodged from the utricular macula and have moved into one of the semicircular canals, usually the posterior canal. When head position changes, gravity causes the otoconia to move within the canal, producing vertigo and nystagmus. With posterior canal BPPV, the nystagmus beats upward and torsionally (the upper poles of the eyes beat toward the affected lower ear). Less commonly, the otoconia enter the horizontal canal, resulting in a horizontal nystagmus when the patient is lying with either ear down. Superior (also called anterior) canal involvement is rare. BPPV is treated with repositioning maneuvers that use gravity to remove the otoconia from the semicircular canal. For posterior canal BPPV, the Epley maneuver **(Fig. 22-1)** is the most commonly used procedure. For more refractory cases of BPPV, patients can be taught a variant of this maneuver that they can perform alone at home. A demonstration of the Epley maneuver is available online (*http://www.dizziness-and-balance.com/disorders/bppv/bppv.html*).

VESTIBULAR MIGRAINE

Vestibular migraine is a common yet underdiagnosed cause of episodic vertigo. Vertigo sometimes precedes a typical migraine headache but more often occurs without headache or with only a mild headache. Some patients who have had frequent migraine headaches in the past present later in life with vestibular migraine as the predominant problem. In vestibular migraine, the duration of vertigo may be from minutes to hours, and some migraineurs also experience more prolonged periods of disequilibrium (lasting days to weeks). Motion sensitivity and sensitivity to visual motion (e.g., movies) are common. Even in the absence of headache, other migraine features may be present, such as photophobia, phonophobia, or a visual aura. Although data from controlled studies are generally lacking, vestibular migraine typically is treated with medications that are used for prophylaxis of migraine headaches **(Chap. 430)**. Antiemetics may be helpful to relieve symptoms at the time of an attack.

MÉNIÈRE'S DISEASE

Attacks of Ménière's disease consist of vertigo and hearing loss, as well as pain, pressure, and/or fullness in the affected ear. Low-frequency hearing loss and aural symptoms are key features that distinguish Ménière's disease from other peripheral vestibulopathies and from vestibular migraine. Audiometry at the time of an attack shows a characteristic asymmetric low-frequency hearing loss; hearing commonly improves between attacks, although permanent hearing loss may eventually occur. Ménière's disease is associated with excess endolymph fluid in the inner ear; hence the term *endolymphatic hydrops*. The exact pathophysiological mechanism, however, remains unclear. Patients suspected of having Ménière's disease should be referred to an otolaryngologist for further evaluation. Diuretics and sodium restriction are typically the initial treatments. If attacks persist, injections of

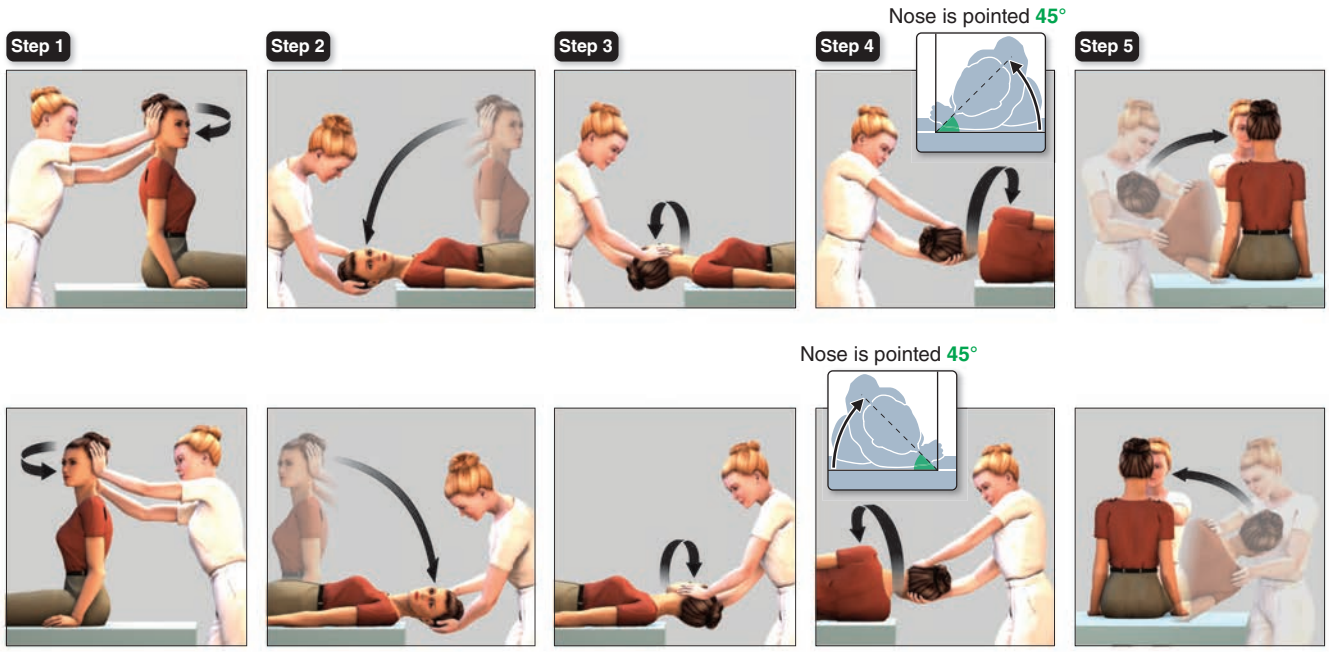

FIGURE 22-1 Modified Epley maneuver for treatment of benign paroxysmal positional vertigo of the right (*top panels*) and left (*bottom panels*) posterior semicircular canals. **Step 1.** With the patient seated, turn the head 45 degrees toward the affected ear. **Step 2.** Keeping the head turned, lower the patient to the head-hanging position and hold for at least 30 s and until nystagmus disappears. **Step 3.** Without lifting the head, turn it 90 degrees toward the other side. Hold for another 30 s. **Step 4.** Rotate the patient onto her side while turning the head another 90 degrees, so that the nose is pointed down 45 degrees. Hold again for 30 s. **Step 5.** Have the patient sit up on the side of the table. After a brief rest, the maneuver should be repeated to confirm successful treatment. *(Reproduced with permission from Chicago dizziness and Hearing (CDH). Figure adapted from http://www.dizziness-and-balance.com/disorders/bppv/movies/Epley-480x640.avi)*

glucocorticoids or gentamicin into the middle ear may be considered. Nonablative surgical options include decompression and shunting of the endolymphatic sac. Full ablative procedures (vestibular nerve section, labyrinthectomy) are seldom required.

VESTIBULAR SCHWANNOMA

Vestibular schwannomas (sometimes termed *acoustic neuromas*) and other tumors at the cerebellopontine angle cause slowly progressive unilateral sensorineural hearing loss and vestibular hypofunction. These patients typically do not have vertigo, because the gradual vestibular deficit is compensated centrally as it develops. The diagnosis often is not made until there is sufficient hearing loss to be noticed. The vestibular examination will show a deficient response to the head impulse test when the head is rotated toward the affected side, but nystagmus will not be prominent. As noted above, patients with unexplained unilateral sensorineural hearing loss or vestibular hypofunction require MRI of the internal auditory canals to look for a schwannoma.

BILATERAL VESTIBULAR HYPOFUNCTION

Patients with bilateral loss of vestibular function also typically do not have vertigo, because vestibular function is lost on both sides simultaneously, and there is no asymmetry of vestibular input. Symptoms include loss of balance, particularly in the dark, where vestibular input is most critical, and oscillopsia during head movement, such as while walking or riding in a car. Bilateral vestibular hypofunction may be (1) idiopathic and progressive, (2) part of a neurodegenerative disorder, or (3) iatrogenic due to medication ototoxicity (most commonly gentamicin or other aminoglycoside antibiotics). Other causes include bilateral vestibular schwannomas (neurofibromatosis type 2), autoimmune disease, superficial siderosis, and meningeal-based infection or tumor. It also may occur in patients with peripheral polyneuropathy; in these patients, both vestibular loss and impaired proprioception may contribute to poor balance. Finally, unilateral processes such as vestibular neuritis and Ménière's disease may involve both ears sequentially, resulting in bilateral vestibulopathy.

Examination findings include diminished *dynamic visual acuity* (see above) due to loss of stable vision when the head is moving, abnormal head impulse responses in both directions, and a Romberg sign. Responses to caloric testing are reduced. Patients with bilateral vestibular hypofunction should be referred for vestibular rehabilitation therapy. Vestibular suppressant medications should not be used, as they will increase the imbalance. Evaluation by a neurologist is important not only to confirm the diagnosis but also to consider any other associated neurologic abnormalities that may clarify the etiology.

CENTRAL VESTIBULAR DISORDERS

Central lesions causing vertigo typically involve vestibular pathways in the brainstem and/or cerebellum. They may be due to discrete lesions, such as from ischemic or hemorrhagic stroke **(Chaps. 426–428)**, demyelination **(Chap. 444)**, or tumors **(Chap. 90)**, or they may be due to neurodegenerative conditions that include the vestibulocerebellum **(Chaps. 431–434)**. Subacute cerebellar degeneration may be due to immune, including paraneoplastic, processes **(Chaps. 94 and 439)**. Table 22-1 outlines important features of the history and examination that help to identify central vestibular disorders. Acute central vertigo is a medical emergency, due to the possibility of life-threatening stroke or hemorrhage. All patients with suspected central vestibular disorders should undergo brain MRI, and the patient should be referred for full neurologic evaluation.

PSYCHOSOMATIC AND FUNCTIONAL DIZZINESS

Psychological factors play an important role in chronic dizziness. First, dizziness may be a somatic manifestation of a psychiatric condition such as major depression, anxiety, or panic disorder **(Chap. 452)**. Second, patients may develop anxiety and autonomic symptoms as a consequence or comorbidity of an independent vestibular disorder. One particular form of this has been termed variously *phobic postural vertigo*, *psychophysiologic vertigo*, or *chronic subjective dizziness*, but is now referred to as *persistent postural-perceptual dizziness (PPPD)*. These patients have a chronic feeling (3 months or longer) of fluctuating dizziness and disequilibrium that is present at rest but worse while standing. There is an increased sensitivity to self-motion and visual motion (e.g., watching movies), and a particular intensification of symptoms when moving through complex visual environments such as supermarkets. Although there may be a past history of an acute vestibular disorder (e.g., vestibular neuritis), the neuro-otologic examination

TABLE 22-2 Treatment of Vertigo

AGENT[a]	DOSE[b]
Antihistamines	
Meclizine	25–50 mg 3 times daily
Dimenhydrinate	50 mg 1–2 times daily
Promethazine	25 mg 2–3 times daily (also can be given rectally and IM)
Benzodiazepines	
Diazepam	2.5 mg 1–3 times daily
Clonazepam	0.25 mg 1–3 times daily
Anticholinergic	
Scopolamine transdermal[c]	Patch
Physical therapy

Vestibular rehabilitation	
Other	
Diuretics and/or low-sodium (1000 mg/d) diet[e]	
Antimigrainous drugs[f]	
Selective serotonin reuptake inhibitors[g]	

[a]All listed drugs are approved by the US Food and Drug Administration, but most are not approved for the treatment of vertigo. [b]Usual oral (unless otherwise stated) starting dose in adults; a higher maintenance dose can be reached by a gradual increase. [c]For motion sickness only. [d]For benign paroxysmal positional vertigo. [e]For Ménière's disease. [f]For vestibular migraine. [g]For persistent postural-perceptual vertigo and anxiety.

and vestibular testing are normal or indicative of a compensated vestibular deficit, indicating that the ongoing subjective dizziness cannot be explained by a primary vestibular pathology. Anxiety disorders are particularly common in patients with chronic dizziness; when present, they contribute substantially to the morbidity. Treatment approaches for PPPD include pharmacological therapy with selective serotonin reuptake inhibitors (SSRIs), cognitive-behavioral psychotherapy, and vestibular rehabilitation. Vestibular suppressant medications generally should be avoided.

TREATMENT

Vertigo

Table 22-2 provides a list of commonly used medications for suppression of vertigo. As noted, these medications should be reserved for short-term control of active vertigo, such as during the first few days of acute vestibular neuritis, or for acute attacks of Ménière's disease. They are less helpful for chronic dizziness and, as previously stated, may hinder central compensation. An exception is that benzodiazepines may attenuate psychosomatic dizziness and the associated anxiety, although SSRIs are generally preferable in such patients.

Vestibular rehabilitation therapy promotes central adaptation processes that compensate for vestibular loss and also may help habituate motion sensitivity and other symptoms of psychosomatic dizziness. The general approach is to use a graded series of exercises that progressively challenge gaze stabilization and balance.

23 Fatigue

Jeffrey M. Gelfand, Vanja C. Douglas

Fatigue is one of the most common symptoms in clinical medicine. It is a prominent manifestation of a number of systemic, neurologic, and psychiatric syndromes, although a precise cause will not be identified in a substantial minority of patients. Fatigue refers to the subjective experience of physical and mental weariness, sluggishness, low energy, and exhaustion. In the context of clinical medicine, fatigue is most practically defined as difficulty initiating or maintaining voluntary mental or physical activity. Nearly everyone who has ever been ill with a self-limited infection has experienced this near-universal symptom, and fatigue is usually brought to medical attention only when it is either of unclear cause, fails to remit, or the severity is out of proportion with what would be expected for the associated trigger.

Fatigue should be distinguished from *muscle weakness*, a reduction of neuromuscular power (Chap. 24); most patients complaining of fatigue are not truly weak when direct muscle power is tested. Fatigue is also distinct from *somnolence*, which refers to sleepiness in the context of disturbed sleep-wake physiology (Chap. 31), and from *dyspnea on exertion*, although patients may use the word fatigue to describe any of these symptoms. The task facing clinicians when a patient presents with fatigue is to identify the underlying cause and develop a therapeutic alliance, the goal of which is to spare patients expensive and fruitless diagnostic workups and steer them toward effective therapy.

EPIDEMIOLOGY AND GLOBAL CONSIDERATIONS

Variability in the definitions of fatigue and the survey instruments used in different studies makes it difficult to arrive at precise figures about the global burden of fatigue. The point prevalence of fatigue was 6.7% and the lifetime prevalence was 25% in a large National Institute of Mental Health survey of the U.S. general population. In primary care clinics in Europe and the United States, between 10 and 25% of patients surveyed endorsed symptoms of prolonged (present for >1 month) or chronic (present for >6 months) fatigue, but in only a minority was fatigue the primary reason for seeking medical attention. In a community survey of women in India, 12% reported chronic fatigue. By contrast, the prevalence of chronic fatigue syndrome (Chap. 450), as defined by the U.S. Centers for Disease Control and Prevention, is low.

DIFFERENTIAL DIAGNOSIS

Psychiatric Disease Fatigue is a common somatic manifestation of many major psychiatric syndromes, including depression, anxiety, and somatoform disorders (Chap. 452). Psychiatric symptoms are reported in more than three-quarters of patients with unexplained chronic fatigue. Even in patients with systemic or neurologic disorders in which fatigue is independently recognized as a symptom, comorbid psychiatric disease may still be an important contributor.

Neurologic Disease Patients complaining of fatigue often say they feel weak, but upon careful examination, objective muscle weakness is rarely discernible. If found, muscle weakness must then be localized to the central nervous system, peripheral nervous system, neuromuscular junction, or muscle, and appropriate follow-up studies obtained (Chap. 24). *Fatigability* of muscle power is a cardinal manifestation of some neuromuscular disorders such as myasthenia gravis and is distinguished from *fatigue* by finding clinically evident diminution of the amount of force that a muscle generates upon repeated contraction (Chap. 448). Fatigue is one of the most common and bothersome symptoms reported in multiple sclerosis (MS) (Chap. 444), affecting nearly 90% of patients; fatigue in MS can persist between MS attacks and does not necessarily correlate with magnetic resonance imaging (MRI) disease activity. Fatigue is also increasingly identified as a troublesome feature of many neurodegenerative diseases, including Parkinson's disease (Chap. 435), amyotrophic lateral sclerosis

(Chap. 437), and central nervous system dysautonomias (Chap. 440). Fatigue after stroke (Chap. 426) is a well-described but poorly understood entity with a widely varying prevalence. Episodic fatigue can be a premonitory symptom of migraine (Chap. 430). Fatigue is also a frequent consequence of traumatic brain injury (Chap. 443), often occurring in association with depression and sleep disorders.

Sleep Disorders Obstructive sleep apnea is an important cause of excessive daytime sleepiness in association with fatigue and should be investigated using overnight polysomnography, particularly in those with prominent snoring, obesity, or other predictors of obstructive sleep apnea (Chap. 297). Whether the cumulative sleep deprivation that is common in modern society contributes to clinically apparent fatigue is not known (Chap. 31).

Endocrine Disorders Fatigue, sometimes in association with true muscle weakness, can be a heralding symptom of hypothyroidism (Chap. 383), particularly in the context of hair loss, dry skin, cold intolerance, constipation, and weight gain. Fatigue associated with heat intolerance, sweating, and palpitations is typical of hyperthyroidism (Chap. 384). Adrenal insufficiency (Chap. 386) can also manifest with unexplained fatigue as a primary or prominent symptom, often with anorexia, weight loss, nausea, myalgias, and arthralgias; hyponatremia, hyperkalemia, and hyperpigmentation may be present at time of diagnosis. Mild hypercalcemia can cause fatigue, which may be relatively vague, whereas severe hypercalcemia can lead to lethargy, stupor, and coma (Chap. 410). Both hypoglycemia and hyperglycemia can cause lethargy, often in association with confusion; diabetes mellitus, and in particular type 1 diabetes, is also associated with fatigue independent of glucose levels (Chap. 403). Fatigue may also accompany Cushing's disease, hypoaldosteronism, and hypogonadism. Low vitamin D status has also been associated with fatigue.

Liver and Kidney Disease Both chronic liver failure and chronic kidney disease can cause fatigue. Over 80% of hemodialysis patients complain of fatigue, which makes it one of the most common symptoms reported by patients in chronic kidney disease (Chap. 311).

Obesity Obesity (Chap. 401) is associated with fatigue and sleepiness independent of the presence of obstructive sleep apnea. Obese patients undergoing bariatric surgery experience improvement in daytime sleepiness sooner than would be expected if the improvement were solely the result of weight loss and resolution of sleep apnea. A number of other factors common in obese patients are likely contributors as well, including physical inactivity, diabetes, and depression.

Physical Inactivity Physical inactivity is associated with fatigue, and increasing physical activity can improve fatigue in some patients.

Malnutrition Although fatigue can be a presenting feature of malnutrition (Chap. 334), nutritional status may also be an important comorbidity and contributor to fatigue in other chronic illnesses, including cancer-associated fatigue.

Infection Both acute and chronic infections commonly lead to fatigue as part of the broader infectious syndrome. Evaluation for undiagnosed infection as the cause of unexplained fatigue, and particularly prolonged or chronic fatigue, should be guided by the history, physical examination, and infectious risk factors, with particular attention to risk for tuberculosis, HIV, chronic hepatitis, and endocarditis. Infectious mononucleosis may cause prolonged fatigue that persists for weeks to months following the acute illness, but infection with the Epstein-Barr virus is only very rarely the cause of unexplained chronic fatigue. Postinfectious fatigue may also occur following a variety of acute infections. For example, a substantial minority of patients who have recovered from SARS-CoV-1, SARS-CoV-2, and Ebola virus complain of persistent fatigue.

Drugs Many medications, drugs, drug withdrawal, and chronic alcohol use can all lead to fatigue. Medications that are more likely to be causative include antidepressants, antipsychotics, anxiolytics, opiates, antispasticity agents, antiseizure agents, and beta blockers.

Cardiovascular and Pulmonary Disorders Fatigue is one of the most taxing symptoms reported by patients with congestive heart failure and chronic obstructive pulmonary disease and negatively affects quality of life. In a population-based cohort study in Norfolk, United Kingdom, fatigue was associated with an increased hazard of all-cause mortality in the general population, but particularly for deaths related to cardiovascular disease.

Malignancy Fatigue, particularly in association with unexplained weight loss, can be a sign of occult malignancy, but cancer is rarely identified in patients with unexplained chronic fatigue in the absence of other telltale signs or symptoms. Cancer-related fatigue is experienced by 40% of patients at the time of diagnosis and by >80% at some time in the disease course.

Hematologic Disorders Chronic or progressive anemia may present with fatigue, sometimes in association with exertional tachycardia and breathlessness. Anemia may also contribute to fatigue in chronic illness. Low serum ferritin in the absence of anemia may also cause fatigue that is reversible with iron replacement.

Immune-Mediated Disorders Fatigue is a prominent complaint in many chronic inflammatory disorders, including systemic lupus erythematosus, polymyalgia rheumatica, rheumatoid arthritis, inflammatory bowel disease, antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, sarcoidosis, and Sjögren's syndrome, but is not usually an isolated symptom. Fatigue is also associated with primary immunodeficiency diseases.

Pregnancy Fatigue is very commonly reported by women during all stages of pregnancy and postpartum.

Disorders of Unclear Cause Myalgic encephalomyelitis (ME)/chronic fatigue syndrome (CFS) (Chap. 450) and fibromyalgia (Chap. 373) incorporate chronic fatigue as part of the syndromic definition when fatigue is present in association with other criteria, as discussed in the respective chapters. Chronic multisymptom illness, also known as Gulf-War syndrome, is another symptom complex with prominent fatigue; it is most commonly, although not exclusively, observed in veterans of the 1991 Gulf War conflict (Chap. S7). Idiopathic chronic fatigue is used to describe the syndrome of unexplained chronic fatigue in the absence of enough additional clinical features to meet the diagnostic criteria for ME/CFS.

APPROACH TO THE PATIENT

Fatigue

A detailed history focusing on the quality, pattern, time course, associated symptoms, and alleviating factors of fatigue is necessary to define the syndrome and help direct further evaluation and treatment. It is important to determine if fatigue is the appropriate designation, whether symptoms are acute or chronic, and if the impairment is primarily mental, physical, or a combination of the two. The review of systems should attempt to distinguish fatigue from excessive sleepiness, dyspnea on exertion, exercise intolerance, and muscle weakness. The presence of fever, chills, night sweats, or weight loss should raise suspicion for an occult infection or malignancy. A careful review of prescription, over-the-counter, herbal, and recreational drug and alcohol use is required. Circumstances surrounding the onset of symptoms and potential triggers should be investigated. The social history is important, with attention paid to life stressors and adverse experiences, workhours, the social support network, and domestic affairs including a screen for intimate partner violence. Sleep habits and sleep hygiene should be questioned. The impact of fatigue on daily functioning is important to understand the patient's experience and gauge recovery and the success of treatment.

The physical examination of patients with fatigue is guided by the history and differential diagnosis. A detailed mental status examination should be performed with particular attention to symptoms of depression and anxiety. A formal neurologic examination is required to determine whether objective muscle weakness is present. This is usually a straightforward exercise, although occasionally patients with fatigue have difficulty sustaining effort against resistance and sometimes report that generating full power requires substantial mental effort. On confrontational testing, full power may be generated for only a brief period before the patient suddenly gives way to the examiner. This type of weakness is often referred to as *breakaway weakness* and may or may not be associated with pain. This is contrasted with weakness due to lesions in the motor tracts or lower motor unit, in which the patient's resistance can be overcome in a smooth and steady fashion and full power can never be generated. Occasionally, a patient may demonstrate fatigable weakness, in which power is full when first tested but becomes weak upon repeat evaluation without interval rest. Fatigable weakness, which usually indicates a problem of neuromuscular transmission, never has the sudden breakaway quality that one occasionally observes in patients with fatigue. If the presence or absence of muscle weakness cannot be determined with the physical examination, electromyography with nerve conductions studies can be a helpful ancillary test.

The general physical examination should screen for signs of cardiopulmonary disease, malignancy, lymphadenopathy, organomegaly, infection, liver failure, kidney disease, malnutrition, endocrine abnormalities, and connective tissue disease. In patients with associated widespread musculoskeletal pain, assessment of tender points may help to reveal fibromyalgia. Although the diagnostic yield of the general physical examination may be relatively low in the context of evaluation of unexplained chronic fatigue, elucidating the cause of only 2% of cases in one prospective analysis, the yield of a detailed neuropsychiatric and mental status evaluation is likely to be much higher, revealing a potential explanation for fatigue in up to 75–80% of patients in some series. Furthermore, a complete physical examination demonstrates a serious and systematic approach to the patient's complaint and helps build trust and a therapeutic alliance.

Laboratory testing is likely to identify the cause of chronic fatigue in only about 5% of cases. Beyond a few standard screening tests, laboratory evaluation should be guided by the history and physical examination; extensive testing is likely to lead to incidental findings that require explanation and unnecessary follow-up investigation, and should be avoided in lieu of frequent clinical follow-up. A reasonable approach to screening includes a complete blood count with differential (to screen for anemia, infection, and malignancy), electrolytes (including sodium, potassium, and calcium), glucose, renal function, liver function, and thyroid function. Testing for HIV and adrenal function can also be considered. Published guidelines for chronic fatigue syndrome also recommend an erythrocyte sedimentation rate (ESR) as part of the evaluation for mimics, but unless the value is very high, such nonspecific testing in the absence of other features is unlikely to clarify the situation. Routine screening with an antinuclear antibody (ANA) test is also unlikely to be informative in isolation and is frequently positive at low titers in otherwise healthy adults. Additional unfocused studies, such as whole-body imaging scans, are usually not indicated; in addition to their inconvenience, potential risk, and cost, they often reveal unrelated incidental findings that can prolong the workup unnecessarily.

TREATMENT

Fatigue

The first priority is to address the underlying disorder or disorders that account for fatigue, because this can be curative in select contexts and palliative in others. Unfortunately, in many chronic illnesses, fatigue may be refractory to traditional disease-modifying therapies, but it is nevertheless important in such cases to evaluate for other potential contributors because the cause may be multifactorial. Antidepressants **(Chap. 452)** may be helpful for treatment of chronic fatigue when symptoms of depression are present and are generally most effective as part of a multimodal approach. However, antidepressants can also cause fatigue and should be discontinued if they are not clearly effective. Cognitive-behavioral therapy has also been demonstrated to be helpful in ME/CFS as well as cancer-associated fatigue. Both cognitive-behavioral therapy and graded exercise therapy, in which physical exercise, most typically walking, is gradually increased with attention to target heart rates to avoid overexertion, were shown to modestly improve walking times and self-reported fatigue measures when compared to standard medical care in patients in the United Kingdom with chronic fatigue. These benefits were maintained after a median follow-up of 2.5 years. Psychostimulants such as amphetamines, modafinil, and armodafinil can help increase alertness and concentration and reduce excessive daytime sleepiness in certain clinical contexts, which may in turn help with symptoms of fatigue in a minority of patients, but they have generally proven to be unhelpful in randomized trials for treating fatigue in posttraumatic brain injury, Parkinson's disease, cancer, and MS. In patients with low vitamin D status, vitamin D replacement may lead to improvement in fatigue.

Development of more effective therapy for fatigue is hampered by limited knowledge of the biologic basis of this symptom, including how fatigue is detected and registered in the nervous system. Proinflammatory cytokines, such as interleukin 1α and 1β and tumor necrosis factor α, might mediate fatigue in some patients. While preliminary studies of biologic therapies that inhibit cytokines have suggested a benefit against fatigue in some patients with inflammatory conditions, this approach has largely not led to improvement in clinical trials that focused on fatigue as the primary endpoint. Nonetheless, specific targeting with cytokine antagonists could represent a possible future approach for some patients.

PROGNOSIS

Acute fatigue significant enough to require medical evaluation is more likely to lead to an identifiable medical, neurologic, or psychiatric cause than is unexplained chronic fatigue. Evaluation of unexplained chronic fatigue most commonly leads to diagnosis of a psychiatric condition or remains unexplained. Identification of a previously undiagnosed serious or life-threatening culprit etiology is rare, even with longitudinal follow-up of patients with unexplained chronic fatigue. Complete resolution is uncommon, at least over the short term, but multidisciplinary treatment approaches can lead to symptomatic improvements that substantially improve quality of life.

24 Neurologic Causes of Weakness and Paralysis

Stephen L. Hauser

Normal motor function involves integrated muscle activity that is modulated by the activity of the cerebral cortex, basal ganglia, cerebellum, red nucleus, brainstem reticular formation, lateral vestibular nucleus, and spinal cord. Motor system dysfunction leads to weakness or paralysis, discussed in this chapter, or to ataxia **(Chap. 439)** or abnormal movements **(Chap. 436)**. *Weakness* is a reduction in the power that can be exerted by one or more muscles. It must be distinguished from increased *fatigability* (i.e., the inability to sustain the performance of an activity that should be normal for a person of the same age, sex, and size), limitation in function due to pain or articular stiffness, or impaired motor activity because severe *proprioceptive sensory loss* prevents adequate feedback information about the direction and power of movements. It is also distinct from *bradykinesia* (in which increased time is required for full power to be exerted) and *apraxia,* a disorder of planning and initiating a skilled or learned movement unrelated to a significant motor or sensory deficit **(Chap. 30)**.

Paralysis or the suffix "-plegia" indicates weakness so severe that a muscle cannot be contracted at all, whereas *paresis* refers to less severe weakness. The prefix "hemi-" refers to one-half of the body, "para-" to both legs, and "quadri-" to all four limbs.

The *distribution* of weakness helps to localize the underlying lesion. Weakness from involvement of upper motor neurons occurs particularly in the extensors and abductors of the upper limb and the flexors of the lower limb. Lower motor neuron weakness depends on whether involvement is at the level of the anterior horn cells, nerve root, limb plexus, or peripheral nerve—only muscles supplied by the affected structure are weak. Myopathic weakness is generally most marked in proximal muscles. Weakness from impaired neuromuscular transmission has no specific pattern of involvement.

Weakness often is accompanied by other neurologic abnormalities that help indicate the site of the responsible lesion **(Table 24-1)**.

Tone is the resistance of a muscle to passive stretch. Increased tone may be of several types. *Spasticity* is the increase in tone associated with disease of upper motor neurons. It is velocity dependent, has a sudden release after reaching a maximum (the "clasp-knife" phenomenon), and predominantly affects the antigravity muscles (i.e., upper-limb flexors and lower-limb extensors). *Rigidity* is hypertonia that is present throughout the range of motion (a "lead pipe" or "plastic" stiffness) and affects flexors and extensors equally; it sometimes has a cogwheel quality that is enhanced by voluntary movement of the contralateral limb (reinforcement). Rigidity occurs with certain extrapyramidal disorders, such as Parkinson's disease. *Paratonia* (or *gegenhalten*) is increased tone that varies irregularly in a manner seemingly related to the degree of relaxation, is present throughout the range of motion, and affects flexors and extensors equally; it usually results from disease of the frontal lobes. Weakness with *decreased tone (flaccidity)* or normal tone occurs with disorders of *motor units.* A motor unit consists of a single lower motor neuron and all the muscle fibers that it innervates.

Muscle bulk generally is not affected by upper motor neuron lesions, although mild disuse atrophy eventually may occur. By contrast, atrophy is often conspicuous when a lower motor neuron lesion is responsible for weakness and also may occur with advanced muscle disease.

Muscle stretch (tendon) reflexes are usually increased with upper motor neuron lesions but may be decreased or absent for a variable period immediately after onset of an acute lesion. Hyperreflexia is usually—but not invariably—accompanied by loss of *cutaneous reflexes* (such as superficial abdominals; **Chap. 422**) and, in particular, by an extensor plantar (Babinski) response. The muscle stretch reflexes are depressed with lower motor neuron lesions directly involving specific reflex arcs. They generally are preserved in patients with myopathic weakness except in advanced stages, when they sometimes are attenuated. In disorders of the neuromuscular junction, reflex responses may be affected by preceding voluntary activity of affected muscles; such activity may lead to enhancement of initially depressed reflexes in Lambert-Eaton myasthenic syndrome and, conversely, to depression of initially normal reflexes in myasthenia gravis **(Chap. 448)**.

The distinction of *neuropathic* (lower motor neuron) from *myopathic* weakness is sometimes difficult clinically, although distal weakness is likely to be neuropathic, and symmetric proximal weakness myopathic. *Fasciculations* (visible or palpable twitches within a muscle due to the spontaneous discharge of a motor unit) and early atrophy indicate that weakness is neuropathic.

PATHOGENESIS

Upper Motor Neuron Weakness Lesions of the upper motor neurons or their descending axons to the spinal cord **(Fig. 24-1)** produce weakness through decreased activation of lower motor neurons. In general, distal muscle groups are affected more severely than proximal ones, and axial movements are spared unless the lesion is severe and bilateral. Spasticity is typical but may not be present acutely. Rapid repetitive movements are slowed and coarse, but normal rhythmicity is maintained. With corticobulbar involvement, weakness occurs in the lower face and tongue; extraocular, upper facial, pharyngeal, and jaw muscles are typically spared. Bilateral corticobulbar lesions produce a *pseudobulbar palsy*: dysarthria, dysphagia, dysphonia, and emotional lability accompany bilateral facial weakness and a brisk jaw jerk. Electromyogram (EMG) **(Chap. 446)** shows that with weakness of the upper motor neuron type, motor units have a diminished maximal discharge frequency.

Lower Motor Neuron Weakness This pattern results from disorders of lower motor neurons in the brainstem motor nuclei and the anterior horn of the spinal cord or from dysfunction of the axons of these neurons as they pass to skeletal muscle **(Fig. 24-2)**. Weakness is due to a decrease in the number of muscle fibers that can be activated through a loss of α motor neurons or disruption of their connections to muscle. Loss of γ motor neurons does not cause weakness but decreases tension on the muscle spindles, which decreases muscle tone and attenuates the stretch reflexes. An absent stretch reflex suggests involvement of spindle afferent fibers.

When a motor unit becomes diseased, especially in anterior horn cell diseases, it may discharge spontaneously, producing *fasciculations.* When α motor neurons or their axons degenerate, the denervated muscle fibers also may discharge spontaneously. These single muscle

TABLE 24-1 Signs That Distinguish the Origin of Weakness

SIGN	UPPER MOTOR NEURON	LOWER MOTOR NEURON	MYOPATHIC	PSYCHOGENIC
Atrophy	None	Severe	Mild	None
Fasciculations	None	Common	None	None
Tone	Spastic	Decreased	Normal/decreased	Variable/paratonia
Distribution of weakness	Pyramidal/regional	Distal/segmental	Proximal	Variable/inconsistent with daily activities
Muscle stretch reflexes	Hyperactive	Hypoactive/absent	Normal/hypoactive	Normal
Babinski sign	Present	Absent	Absent	Absent

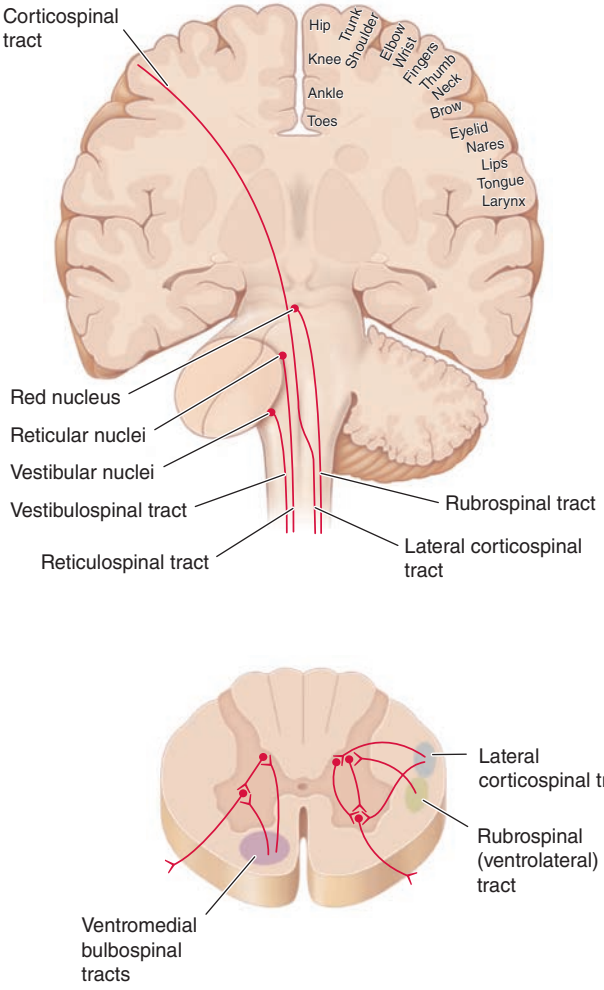

FIGURE 24-1 The corticospinal and bulbospinal upper motor neuron pathways. Upper motor neurons have their cell bodies in layer V of the primary motor cortex (the precentral gyrus, or Brodmann area 4) and in the premotor and supplemental motor cortex (area 6). The upper motor neurons in the primary motor cortex are somatotopically organized (*right side of figure*). Axons of the upper motor neurons descend through the subcortical white matter and the posterior limb of the internal capsule. Axons of the pyramidal or corticospinal system descend through the brainstem in the cerebral peduncle of the midbrain, the basis pontis, and the medullary pyramids. At the cervicomedullary junction, most corticospinal axons decussate into the contralateral corticospinal tract of the lateral spinal cord, but 10–30% remain ipsilateral in the anterior spinal cord. Corticospinal neurons synapse on premotor interneurons, but some—especially in the cervical enlargement and those connecting with motor neurons to distal limb muscles—make direct monosynaptic connections with lower motor neurons. They innervate most densely the lower motor neurons of hand muscles and are involved in the execution of learned, fine movements. Corticobulbar neurons are similar to corticospinal neurons but innervate brainstem motor nuclei. Bulbospinal upper motor neurons influence strength and tone but are not part of the pyramidal system. The descending ventromedial bulbospinal pathways originate in the tectum of the midbrain (tectospinal pathway), the vestibular nuclei (vestibulospinal pathway), and the reticular formation (reticulospinal pathway). These pathways influence axial and proximal muscles and are involved in the maintenance of posture and integrated movements of the limbs and trunk. The descending ventrolateral bulbospinal pathways, which originate predominantly in the red nucleus (rubrospinal pathway), facilitate distal limb muscles. The bulbospinal system sometimes is referred to as the extrapyramidal upper motor neuron system. In all figures, nerve cell bodies and axon terminals are shown, respectively, as *closed circles* and *forks*.

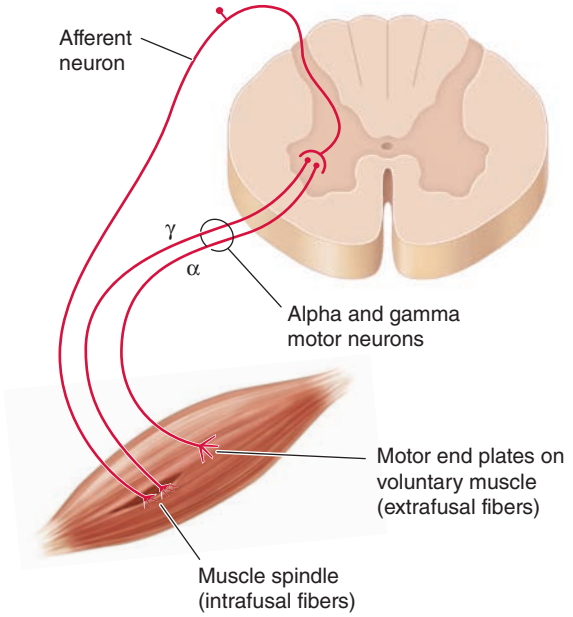

FIGURE 24-2 Lower motor neurons are divided into α and γ types. The larger α motor neurons are more numerous and innervate the extrafusal muscle fibers of the motor unit. Loss of α motor neurons or disruption of their axons produces lower motor neuron weakness. The smaller, less numerous γ motor neurons innervate the intrafusal muscle fibers of the muscle spindle and contribute to normal tone and stretch reflexes. The α motor neuron receives direct excitatory input from corticomotoneurons and primary muscle spindle afferents. The α and γ motor neurons also receive excitatory input from other descending upper motor neuron pathways, segmental sensory inputs, and interneurons. The α motor neurons receive direct inhibition from Renshaw cell interneurons, and other interneurons indirectly inhibit the α and γ motor neurons. A muscle stretch (tendon) reflex requires the function of all the illustrated structures. A tap on a tendon stretches muscle spindles (which are tonically activated by γ motor neurons) and activates the primary spindle afferent neurons. These neurons stimulate the α motor neurons in the spinal cord, producing a brief muscle contraction, which is the familiar tendon reflex.

fiber discharges, or *fibrillation potentials,* cannot be seen but can be recorded with EMG. Weakness leads to delayed or reduced recruitment of motor units, with fewer than normal activated at a particular discharge frequency.

Neuromuscular Junction Weakness Disorders of the neuromuscular junction produce weakness of variable degree and distribution. The number of muscle fibers that are activated varies over time, depending on the state of rest of the neuromuscular junctions. Strength is influenced by preceding activity of the affected muscle. In myasthenia gravis, for example, sustained or repeated contractions of affected muscle decline in strength despite continuing effort (**Chap. 440**). Thus, fatigable weakness is suggestive of disorders of the neuromuscular junction, which cause functional loss of muscle fibers due to failure of their activation.

Myopathic Weakness Myopathic weakness is produced by a decrease in the number or contractile force of muscle fibers activated within motor units. With muscular dystrophies, inflammatory myopathies, or myopathies with muscle fiber necrosis, the number of muscle fibers is reduced within many motor units. On EMG, the size of each motor unit action potential is decreased, and motor units must be recruited more rapidly than normal to produce the desired power. Some myopathies produce weakness through loss of contractile force of muscle fibers or through relatively selective involvement of type II (fast) fibers. These myopathies may not affect the size of individual motor unit action potentials and are detected by a discrepancy between the electrical activity and force of a muscle.

Psychogenic Weakness Weakness may occur without a recognizable organic basis. It tends to be variable, inconsistent, and with a pattern of distribution that cannot be explained on a neuroanatomic basis. On formal testing, antagonists may contract when the patient is supposedly activating the agonist muscle. The severity of weakness is out of keeping with the patient's daily activities.

DISTRIBUTION OF WEAKNESS

Hemiparesis Hemiparesis results from an upper motor neuron lesion above the midcervical spinal cord; most such lesions are above the foramen magnum. The presence of other neurologic deficits helps localize the lesion. Thus language disorders, for example, point to a

cortical lesion. Homonymous visual field defects reflect either a cortical or a subcortical hemispheric lesion. A "pure motor" hemiparesis of the face, arm, and leg often is due to a small, discrete lesion in the posterior limb of the internal capsule, cerebral peduncle in the midbrain, or upper pons. Some brainstem lesions produce "crossed paralyses," consisting of ipsilateral cranial nerve signs and contralateral hemiparesis (Chap. 426). The absence of cranial nerve signs or facial weakness suggests that a hemiparesis is due to a lesion in the high cervical spinal cord, especially if associated with Brown-Séquard syndrome, consisting of loss of joint position and vibration sense on the side of the weakness, and loss of pain and temperature sense on the opposite side (Chap. 442).

Acute or episodic hemiparesis usually results from focal structural lesions, particularly vascular etiologies, rapidly expanding lesions, or an inflammatory process. *Subacute hemiparesis* that evolves over days or weeks may relate to subdural hematoma, infectious or inflammatory disorders (e.g., cerebral abscess, fungal granuloma or meningitis, parasitic infection, multiple sclerosis, sarcoidosis), or primary or metastatic neoplasms. AIDS may present with subacute hemiparesis due to toxoplasmosis or primary central nervous system (CNS) lymphoma. *Chronic hemiparesis* that evolves over months usually is due to a neoplasm or vascular malformation, a chronic subdural hematoma, or a degenerative disease.

Investigation of hemiparesis (Fig. 24-3) of acute origin usually starts with a CT scan of the brain and laboratory studies. If the CT is normal, or in subacute or chronic cases of hemiparesis, MRI of the brain and/or cervical spine (including the foramen magnum) is performed, depending on the clinical accompaniments.

Paraparesis *Acute paraparesis* is caused most commonly by an intraspinal lesion, but its spinal origin may not be recognized initially if the legs are flaccid and areflexic. Usually, however, there is sensory loss in the legs with an upper level on the trunk; a dissociated sensory loss (loss of pain and temperature but not touch, position, and vibration sense) suggestive of a central cord syndrome; or hyperreflexia in the legs with normal reflexes in the arms (Chap. 442). Imaging the spinal cord (Fig. 24-3) may reveal compressive lesions, infarction (proprioception usually is spared), arteriovenous fistulas or other vascular anomalies, or transverse myelitis (Chap. 442).

Diseases of the cerebral hemispheres that produce acute paraparesis include anterior cerebral artery ischemia (shoulder shrug also is affected), superior sagittal sinus or cortical venous thrombosis, and acute hydrocephalus.

Paraparesis may also result from a cauda equina syndrome, for example, after trauma to the low back, a midline disk herniation, or an intraspinal tumor. The sphincters are commonly affected, whereas hip flexion often is spared, as is sensation over the anterolateral thighs. Rarely, paraparesis is caused by a rapidly evolving anterior horn cell disease (such as poliovirus or West Nile virus infection), peripheral neuropathy (such as Guillain-Barré syndrome; Chap. 447), or myopathy (Chap. 449).

Subacute or chronic spastic paraparesis is caused by upper motor neuron disease. When associated with lower-limb sensory loss and sphincter involvement, a chronic spinal cord disorder should be considered (Chap. 442). If hemispheric signs are present, a parasagittal meningioma or chronic hydrocephalus is likely. The absence of spasticity in a long-standing paraparesis suggests a lower motor neuron or myopathic etiology.

Investigations typically begin with spinal MRI, but when upper motor neuron signs are associated with drowsiness, confusion, seizures, or other hemispheric signs, brain MRI should also be performed, sometimes as the initial investigation. Electrophysiologic studies are diagnostically helpful when clinical findings suggest an underlying neuromuscular disorder.

Quadriparesis or Generalized Weakness Generalized weakness may be due to disorders of the CNS or the motor unit. Although the terms often are used interchangeably, *quadriparesis* is commonly used when an upper motor neuron cause is suspected, and *generalized weakness* is used when a disease of the motor units is likely. Weakness from CNS disorders usually is associated with changes in consciousness or cognition and accompanied by spasticity, hyperreflexia, and sensory disturbances. Most neuromuscular causes of generalized weakness are associated with normal mental function, hypotonia, and hypoactive muscle stretch reflexes. The major causes of intermittent weakness are listed in Table 24-2. A patient with generalized fatigability without objective weakness may have chronic fatigue syndrome (Chap. 450).

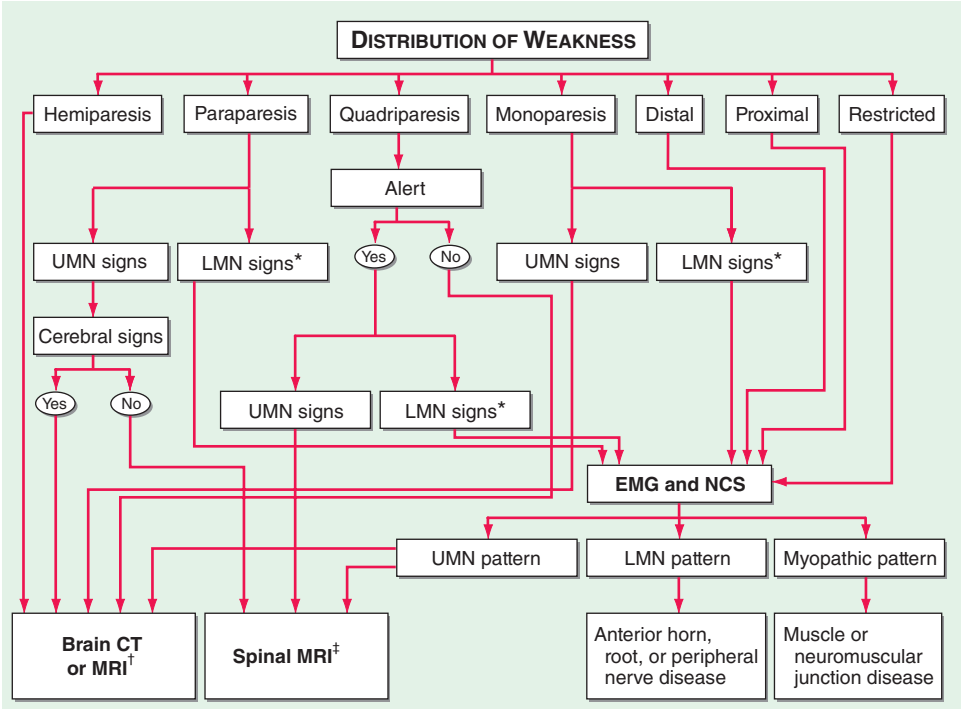

FIGURE 24-3 An algorithm for the initial workup of a patient with weakness. CT, computed tomography; EMG, electromyography; LMN, lower motor neuron; MRI, magnetic resonance imaging; NCS, nerve conduction studies; UMN, upper motor neuron.

ACUTE QUADRIPARESIS Quadriparesis with onset over minutes may result from disorders of upper motor neurons (such as from anoxia, hypotension, brainstem or cervical cord ischemia, trauma, and systemic metabolic abnormalities) or muscle (electrolyte disturbances, certain inborn errors of muscle energy metabolism, toxins, and periodic paralyses). Onset over hours to weeks may, in addition to these disorders, be due to lower motor neuron disorders such as Guillain-Barré syndrome (Chap. 447).

In obtunded patients, evaluation begins with a CT or MRI scan of the brain. If upper motor neuron signs are present but the patient is alert, the initial test is usually an MRI of the cervical cord. If weakness is lower motor neuron, myopathic, or uncertain in origin, the clinical approach begins with blood studies to determine the level of muscle enzymes and electrolytes and with EMG and nerve conduction studies.

TABLE 24-2 Causes of Episodic Generalized Weakness

1. Electrolyte disturbances, e.g., hypokalemia, hyperkalemia, hypercalcemia, hypernatremia, hyponatremia, hypophosphatemia, hypermagnesemia
2. Muscle disorders
   a. Channelopathies (periodic paralyses)
   b. Metabolic defects of muscle (impaired carbohydrate or fatty acid utilization; abnormal mitochondrial function)
3. Neuromuscular junction disorders
   a. Myasthenia gravis
   b. Lambert-Eaton myasthenic syndrome
4. Central nervous system disorders
   a. Transient ischemic attacks of the brainstem
   b. Transient global cerebral ischemia
   c. Multiple sclerosis
5. Lack of voluntary effort
   a. Anxiety
   b. Pain or discomfort
   c. Somatization disorder

SUBACUTE OR CHRONIC QUADRIPARESIS Quadriparesis due to upper motor neuron disease may develop over weeks to years from chronic myelopathies, multiple sclerosis, brain or spinal tumors, chronic subdural hematomas, and various metabolic, toxic, and infectious disorders. It may also result from lower motor neuron disease, a chronic neuropathy (in which weakness is often most profound distally), or myopathic weakness (typically proximal).

When quadriparesis develops acutely in obtunded patients, evaluation begins with a CT scan of the brain. If upper motor neuron signs have developed acutely but the patient is alert, the initial test is usually an MRI of the cervical cord. When onset has been gradual, disorders of the cerebral hemispheres, brainstem, and cervical spinal cord can usually be distinguished clinically, and imaging is directed first at the clinically suspected site of pathology. If weakness is lower motor neuron, myopathic, or uncertain in origin, laboratory studies can determine the levels of muscle enzymes and electrolytes, and EMG and nerve conduction studies help to localize the pathologic process **(Chap. 449)**.

Monoparesis Monoparesis usually is due to lower motor neuron disease, with or without associated sensory involvement. Upper motor neuron weakness occasionally presents as a monoparesis of distal and nonantigravity muscles. Myopathic weakness rarely is limited to one limb.

ACUTE MONOPARESIS If weakness is predominantly distal and of upper motor neuron type and is not associated with sensory impairment or pain, focal cortical ischemia is likely **(Chap. 427)**; diagnostic possibilities are similar to those for acute hemiparesis. Sensory loss and pain usually accompany acute lower motor neuron weakness; the weakness commonly localizes to a single nerve root or peripheral nerve, but occasionally reflects plexus involvement. If lower motor neuron weakness is likely, evaluation begins with EMG and nerve conduction studies.

SUBACUTE OR CHRONIC MONOPARESIS Weakness and atrophy that develop over weeks or months are usually of lower motor neuron origin. When associated with sensory symptoms, a peripheral cause (nerve, root, or plexus) is likely; otherwise, anterior horn cell disease should be considered. In either case, an electrodiagnostic study is indicated. If weakness is of the upper motor neuron type, a discrete cortical (precentral gyrus) or cord lesion may be responsible, and appropriate imaging is performed.

Distal Weakness Involvement of two or more limbs distally suggests lower motor neuron or peripheral nerve disease. Acute distal lower-limb weakness results occasionally from an acute toxic polyneuropathy or cauda equina syndrome. Distal symmetric weakness usually develops over weeks, months, or years and, when associated with numbness, is due to peripheral neuropathy **(Chap. 446)**. Anterior horn cell disease may begin distally but is typically asymmetric and without accompanying numbness **(Chap. 437)**. Rarely, myopathies present with distal weakness **(Chap. 449)**. Electrodiagnostic studies help localize the disorder (Fig. 24-3).

Proximal Weakness Myopathy often produces symmetric weakness of the pelvic or shoulder girdle muscles **(Chap. 449)**. Diseases of the neuromuscular junction, such as myasthenia gravis **(Chap. 448)**, may present with symmetric proximal weakness often associated with ptosis, diplopia, or bulbar weakness and fluctuate in severity during the day. In anterior horn cell disease, proximal weakness is usually asymmetric, but it may be symmetric especially in genetic forms. Numbness does not occur with any of these diseases. The evaluation usually begins with determination of the serum creatine kinase level and electrophysiologic studies.

Weakness in a Restricted Distribution Weakness may not fit any of these patterns, being limited, for example, to the extraocular, hemifacial, bulbar, or respiratory muscles. If it is unilateral, restricted weakness usually is due to lower motor neuron or peripheral nerve disease, such as in a facial palsy. Weakness of part of a limb is commonly due to a peripheral nerve lesion such as an entrapment neuropathy. Relatively symmetric weakness of extraocular or bulbar muscles frequently is due to a myopathy **(Chap. 449)** or neuromuscular junction disorder **(Chap. 448)**. Bilateral facial palsy with areflexia suggests Guillain-Barré syndrome **(Chap. 447)**. Worsening of relatively symmetric weakness with fatigue is characteristic of neuromuscular junction disorders. Asymmetric bulbar weakness usually is due to motor neuron disease. Weakness limited to respiratory muscles is uncommon and usually is due to motor neuron disease, myasthenia gravis, or polymyositis/dermatomyositis **(Chap. 365)**.

25 Numbness, Tingling, and Sensory Loss

Stephen L. Hauser

Normal somatic sensation reflects a continuous monitoring process, little of which reaches consciousness under ordinary conditions. By contrast, disordered sensation, particularly when experienced as painful, is alarming and dominates the patient's attention. Physicians should be able to recognize abnormal sensations by how they are described, know their type and likely site of origin, and understand their implications. **Pain is considered separately in Chap. 13.**

POSITIVE AND NEGATIVE SYMPTOMS

Abnormal sensory symptoms can be divided into two categories: positive and negative. The prototypical positive symptom is tingling (pins and needles); other positive sensory phenomena include itch and altered sensations that are described as pricking, bandlike, lightning-like shooting feelings (lancinations), aching, knifelike, twisting, drawing,

pulling, tightening, burning, searing, electrical, or raw feelings. Such symptoms are often painful.

Positive phenomena usually result from trains of impulses generated at sites of lowered threshold or heightened excitability along a peripheral or central sensory pathway. The nature and severity of the abnormal sensation depend on the number, rate, timing, and distribution of ectopic impulses and the type and function of nervous tissue in which they arise. Because positive phenomena represent excessive activity in sensory pathways, they are not necessarily associated with a sensory deficit (loss) on examination.

Negative phenomena represent loss of sensory function and are characterized by diminished or absent feeling that often is experienced as numbness and by abnormal findings on sensory examination. In disorders affecting peripheral sensation, at least one-half of the afferent axons innervating a particular site are probably lost or functionless before a sensory deficit can be demonstrated by clinical examination. If the rate of loss is slow, however, lack of cutaneous feeling may be unnoticed by the patient and difficult to demonstrate on examination, even though few sensory fibers are functioning; if it is rapid, both positive and negative phenomena are usually conspicuous. Subclinical degrees of sensory dysfunction may be revealed by sensory nerve conduction studies or somatosensory-evoked potentials.

Whereas sensory symptoms may be either positive or negative, sensory signs on examination are always a measure of negative phenomena.

TERMINOLOGY

Paresthesias and dysesthesias are general terms used to denote positive sensory symptoms. The term *paresthesias* typically refers to tingling or pins-and-needles sensations but may include a wide variety of other abnormal sensations, except pain; it sometimes implies that the abnormal sensations are perceived spontaneously. The more general term *dysesthesias* denotes all types of abnormal sensations, including painful ones, regardless of whether a stimulus is evident.

Another set of terms refers to sensory abnormalities found on examination. *Hypesthesia* or *hypoesthesia* refers to a reduction of cutaneous sensation to a specific type of testing such as pressure, light touch, and warm or cold stimuli; *anesthesia,* to a complete absence of skin sensation to the same stimuli plus pinprick; and *hypalgesia* or *analgesia*, to reduced or absent pain perception (nociception). *Hyperesthesia* means pain or increased sensitivity in response to touch. Similarly, *allodynia* describes the situation in which a nonpainful stimulus, once perceived, is experienced as painful, even excruciating. An example is elicitation of a painful sensation by application of a vibrating tuning fork. *Hyperalgesia* denotes severe pain in response to a mildly noxious stimulus, and *hyperpathia*, a broad term, encompasses all the phenomena described by hyperesthesia, allodynia, and hyperalgesia. With hyperpathia, the threshold for a sensory stimulus is increased and perception is delayed, but once felt, it is unduly painful.

Disorders of deep sensation arising from muscle spindles, tendons, and joints affect proprioception (position sense). Manifestations include imbalance (particularly with eyes closed or in the dark), clumsiness of precision movements, and unsteadiness of gait, which are referred to collectively as *sensory ataxia*. Other findings on examination usually, but not invariably, include reduced or absent joint position and vibratory sensibility and absent deep tendon reflexes in the affected limbs. The Romberg sign is positive, which means that the patient sways markedly or topples when asked to stand with feet close together and eyes closed. In severe states of deafferentation involving deep sensation, the patient cannot walk or stand unaided or even sit unsupported. Continuous involuntary movements (*pseudoathetosis*) of the outstretched hands and fingers occur, particularly with eyes closed.

ANATOMY OF SENSATION

Cutaneous receptors are classified by the type of stimulus that optimally excites them. They consist of naked nerve endings (nociceptors, which respond to tissue-damaging stimuli, and thermoreceptors, which respond to noninjurious thermal stimuli) and encapsulated terminals (several types of mechanoreceptor, activated by physical deformation of the skin or stretch of muscles). Each type of receptor has its own set of sensitivities to specific stimuli, size and distinctness of receptive fields, and adaptational qualities.

Afferent peripheral nerve fibers conveying somatosensory information from the limbs and trunk traverse the dorsal roots and enter the dorsal horn of the spinal cord **(Fig. 25-1)**; the cell bodies of first-order neurons are located in the dorsal root ganglia (DRG). In an analogous fashion, sensations from the face and head are conveyed through the trigeminal system **(Fig. 441-2)**. Once fiber tracts enter the spinal cord, the polysynaptic projections of the smaller fibers (unmyelinated and small myelinated), which subserve mainly nociception, itch, temperature sensibility, and touch, cross and ascend in the opposite anterior and lateral columns of the spinal cord, through the brainstem, to the ventral posterolateral (VPL) nucleus of the thalamus and ultimately project to the postcentral gyrus of the parietal cortex and other cortical areas **(Chap. 13)**. This is the *spinothalamic pathway* or *anterolateral system*. The larger fibers, which subserve tactile and position sense and kinesthesia, project rostrally in the posterior and posterolateral columns on the same side of the spinal cord and make their first synapse in the gracile or cuneate nucleus of the lower medulla. Axons of second-order neurons decussate and ascend in the medial lemniscus located medially in the medulla and in the tegmentum of the pons and midbrain and synapse in the VPL nucleus; third-order neurons project to parietal cortex as well as to other cortical areas. This large-fiber system is referred to as the *posterior column–medial lemniscal pathway* (lemniscal, for short). Although the fiber types and functions that make up the spinothalamic and lemniscal systems are relatively well known, many other fibers, particularly those associated with touch, pressure, and position sense, ascend in a diffusely distributed pattern both ipsilaterally and contralaterally in the anterolateral quadrants of the spinal cord. This explains why a complete lesion of the posterior columns of the spinal cord may be associated with little sensory deficit on examination.

APPROACH TO THE PATIENT

Clinical Examination of Sensation

The main components of the sensory examination are tests of primary sensation (pain, touch, vibration, joint position, and thermal sensation) **(Table 25-1)**. The examiner must depend on patient responses, and this complicates interpretation. Further, examination may be limited in some patients. In a stuporous patient, for example, sensory examination is reduced to observing the briskness of withdrawal in response to a pinch or another noxious stimulus. Comparison of responses on the two sides of the body is essential. In an alert but uncooperative patient, it may not be possible to examine cutaneous sensation, but some idea of proprioceptive function may be gained by noting the patient's best performance of movements requiring balance and precision.

In patients with sensory complaints, testing should begin in the center of the affected region and proceed radially until sensation is perceived as normal. The distribution of any abnormality is defined and compared to root and peripheral nerve territories **(Figs. 25-2 and 25-3)**. Some patients present with sensory symptoms that do not fit an anatomic localization and are accompanied by either no abnormalities or gross inconsistencies on examination. The examiner should consider in such cases the possibility of a psychologic cause (see "Psychogenic Symptoms," below). Sensory examination of a patient who has no neurologic complaints can be brief and consist of pinprick, touch, and vibration testing in the hands and feet plus evaluation of stance and gait, including the Romberg maneuver **(Chap. V6)**. Evaluation of stance and gait also tests the integrity of motor and cerebellar systems.

PRIMARY SENSATION

The sense of pain usually is tested with a clean pin, which is then discarded. The patient is asked to close the eyes and focus on the pricking or unpleasant quality of the stimulus, not just the pressure

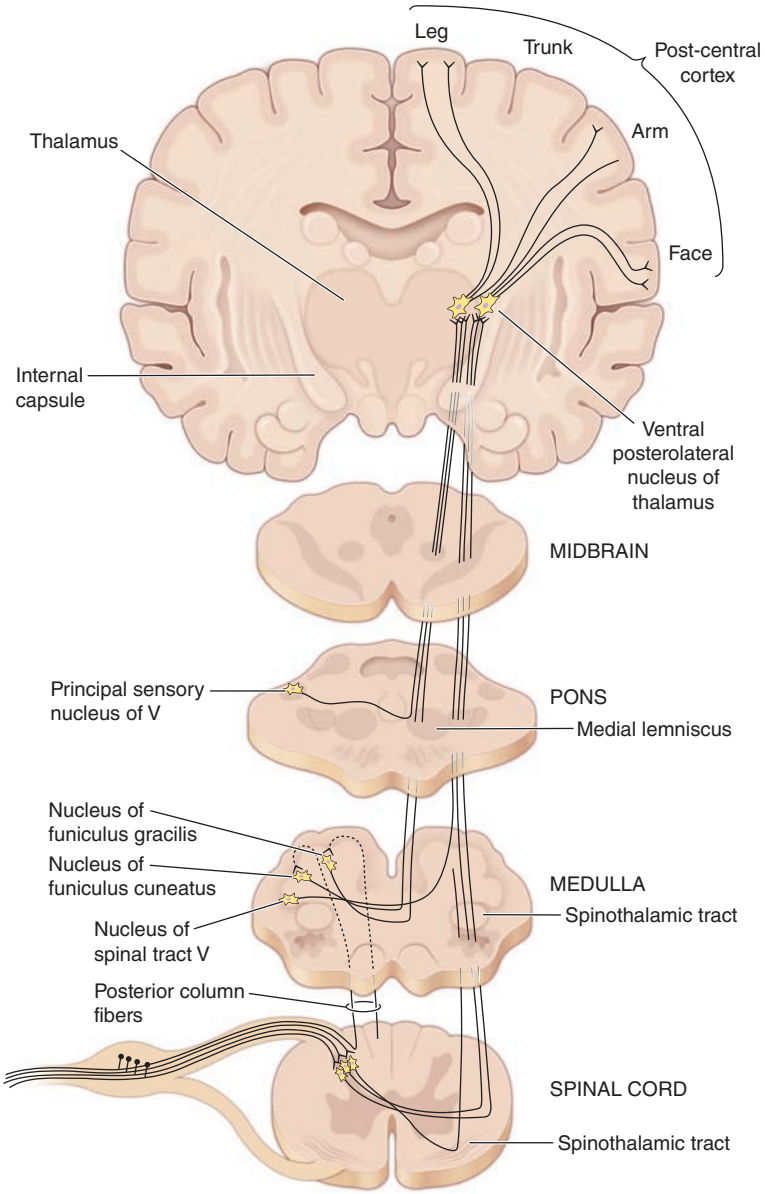

FIGURE 25-1 The main somatosensory pathways. The spinothalamic tract (pain, thermal sense) and the posterior column–lemniscal system (touch, pressure, joint position) are shown. Offshoots from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated. *(Reproduced with permission from AH Ropper, MA Samuels: Adams and Victor's Principles of Neurology, 9th ed. New York, McGraw-Hill, 2009.)*

or touch sensation elicited. Areas of hypalgesia should be mapped by proceeding radially from the most hypalgesic site. Temperature sensation to both hot and cold is best tested with small containers filled with water of the desired temperature. An alternative way to test cold sensation is to touch a metal object, such as a tuning fork at room temperature, to the skin. For testing warm temperatures, the tuning fork or another metal object may be held under warm water of the desired temperature and then used. The appreciation of both cold and warmth should be tested because different receptors respond to each. Touch usually is tested with a wisp of cotton,

TABLE 25-1 Testing Primary Sensation

SENSE	TEST DEVICE	ENDINGS ACTIVATED	FIBER SIZE MEDIATING	CENTRAL PATHWAY
Pain	Pinprick	Cutaneous nociceptors	Small	SpTh, also D
Temperature, heat	Warm metal object	Cutaneous thermoreceptors for hot	Small	SpTh
Temperature, cold	Cold metal object	Cutaneous thermoreceptors for cold	Small	SpTh
Touch	Cotton wisp, fine brush	Cutaneous mechanoreceptors, also naked endings	Large and small	Lem, also D and SpTh
Vibration	Tuning fork, 128 Hz	Mechanoreceptors, especially pacinian corpuscles	Large	Lem, also D
Joint position	Passive movement of specific joints	Joint capsule and tendon endings, muscle spindles	Large	Lem, also D

Abbreviations: D, diffuse ascending projections in ipsilateral and contralateral anterolateral columns; Lem, posterior column and lemniscal projection, ipsilateral; SpTh, spinothalamic projection, contralateral.

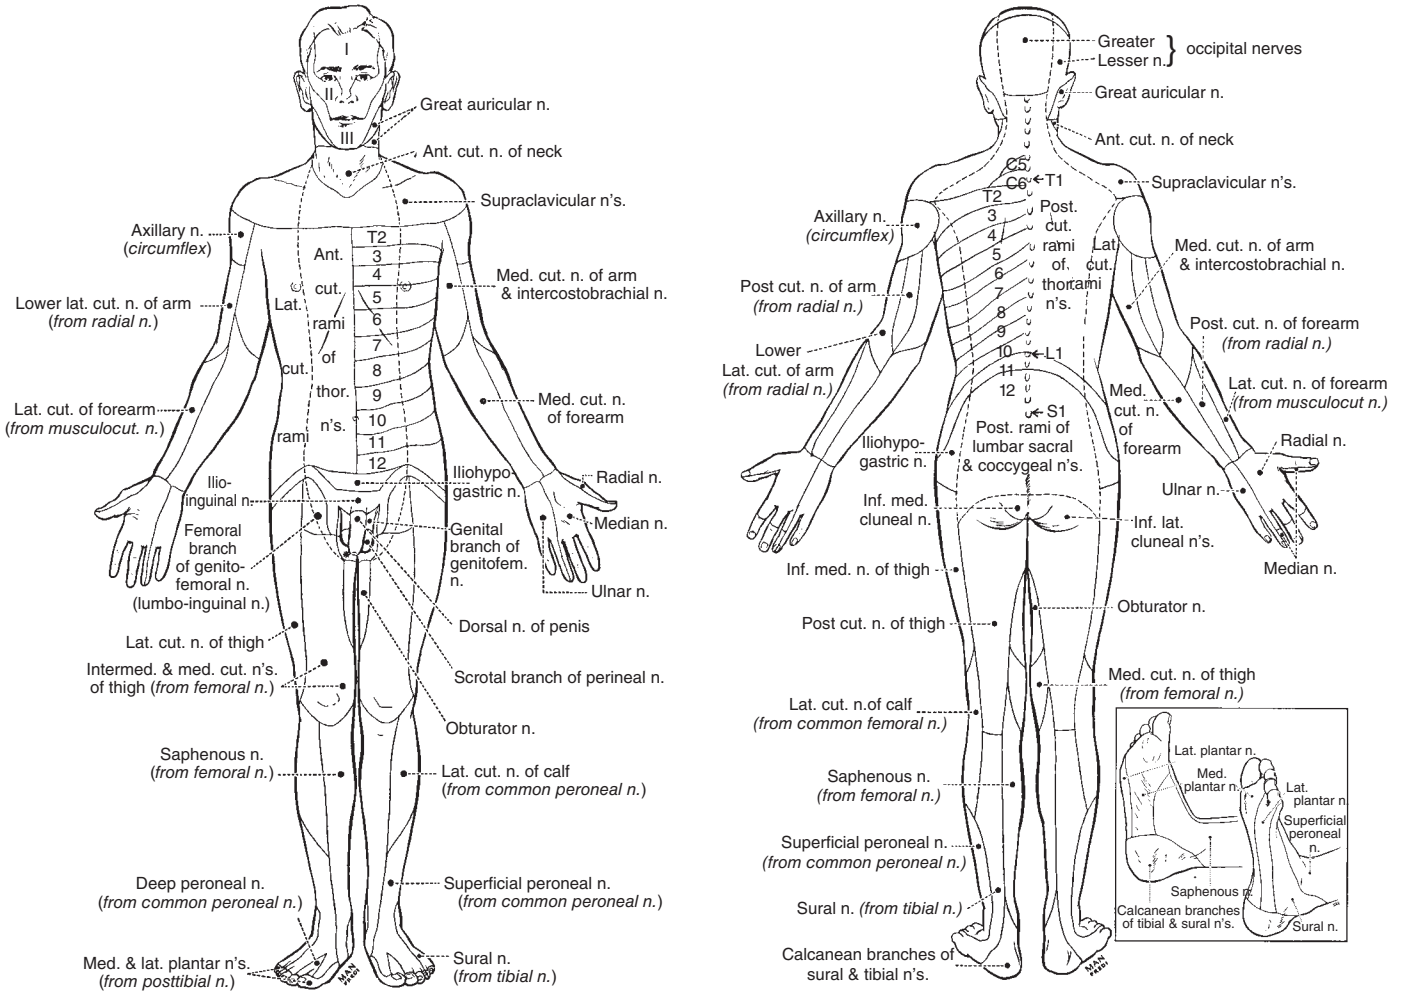

FIGURE 25-2 The cutaneous fields of peripheral nerves. *(Reproduced with permission from W Haymaker, B Woodhall: Peripheral Nerve Injuries, 2nd ed. Philadelphia, Saunders, 1953.)*

minimizing pressure on the skin. In general, it is better to avoid testing touch on hairy skin because of the profusion of the sensory endings that surround each hair follicle. The patient is tested with the eyes closed and should respond as soon as the stimulus is perceived, indicating its location.

Joint position testing is a measure of proprioception. With the patient's eyes closed, joint position is tested in the distal interphalangeal joint of the great toe and fingers. The digit is held by its sides, distal to the joint being tested, and moved passively while more proximal joints are stabilized—the patient indicates the change in position or direction of movement. If errors are made, more proximal joints are tested. A test of proximal joint position sense, primarily at the shoulder, is performed by asking the patient to bring the two index fingers together with arms extended and eyes closed. Normal individuals can do this accurately, with errors of 1 cm or less.

The sense of vibration is tested with an oscillating tuning fork that vibrates at 128 Hz. Vibration is tested over bony points, beginning distally; in the feet, it is tested over the dorsal surface of the distal phalanx of the big toes and at the malleoli of the ankles, and in the hands, it is tested dorsally at the distal phalanx of the fingers. If abnormalities are found, more proximal sites should be examined. Vibratory thresholds at the same site in the patient and the examiner may be compared for control purposes.

CORTICAL SENSATION

The most commonly used tests of cortical function are two-point discrimination, touch localization, and bilateral simultaneous stimulation, and tests for graphesthesia and stereognosis. Abnormalities

of these sensory tests, in the presence of normal primary sensation in an alert cooperative patient, signify a lesion of the parietal cortex or thalamocortical projections. If primary sensation is altered, these cortical discriminative functions usually will be abnormal also. Comparisons should always be made between analogous sites on the two sides of the body because the deficit with a specific parietal lesion is likely to be unilateral.

Two-point discrimination can be tested with calipers, the points of which may be set from 2 mm to several centimeters apart and then applied simultaneously to the test site. On the fingertips, a normal individual can distinguish about a 3-mm separation of points.

Touch localization is performed by light pressure for an instant with the examiner's fingertip or a wisp of cotton wool; the patient, whose eyes are closed, is required to identify the site of touch. *Bilateral simultaneous stimulation* at analogous sites (e.g., the dorsum of both hands) can be carried out to determine whether the perception of touch is extinguished consistently on one side (*extinction* or *neglect*). *Graphesthesia* refers to the capacity to recognize, with eyes closed, letters or numbers drawn by the examiner's fingertip on the palm of the hand. Once again, interside comparison is of prime importance. Inability to recognize numbers or letters is termed *agraphesthesia*.

Stereognosis refers to the ability to identify common objects by palpation, recognizing their shape, texture, and size. Common standard objects such as keys, paper clips, and coins are best used. Patients with normal stereognosis should be able to distinguish a dime from a penny and a nickel from a quarter without looking. Patients should feel the object with only one hand at a time. If they are unable to identify it in one hand, it should be placed in the other for comparison. Individuals who are unable to identify common objects and coins in one hand but can do so in the other are said to have *astereognosis* of the abnormal hand.

QUANTITATIVE SENSORY TESTING

Effective sensory testing devices are commercially available. Quantitative sensory testing is particularly useful for serial evaluation of cutaneous sensation in clinical trials. Threshold testing for touch and vibratory and thermal sensation is the most widely used application.

ELECTRODIAGNOSTIC STUDIES AND NERVE BIOPSY

Nerve conduction studies and nerve biopsy are important means of investigating the peripheral nervous system, but they do not evaluate the function or structure of cutaneous receptors and free nerve endings or of unmyelinated or thinly myelinated nerve fibers in the nerve trunks. Skin biopsy can be used to evaluate these structures in the dermis and epidermis.

LOCALIZATION OF SENSORY ABNORMALITIES

Sensory symptoms and signs can result from lesions at many different levels of the nervous system from the parietal cortex to the peripheral sensory receptor. Noting their distribution and nature is the most important way to localize their source. Their extent, configuration, symmetry, quality, and severity are the key observations.

Dysesthesias without sensory findings by examination may be difficult to interpret. To illustrate, tingling dysesthesias in an acral distribution (hands and feet) can be systemic in origin, for example, secondary to hyperventilation, or induced by a medication such as acetazolamide. Distal dysesthesias can also be an early event in an evolving polyneuropathy or may herald a myelopathy, such as from vitamin B_{12} deficiency. Sometimes, distal dysesthesias have no definable basis. In contrast, dysesthesias that correspond in distribution to that of a particular peripheral nerve structure denote a lesion at that site. For instance, dysesthesias restricted to the fifth digit and the adjacent one-half of the fourth finger on one hand reliably point to disorder of the ulnar nerve, most commonly at the elbow.

Nerve and Root In focal nerve trunk lesions, sensory abnormalities are readily mapped and generally have discrete boundaries (Figs. 25-2 and 25-3). Root ("radicular") lesions frequently are accompanied by deep, aching pain along the course of the related nerve trunk. With compression of a fifth lumbar (L5) or first sacral (S1) root, as from a ruptured intervertebral disk, sciatica (radicular pain relating to the sciatic nerve trunk) is a common manifestation **(Chap. 17)**. With a lesion affecting a single root, sensory deficits may be minimal or absent because adjacent root territories overlap extensively.

Isolated mononeuropathies may cause symptoms beyond the territory supplied by the affected nerve, but abnormalities on examination typically are confined to expected anatomic boundaries. In multiple mononeuropathies, symptoms and signs occur in discrete territories supplied by different individual nerves and—as more nerves are affected—may simulate a polyneuropathy if deficits become confluent. With polyneuropathies, sensory deficits are generally graded, distal, and symmetric in distribution **(Chap. 446)**. Dysesthesias, followed by numbness, begin in the toes and ascend symmetrically. When dysesthesias reach the knees, they usually also have appeared in the fingertips. The process is nerve length–dependent, and the deficit is often described as "stocking glove" in type. Involvement of both hands and feet also occurs with lesions of the upper cervical cord or the brainstem, but an upper level of the sensory disturbance may then be found on the trunk and other evidence of a central lesion may be present, such as sphincter involvement or signs of an upper motor neuron lesion **(Chap. 24)**. Although most polyneuropathies are pansensory and affect all modalities of sensation, selective sensory dysfunction according to nerve fiber size may occur. Small-fiber polyneuropathies are characterized by burning, painful dysesthesias with reduced pinprick and thermal sensation but with sparing of proprioception, motor function, and deep tendon reflexes. Touch is involved variably; when it is spared, the sensory pattern is referred to as exhibiting *sensory dissociation*. Sensory dissociation may occur also with spinal cord lesions **(Chap. 442)**. Large-fiber polyneuropathies are characterized by vibration and position sense deficits, imbalance, absent tendon reflexes, and variable motor dysfunction but preservation of most cutaneous sensation. Dysesthesias, if present at all, tend to be tingling or bandlike in quality.

Sensory neuronopathy (or ganglionopathy) is characterized by widespread but asymmetric sensory loss occurring in a non-length-dependent manner so that it may occur proximally or distally, and in the arms, legs, or both. Pain and numbness progress to sensory ataxia and impairment of all sensory modalities over time. This condition is usually paraneoplastic or idiopathic in origin **(Chaps. 94 and 445)** or related to an autoimmune disease, particularly Sjögren's syndrome **(Chap. 361)**.

Spinal Cord **(See also Chap. 442)** If the spinal cord is transected, all sensation is lost below the level of transection. Bladder and bowel function also are lost, as is motor function. Lateral hemisection of the spinal cord produces the Brown-Séquard syndrome, with absent pain and temperature sensation contralaterally and loss of proprioceptive sensation and power ipsilaterally below the lesion (see **Figs.** 25-1 and **442-1**); ipsilateral pain or hyperesthesia may also occur.

Numbness or paresthesias in both feet may arise from a spinal cord lesion; this is especially likely when the upper level of the sensory loss extends to the trunk. When all extremities are affected, the lesion is probably in the cervical region or brainstem unless a peripheral neuropathy is responsible. The presence of upper motor neuron signs **(Chap. 24)** supports a central lesion; a hyperesthetic band on the trunk may suggest the level of involvement.

A dissociated sensory loss can reflect spinothalamic tract involvement in the spinal cord, especially if the deficit is unilateral and has an upper level on the torso. Bilateral spinothalamic tract involvement occurs with lesions affecting the center of the spinal cord, such as in syringomyelia. There is a dissociated sensory loss with impairment of pinprick and temperature appreciation but relative preservation of light touch, position sense, and vibration appreciation.

Dysfunction of the posterior columns in the spinal cord or of the posterior root entry zone may lead to a bandlike sensation around the trunk or a feeling of tight pressure in one or more limbs. Flexion

of the neck sometimes leads to an electric shock–like sensation that radiates down the back and into the legs (Lhermitte's sign) in patients with a cervical lesion affecting the posterior columns, such as from multiple sclerosis, cervical spondylosis, or following irradiation to the cervical region.

Brainstem Crossed patterns of sensory disturbance, in which one side of the face and the opposite side of the body are affected, localize to the lateral medulla. Here a small lesion may damage both the ipsilateral descending trigeminal tract and the ascending spinothalamic fibers subserving the opposite arm, leg, and hemitorso (see "Lateral medullary syndrome" in Fig. 426-7). A lesion in the tegmentum of the pons and midbrain, where the lemniscal and spinothalamic tracts merge, causes pansensory loss contralaterally.

Thalamus Hemisensory disturbance with tingling numbness from head to foot is often thalamic in origin but also can arise from the anterior parietal region. If abrupt in onset, the lesion is likely to be due to a small stroke (lacunar infarction), particularly if localized to the thalamus. Occasionally, with lesions affecting the VPL nucleus or adjacent white matter, a syndrome of thalamic pain, also called *Déjerine-Roussy syndrome*, may ensue. The persistent, unrelenting unilateral pain often is described in dramatic terms.

Cortex With lesions of the parietal lobe involving either the cortex or subjacent white matter, the most prominent symptoms are contralateral hemineglect, hemi-inattention, and a tendency not to use the affected hand and arm. On cortical sensory testing (e.g., two-point discrimination, graphesthesia), abnormalities are often found but primary sensation is usually intact. Anterior parietal infarction may present as a pseudothalamic syndrome with contralateral loss of primary sensation from head to toe. Dysesthesias or a sense of numbness and, rarely, a painful state may also occur.

Focal Sensory Seizures These seizures generally are due to lesions in the area of the postcentral or precentral gyrus. The principal symptom of focal sensory seizures is tingling, but additional, more complex sensations may occur, such as a rushing feeling, a sense of warmth, or a sense of movement without detectable motion. Symptoms typically are unilateral; commonly begin in the arm or hand, face, or foot; and often spread in a manner that reflects the cortical representation of different bodily parts, as in a Jacksonian march. Their duration is variable; seizures may be transient, lasting only for seconds, or persist for an hour or more. Focal motor features may supervene, often becoming generalized with loss of consciousness and tonic-clonic jerking.

Psychogenic Symptoms Sensory symptoms may have a psychogenic basis. Such symptoms may be generalized or have an anatomic boundary that is difficult to explain neurologically, for example, circumferentially at the groin or shoulder or around a specific joint. Pain is common, but the nature and intensity of any sensory disturbances are variable. The diagnosis should not be one of exclusion but based on suggestive findings that are otherwise difficult to explain, such as midline splitting of impaired vibration, pinprick, or light touch appreciation; variability or poor reproducibility of sensory deficits; or normal performance of tasks requiring sensory input that is seemingly abnormal on formal testing, such as good performance with eyes closed of the finger-to-nose test despite an apparent loss of position sense in the upper limb. The side with abnormal sensation may be confused when the limbs are placed in an unusual position, such as crossed behind the back. Sensory complaints should not be regarded as psychogenic simply because they are unusual.

TREATMENT

Management is based on treatment of the underlying condition. Symptomatic treatment of acute and chronic pain is discussed in Chap. 13. Dysesthesias, when severe and persistent, may respond to anticonvulsants (carbamazepine, 100–1000 mg/d; gabapentin, 300–3600 mg/d; or pregabalin, 50–300 mg/d), antidepressants (amitriptyline, 25–150 mg/d; nortriptyline, 25–150 mg/d; desipramine, 100–300 mg/d; or venlafaxine, 75–225 mg/d).

26 Gait Disorders, Imbalance, and Falls

Jessica M. Baker

PREVALENCE, MORBIDITY, AND MORTALITY

Gait and balance problems are common in the elderly and contribute to the risk of falls and injury. Gait disorders have been described in 15% of individuals aged >65. By age 80, one person in four will use a mechanical aid to assist with ambulation. Among those aged ≥85, the prevalence of gait abnormality approaches 40%. In epidemiologic studies, gait disorders are consistently identified as a major risk factor for falls and injury.

ANATOMY AND PHYSIOLOGY

An upright bipedal gait depends on the successful integration of postural control and locomotion. These functions are widely distributed in the central nervous system. The biomechanics of bipedal walking are complex, and the performance is easily compromised by a neurologic deficit at any level. Command and control centers in the brainstem, cerebellum, and forebrain modify the action of spinal pattern generators to promote stepping. While a form of "fictive locomotion" can be elicited from quadrupedal animals after spinal transection, this capacity is limited in primates. Step generation in primates is dependent on locomotor centers in the pontine tegmentum, midbrain, and subthalamic region. Locomotor synergies are executed through the reticular formation and descending pathways in the ventromedial spinal cord. Cerebral control provides a goal and purpose for walking and is involved in avoidance of obstacles and adaptation of locomotor programs to context and terrain.

Postural control requires the maintenance of the center of mass over the base of support through the gait cycle. Unconscious postural adjustments maintain standing balance: long latency responses are measurable in the leg muscles, beginning 110 milliseconds after a perturbation. Forward motion of the center of mass provides propulsive force for stepping, but failure to maintain the center of mass within stability limits results in falls. The anatomic substrate for dynamic balance has not been well defined, but the vestibular nucleus and midline cerebellum contribute to balance control in animals. Patients with damage to these structures have impaired balance while standing and walking.

Standing balance depends on good-quality sensory information about the position of the body center with respect to the environment, support surface, and gravitational forces. Sensory information for postural control is primarily generated by the visual system, the vestibular system, and proprioceptive receptors in the muscle spindles and joints. A healthy redundancy of sensory afferent information is generally available, but loss of two of the three pathways is sufficient to compromise standing balance. Balance disorders in older individuals

sometimes result from multiple insults in the peripheral sensory systems (e.g., visual loss, vestibular deficit, peripheral neuropathy) that critically degrade the quality of afferent information needed for balance stability.

Older patients with cognitive impairment appear to be particularly prone to falls and injury. There is a growing body of literature on the use of attentional resources to manage gait and balance. Walking is generally considered to be unconscious and automatic, but the ability to walk while attending to a cognitive task (*dual-task walking*) may be compromised in the elderly. Older patients with deficits in executive function may have particular difficulty in managing the attentional resources needed for dynamic balance when distracted.

DISORDERS OF GAIT

Disorders of gait may be attributed to neurologic and nonneurologic causes, although significant overlap often exists. The *antalgic gait* results from avoidance of pain associated with weight bearing and is commonly seen in osteoarthritis. Asymmetry is a common feature of gait disorders due to contractures and other orthopedic deformities. Impaired vision rounds out the list of common nonneurologic causes of gait disorders.

Neurologic gait disorders are disabling and equally important to address. The heterogeneity of gait disorders observed in clinical practice reflects the large network of neural systems involved in the task. Walking is vulnerable to neurologic disease at every level. Gait disorders have been classified descriptively on the basis of abnormal physiology and biomechanics. One problem with this approach is that many failing gaits look fundamentally similar. This overlap reflects common patterns of adaptation to threatened balance stability and declining performance. *The gait disorder observed clinically must be viewed as the product of a neurologic deficit and a functional adaptation*. Unique features of the failing gait are often overwhelmed by the adaptive response. Some common patterns of abnormal gait are summarized next. Gait disorders can also be classified by etiology **(Table 26-1)**.

CAUTIOUS GAIT

The term *cautious gait* is used to describe the patient who walks with an abbreviated stride, widened base, and lowered center of mass, as if walking on a slippery surface. Arms are often held abducted. This disorder is both common and nonspecific. It is, in essence, an adaptation to a perceived postural threat. There may be an associated fear of falling. This disorder can be observed in more than one-third of older patients with gait impairment. Physical therapy often improves walking to the degree that follow-up observation may reveal a more specific underlying disorder.

STIFF-LEGGED GAIT

Spastic gait is characterized by stiffness in the legs, an imbalance of muscle tone, and a tendency to circumduct and scuff the feet. The disorder reflects compromise of corticospinal command and overactivity of spinal reflexes. The patient may walk on the toes. In extreme instances, the legs cross due to increased tone in the adductors ("scissoring" gait). Upper motor neuron signs are present on physical examination. The disorder may be cerebral or spinal in origin.

Myelopathy from cervical spondylosis is a common cause of spastic or spastic-ataxic gait in the elderly. Demyelinating disease and trauma are the leading causes of myelopathy in younger patients. In chronic progressive myelopathy of unknown cause, a workup with laboratory and imaging tests may establish a diagnosis. A structural lesion, such as a tumor or a spinal vascular malformation, should be excluded with appropriate testing. **Spinal cord disorders are discussed in detail in Chap. 442.**

With cerebral spasticity, asymmetry is common, the upper extremities are usually involved, and dysarthria is often an associated feature. Common causes include vascular disease (stroke), multiple sclerosis, motor neuron disease, and perinatal nervous system injury (cerebral palsy).

Other stiff-legged gaits include dystonia **(Chap. 436)** and stiff-person syndrome **(Chap. 94)**. Dystonia is a disorder characterized by sustained muscle contractions resulting in repetitive twisting movements and abnormal posture. It often has a genetic basis. Dystonic spasms can produce plantar flexion and inversion of the feet, sometimes with torsion of the trunk. In autoimmune stiff-person syndrome, exaggerated lordosis of the lumbar spine and overactivation of antagonist muscles restrict trunk and lower-limb movement and result in a wooden or fixed posture.

PARKINSONISM, FREEZING GAIT, AND OTHER MOVEMENT DISORDERSS

Parkinson's disease **(Chap. 435)** is common, affecting 1% of the population >65 years of age. The stooped posture, shuffling gait, and decreased arm swing are characteristic and distinctive features. Patients sometimes accelerate (festinate) with walking, display retropulsion, or exhibit a tendency to turn en bloc. The step-to-step variability

TABLE 26-1 Prevalence of Neurologic Gait Disorders

NEUROLOGIC GAIT DISORDER	NO. (%)[a]	TOTAL NUMBER[b]	CAUSES (NO.)
Single neurologic gait disorder	81 (69%)		
Sensory ataxic	22 (18%)	46	Peripheral sensory neuropathy (46)
Parkinsonian	19 (16%)	34	Parkinson's disease (18), drug-induced parkinsonism (8), dementia with parkinsonism (4), parkinsonism (4)
Higher level	9 (8%)	31	Vascular encephalopathy (20), normal pressure hydrocephalus (1), severe dementia (7), hypoxic ischemic encephalopathy (1), unknown (1)
Cerebellar ataxic	7 (6%)	10	Cerebellar stroke (3), cerebellar lesion due to multiple sclerosis (1), severe essential tremor (3), postvaccinal cerebellitis (1), chronic alcohol abuse (1), multiple system atrophy (1)
Cautious	7 (6%)	7	Idiopathic, associated fear of falling (7)
Paretic/hypotonic	6 (5%)	14	Neurogenic claudication (7), diabetic neuropathy (1), nerve lesion due to trauma or surgery (4), distal paraparesis after Guillain-Barré syndrome (1), unknown (2)
Spastic	6 (5%)	7	Ischemic stroke (3), intracerebral hemorrhage (3), congenital (1)
Vestibular ataxic	4 (3%)	6	Bilateral vestibulopathy (3), recent vestribular neuronitis (1), recent Ménière's attack (1), acoustic neuroma with surgery (1)
Dyskinetic	1 (1%)	4	Levodopa-induced dyskinesia (3), chorea (1)
Multiple neurologic gait disorders	36 (30%)		
Total	117		

[a]Percentage of individuals with a single gait disorder. [b]Includes individuals with multiple gait disorders.

Note: Of 117 patients with a neurologic gait disorder, 81 had a single neurologic gait disorder; the remainder (36) had multiple neurologic gait disorders.

Source: Reproduced with modifications from P Mahlknecht et al: PLoS One 8:e69627, 2013.

of the parkinsonian gait also contributes to falls, which are a major source of morbidity, particularly later in the disease course. Dopamine replacement improves step length, arm swing, turning speed, and gait initiation. There is increasing evidence that deficits in cholinergic circuits in the pedunculopontine nucleus and cortex contribute to the gait disorder of Parkinson's disease. Cholinesterase inhibitors such as donepezil and rivastigmine have been shown in early studies to significantly decrease gait variability, instability, and fall frequency, even in the absence of cognitive impairment, perhaps through improvement in attention.

Freezing is defined as a brief, episodic absence of forward progression of the feet, despite the intention to walk. Freezing may be triggered by approaching a narrow doorway or crowd, may be overcome by visual cueing, and contributes to fall risk. Gait freezing is present in approximately one-quarter of Parkinson's patients within 5 years of onset, and its frequency increases further over time. In treated patients, end-of-dose gait freezing is a common problem that may improve with more frequent administration of dopaminergic drugs or with use of monoamine oxidase type B inhibitors such as rasagiline or selegiline **(Chap. 435)**.

Freezing of gait is also common in other neurodegenerative disorders associated with parkinsonism, including progressive supranuclear palsy (PSP), multiple-system atrophy, and corticobasal degeneration. Patients with these disorders frequently present with axial stiffness, postural instability, and a shuffling, freezing gait while lacking the characteristic pill-rolling tremor of Parkinson's disease. The gait of PSP is typically more erect compared with the stooped posture of typical Parkinson's disease, and falls within the first year also suggest the possibility of PSP. The gait of vascular parkinsonism tends to be broad-based and shuffling with reduced arm swing bilaterally; disproportionate involvement of gait early in the disease course differentiates this entity from Parkinson's disease.

Hyperkinetic movement disorders also produce characteristic and recognizable disturbances in gait. In Huntington's disease **(Chap. 436)**, the unpredictable occurrence of choreic movements gives the gait a dancing quality. Tardive dyskinesia is the cause of many odd, stereotypic gait disorders seen in patients chronically exposed to antipsychotics and other drugs that block the D_2 dopamine receptor. *Orthostatic tremor* is a high-frequency, low-amplitude tremor predominantly involving the lower extremities. Patients often report shakiness or unsteadiness on standing and improvement with sitting or walking. Falls are common. The tremor is often only appreciable by palpating the legs while standing.

FRONTAL GAIT DISORDER

Frontal gait disorder, also known as higher-level gait disorder, is common in the elderly and has a variety of causes. The term is used to describe a shuffling, freezing gait with imbalance, and other signs of higher cerebral dysfunction. Typical features include a wide base of support, a short stride, shuffling along the floor, and difficulty with starts and turns. Many patients exhibit a difficulty with gait initiation that is descriptively characterized as the "slipping clutch" syndrome or gait ignition failure. The term *lower-body parkinsonism* is also used to describe such patients. Strength is generally preserved, and patients are able to make stepping movements when not standing and maintaining their balance at the same time. This disorder is best considered a higher-level motor control disorder, as opposed to an apraxia **(Chap. 30)**, though the term *gait apraxia* persists in the literature.

The most common cause of frontal gait disorder is vascular disease, particularly subcortical small-vessel disease in the deep frontal white matter and centrum ovale. Over three-quarters of patients with subcortical vascular dementia demonstrate gait abnormalities; decreased arm swing and a stooped posture are particularly prevalent features. The clinical syndrome also includes dysarthria, pseudobulbar affect (emotional disinhibition), increased tone, and hyperreflexia in the lower limbs.

Normal pressure (communicating) hydrocephalus (NPH) in adults also presents with a similar gait disorder **(Chap. 431)**. Other features of the diagnostic triad (mental changes, incontinence) may be absent in a substantial number of patients. MRI demonstrates ventricular enlargement, an enlarged flow void about the aqueduct, periventricular white matter change, and high-convexity tightness (disproportionate widening of the sylvian fissures versus the cortical sulci). A lumbar puncture or dynamic test is necessary to confirm a diagnosis of NPH. Neurodegenerative dementias and mass lesions of the frontal lobes cause a similar clinical picture and can be differentiated from vascular disease and hydrocephalus by neuroimaging.

CEREBELLAR GAIT ATAXIA

Disorders of the cerebellum **(Chap. 439)** have a dramatic impact on gait and balance. Cerebellar gait ataxia is characterized by a wide base of support, lateral instability of the trunk, erratic foot placement, and decompensation of balance when attempting to walk on a narrow base. Difficulty maintaining balance when turning is often an early feature. Patients are unable to walk tandem heel to toe and display truncal sway in narrow-based or tandem stance. They show considerable variation in their tendency to fall in daily life.

Causes of cerebellar ataxia in older patients include stroke, trauma, tumor, and neurodegenerative disease such as multiple-system atrophy **(Chap. 440)** and various forms of hereditary cerebellar degeneration **(Chap. 439)**. A short expansion at the site of the fragile X mutation (*fragile X premutation*) has been associated with gait ataxia in older men. Alcohol causes an acute and chronic cerebellar ataxia. In patients with ataxia due to cerebellar degeneration, MRI demonstrates the extent and topography of cerebellar atrophy.

SENSORY ATAXIA

As reviewed earlier in this chapter, balance depends on high-quality afferent information from the visual and the vestibular systems and proprioception. When this information is lost or degraded, balance during locomotion is impaired and instability results. The sensory ataxia of tabetic neurosyphilis is a classic example. The contemporary equivalent is the patient with neuropathy affecting large fibers. Vitamin B_{12} deficiency is a treatable cause of large-fiber sensory loss in the spinal cord and peripheral nervous system. Joint position and vibration sense are diminished in the lower limbs. The stance in such patients is destabilized by eye closure; they often look down at their feet when walking and do poorly in the dark. **Table 26-2** compares sensory ataxia with cerebellar ataxia and frontal gait disorder.

TABLE 26-2 Features of Cerebellar Ataxia, Sensory Ataxia, and Frontal Gait Disorders

FEATURE	CEREBELLAR ATAXIA	SENSORY ATAXIA	FRONTAL GAIT
Base of support	Wide-based	Narrow base, looks down	Wide-based
Velocity	Variable	Slow	Very slow
Stride	Irregular, lurching	Regular with path deviation	Short, shuffling
Romberg test	+/–	Unsteady, falls	+/–
Heel → shin	Abnormal	+/–	Normal
Initiation	Normal	Normal	Hesitant
Turns	Unsteady	+/–	Hesitant, multistep
Postural instability	+	+++	++++ Poor postural synergies rising from a chair
Falls	Late event	Frequent	Frequent

NEUROMUSCULAR DISEASE

Patients with neuromuscular disease often have an abnormal gait, occasionally as a presenting feature. With distal weakness (peripheral neuropathy), the step height is increased to compensate for foot drop, and the sole of the foot may slap on the floor during weight acceptance, termed the *steppage gait*. Patients with myopathy or muscular dystrophy more typically exhibit proximal weakness. Weakness of the hip girdle may result in some degree of excess pelvic sway during locomotion. The stooped posture of lumbar spinal stenosis ameliorates pain from the compression of the cauda equina occurring with a more upright posture while walking and may mimic early parkinsonism.

TOXIC AND METABOLIC DISORDERS

Chronic toxicity from medications and metabolic disturbances can impair motor function and gait. Examination may reveal mental status changes, asterixis, or myoclonus. Static equilibrium is disturbed, and such patients are easily thrown off balance. Disequilibrium is particularly evident in patients with chronic renal disease and those with hepatic failure, in whom asterixis may impair postural support. Sedative drugs, especially neuroleptics and long-acting benzodiazepines, affect postural control and increase the risk for falls. These disorders are especially important to recognize because they are often treatable.

FUNCTIONAL GAIT DISORDER

Functional neurologic disorders (formerly "psychogenic") are common in practice, and the presentation often involves gait. Sudden onset, inconsistent deficits, waxing and waning course, incongruence of symptoms with an organic lesion, and improvement with distraction are key features. Phenomenology is variable; extreme slow motion, an inappropriately overcautious gait, odd gyrations of posture with wastage of muscular energy, astasia–abasia (inability to stand and walk), bouncing, and foot stiffness (dystonia) have been described. Falls are rare, and there are often discrepancies between examination findings and the patient's functional status. Preceding stress or trauma is variably present, and its absence does not preclude the diagnosis of a functional gait disorder. Functional gait disorders may be challenging to diagnose and should be differentiated from the slowness and psychomotor retardation seen in certain patients with major depression.

APPROACH TO THE PATIENT

Slowly Progressive Disorder of Gait

When reviewing the history, it is helpful to inquire about the onset and progression of disability. Initial awareness of an unsteady gait often follows a fall. Stepwise evolution or sudden progression suggests vascular disease. Gait disorder may be associated with urinary urgency and incontinence, particularly in patients with cervical spine disease or hydrocephalus. It is always important to review the use of alcohol and medications that affect gait and balance. Information on localization derived from the neurologic examination can be helpful in narrowing the list of possible diagnoses.

Gait observation provides an immediate sense of the patient's degree of disability. Arthritic and antalgic gaits are recognized by observation, although neurologic and orthopedic problems may coexist. Characteristic patterns of abnormality are sometimes seen, although, as stated previously, failing gaits often look fundamentally similar. Cadence (steps per minute), velocity, and stride length can be recorded by timing a patient over a fixed distance. Watching the patient rise from a chair provides a good functional assessment of balance.

Brain imaging studies may be informative in patients with an undiagnosed disorder of gait. MRI is sensitive for cerebral lesions of vascular or demyelinating disease and is a good screening test for occult hydrocephalus. Patients with recurrent falls are at risk for subdural hematoma. As mentioned earlier, many elderly patients with gait and balance difficulty have white matter abnormalities in the periventricular region and centrum semiovale. While these lesions may be an incidental finding, a substantial burden of white matter disease will ultimately impact cerebral control of locomotion.

DISORDERS OF BALANCE

DEFINITION, ETIOLOGY, AND MANIFESTATIONS

Balance is the ability to maintain equilibrium—a dynamic state in which one's center of mass is controlled with respect to the lower extremities, gravity, and the support surface despite external perturbations. The reflexes required to maintain upright posture require input from cerebellar, vestibular, and somatosensory systems; the premotor cortex and corticospinal and reticulospinal tracts mediate output to axial and proximal limb muscles. These responses are physiologically complex, and the anatomic representation they entail is not well understood. Failure can occur at any level and presents as difficulty maintaining posture while standing and walking.

The history and physical examination may differentiate underlying causes of imbalance. Patients with *cerebellar* ataxia do not generally complain of dizziness, although balance is visibly impaired. Neurologic examination reveals a variety of cerebellar signs. Postural compensation may prevent falls early on, but falls are inevitable with disease progression. The progression of neurodegenerative ataxia is often measured by the number of years to loss of stable ambulation.

Vestibular disorders **(Chap. 22)** have symptoms and signs that fall into three categories: (1) vertigo (the subjective inappropriate perception or illusion of movement); (2) nystagmus (involuntary eye movements); and (3) impaired standing balance. Not every patient has all manifestations. Patients with vestibular deficits related to ototoxic drugs may lack vertigo or obvious nystagmus, but their balance is impaired on standing and walking, and they cannot navigate in the dark. Laboratory testing is available to investigate vestibular deficits.

Somatosensory deficits also produce imbalance and falls. There is often a subjective sense of insecure balance and fear of falling. Postural control is compromised by eye closure (*Romberg's sign*); these patients also have difficulty navigating in the dark. A dramatic example is provided by the patient with autoimmune subacute sensory neuropathy, which is sometimes a paraneoplastic disorder **(Chap. 94)**. Compensatory strategies enable such patients to walk in the virtual absence of proprioception, but the task requires active visual monitoring.

Patients with *higher-level disorders of equilibrium* have difficulty maintaining balance in daily life and may present with falls. Their awareness of balance impairment may be reduced. Patients taking sedating medications are in this category.

FALLS

Falls are common in the elderly; over one-third of people aged >65 who are living in the community fall each year. This number is even higher in nursing homes and hospitals. Elderly people are not only at higher risk for falls but are also more likely to suffer serious complications due to medical comorbidities such as osteoporosis. Hip fractures result in hospitalization, can lead to nursing home admission, and are associated with an increased mortality risk in the subsequent year. Falls may result in brain or spinal injury, the history of which may be difficult for the patient to provide. The proportion of spinal cord injuries due to falls in individuals aged >65 years has doubled in the past decade, perhaps due to increasing activity in this age group. Some falls result in a prolonged time lying on the ground; fractures and CNS injury are a particular concern in this context.

For each person who is physically disabled, there are others whose functional independence is limited by anxiety and fear of falling. Nearly one in five elderly individuals voluntarily restricts his or her activity because of fear of falling. With loss of ambulation, the quality of life diminishes, and rates of morbidity and mortality increase.

RISK FACTORS FOR FALLS

Risk factors for falls may be *intrinsic* (e.g., gait and balance disorders) or *extrinsic* (e.g., polypharmacy, environmental factors); some risk factors are modifiable. The presence of multiple risk factors is associated with a substantially increased risk of falls. **Table 26-3** summarizes a meta-analysis of studies establishing the principal risk factors for falls. Polypharmacy (use of four or more prescription medications) has also been identified as an important risk factor.

TABLE 26-3 Meta-Analysis of Risk Factors for Falls in Older Persons

RISK FACTOR	MEAN RR (OR)	RANGE
Muscle weakness	4.4	1.5–10.3
History of falls	3.0	1.7–7.0
Gait deficit	2.9	1.3–5.6
Balance deficit	2.9	1.6–5.4
Use assistive device	2.6	1.2–4.6
Visual deficit	2.5	1.6–3.5
Arthritis	2.4	1.9–2.9
Impaired ADL	2.3	1.5–3.1
Depression	2.2	1.7–2.5
Cognitive impairment	1.8	1.0–2.3
Age >80 years	1.7	1.1–2.5

Abbreviations: ADL, activity of daily living; OR, odds ratio from retrospective studies; RR, relative risk from prospective studies.

ASSESSMENT OF THE PATIENT WITH FALLS

The most productive approach is to identify the high-risk patient prospectively, before there is a serious injury. All community-dwelling adults should be asked annually about falls and whether or not fear of falling limits daily activities. The Timed Up and Go ("TUG") test involves timing a patient as they stand up from a chair, walk 10 feet, turn, and then sit down. Patients with a history of falls or those requiring >12 s to complete the TUG test are at high risk for falls and should undergo further assessment.

History The history surrounding a fall is often problematic or incomplete, and the underlying mechanism or cause may be difficult to establish in retrospect. Patients should be queried about any provoking factors (including head turn, standing) or prodromal symptoms, such as dizziness, vertigo, presyncopal symptoms, or focal weakness. A history of baseline mobility and medical comorbidities should be elicited. Patients at particular risk include those with mental status changes or dementia. Medications should be reviewed, with particular attention to benzodiazepines, opioids, antipsychotics, antiepileptics, antidepressants, antiarrhythmics, and diuretics, all of which are associated with an increased risk of falls. It is equally important to distinguish *mechanical falls* (those caused by tripping or slipping) due to purely extrinsic or environmental factors from those in which a modifiable intrinsic factor contributes. *Recurrent falls* may indicate an underlying gait or balance disorder. Falls associated with loss of consciousness (syncope, seizure) may require appropriate cardiac or neurologic evaluation and intervention **(Chaps. 21 and 425)**, although a patient's report of change in consciousness may be unreliable.

Physical Examination Examination of the patient with falls should include a basic cardiac examination, including orthostatic blood pressure if indicated by history, and observation of any orthopedic abnormalities. Mental status is easily assessed while obtaining a history from the patient; the remainder of the neurologic examination should include visual acuity, strength and sensation in the lower extremities, muscle tone, and cerebellar function, with particular attention to gait and balance as described earlier in this chapter.

Fall Patterns The description of a fall event may provide further clues to the underlying etiology. While there is no standard nosology of falls, some common clinical patterns may emerge and provide a clue.

DROP ATTACKS AND COLLAPSING FALLS Drop attacks and collapsing falls are associated with a sudden loss of postural tone. Patients may report that their legs just "gave out" underneath them or that they "collapsed in a heap." Syncope or orthostatic hypotension may be a factor in some such falls. Neurologic causes are relatively rare but include atonic seizures, myoclonus, and intermittent obstruction of the foramen of Monro by a colloid cyst of the third ventricle causing acute obstructive hydrocephalus. An emotional trigger suggests cataplexy. While collapsing falls are more common among older patients with vascular risk factors, drop attacks should not be confused with vertebrobasilar ischemic attacks.

TOPPLING FALLS Some patients maintain tone in antigravity muscles but fall over like a tree trunk, as if postural defenses had disengaged. Causes include cerebellar pathology and lesions of the vestibular system. There may be a consistent direction to such falls. Toppling falls are an early feature of progressive supranuclear palsy, and a late feature of Parkinson's disease, once postural instability has developed. Thalamic lesions causing truncal instability (*thalamic astasia*) may also contribute to this type of fall.

FALLS DUE TO GAIT FREEZING Freezing of gait is seen in Parkinson's disease and related disorders. The feet stick to the floor and the center of mass keeps moving, resulting in a disequilibrium from which the patient has difficulty recovering, resulting in a forward fall. Similarly, patients with Parkinson's disease and festinating gait may find their feet unable to keep up and may thus fall forward.

FALLS RELATED TO SENSORY LOSS Patients with somatosensory, visual, or vestibular deficits are prone to falls. These patients have particular difficulty dealing with poor illumination or walking on uneven ground. They often report subjective imbalance, apprehension, and fear of falling. These patients may be especially responsive to a rehabilitation-based intervention.

FALLS RELATED TO WEAKNESS Patients who lack strength in antigravity muscles have difficulty rising from a chair or maintaining their balance after a perturbation. These patients are often unable to get up after a fall and may have to remain on the floor for a prolonged period until help arrives. If due to deconditioning, this is often treatable. Resistance strength training can increase muscle mass and leg strength, even for people in their eighties and nineties.

TREATMENT

Interventions to Reduce the Risk of Falls and Injury

Efforts should be made to define the mechanism underlying falls in a given patient, as specific treatment may be possible once a diagnosis is established. Orthostatic changes in blood pressure and pulse should be recorded. Medications (including over-the-counter) should be reviewed, reevaluating benefits and burdens of medications that might increase fall risk. Treatment of cataracts and avoidance of multifocal lenses could be considered for patients whose falls result from vision impairment. A home visit to look for environmental hazards can be helpful. A variety of modifications may be recommended to improve safety, including improved lighting, installation of grab bars and nonslip surfaces, and use of adaptive equipment.

Home- and group-based exercise programs focusing on leg strength and balance, physical therapy, and use of assistive devices reduce fall risk in individuals with a history of falls or disorders of gait and balance. Rehabilitative interventions aim to improve muscle strength and balance stability and to make the patient more resistant to injury. High-intensity resistance strength training with weights and machines is useful to improve muscle mass, even in frail older patients. Improvements realized in posture and gait should translate to reduced risk of falls and injury. Sensory balance training is another approach to improving balance stability. Measurable gains can be made in a few weeks of training, and benefits can be maintained over 6 months by a 10- to 20-min home exercise program. This strategy is particularly successful in patients with vestibular and somatosensory balance disorders. The National Institute on Aging provides online examples of balance exercises for older adults. A Tai Chi exercise program has been demonstrated to reduce the risk of falls and injury in patients with Parkinson's disease. Cognitive training, including dual-task training, may improve mobility in older adults with cognitive impairment.

27 Confusion and Delirium

S. Andrew Josephson, Bruce L. Miller

Confusion, a mental and behavioral state of reduced comprehension, coherence, and capacity to reason, is one of the most common problems encountered in medicine, accounting for a large number of emergency department visits, hospital admissions, and inpatient consultations. *Delirium*, a term used to describe an acute confusional state, remains a major cause of morbidity and mortality, costing billions of dollars yearly in health care costs in the United States alone. Despite increased efforts targeting awareness of this condition, delirium often goes unrecognized in the face of evidence that it is usually the cognitive manifestation of serious underlying medical or neurologic illness.

CLINICAL FEATURES OF DELIRIUM

A multitude of terms are used to describe patients with delirium, including *encephalopathy, acute brain failure, acute confusional state*, and *postoperative* or *intensive care unit (ICU) psychosis*. Delirium has many clinical manifestations, but it is defined as a relatively acute decline in cognition that fluctuates over hours or days. The hallmark of delirium is a deficit of attention, although all cognitive domains—including memory, executive function, visuospatial tasks, and language—are variably involved. Associated symptoms that may be present in some cases include altered sleep-wake cycles, perceptual disturbances such as hallucinations or delusions, affect changes, and autonomic findings that include heart rate and blood pressure instability.

Delirium is a clinical diagnosis that is made only at the bedside. Two subtypes have been described—hyperactive and hypoactive—based on differential psychomotor features. The cognitive syndrome associated with severe alcohol withdrawal (i.e., "delirium tremens") remains the classic example of the hyperactive subtype, featuring prominent hallucinations, agitation, and hyperarousal, often accompanied by life-threatening autonomic instability. In striking contrast is the hypoactive subtype, exemplified by benzodiazepine intoxication, in which patients are withdrawn and quiet, with prominent apathy and psychomotor slowing.

This dichotomy between subtypes of delirium is a useful construct, but patients often fall somewhere along a spectrum between the hyperactive and hypoactive extremes, sometimes fluctuating from one to the other. Therefore, clinicians must recognize this broad range of presentations of delirium to identify all patients with this potentially reversible cognitive disturbance. Hyperactive patients are often easily recognized by their characteristic severe agitation, tremor, hallucinations, and autonomic instability. Patients who are quietly hypoactive are more often overlooked on the medical wards and in the ICU.

The reversibility of delirium is emphasized because many etiologies, such as infection and medication effects, can be treated easily. The long-term cognitive consequences of delirium remain an area of active research. Some episodes of delirium continue for weeks, months, or even years. The persistence of delirium in some patients and its high recurrence rate may be due to inadequate initial treatment of the underlying etiology. In other instances, delirium appears to cause permanent neuronal damage and long-term cognitive decline. Therefore, prevention strategies are important to implement. Even if an episode of delirium completely resolves, there may be lingering effects of the disorder; a patient's recall of events after delirium varies widely, ranging from complete amnesia to repeated reexperiencing of the frightening period of confusion, similar to what is seen in patients with posttraumatic stress disorder.

RISK FACTORS

An effective primary prevention strategy for delirium begins with identification of high-risk patients. Some hospital systems have initiated comprehensive delirium programs that screen most or all patients upon admission or before elective surgery; positive screens trigger a host of focused prevention measures. Multiple validated scoring systems have been developed as a screen for asymptomatic patients, many of which emphasize well-established risk factors for delirium.

The two most consistently identified risk factors are older age and baseline cognitive dysfunction. Individuals who are aged >65 or exhibit low scores on standardized tests of cognition develop delirium upon hospitalization at a rate approaching 50%. Whether age and baseline cognitive dysfunction are truly independent risk factors is uncertain. Other predisposing factors include sensory deprivation, such as preexisting hearing and visual impairment, as well as indices for poor overall health, including baseline immobility, malnutrition, and underlying medical or neurologic illness.

In-hospital risks for delirium include the use of bladder catheterization, physical restraints, sleep and sensory deprivation, and the addition of three or more new medications. Avoiding such risks remains a key component of delirium prevention as well as treatment. Surgical and anesthetic risk factors for the development of postoperative delirium include procedures such as those involving cardiopulmonary bypass, inadequate or excessive treatment of pain in the immediate postoperative period, and perhaps specific agents such as inhalational anesthetics.

The relationship between delirium and dementia **(Chap. 29)** is complicated by significant overlap between the two conditions, and it is not always simple to distinguish between them. Dementia and preexisting cognitive dysfunction serve as major risk factors for delirium, and at least two-thirds of cases of delirium occur in patients with coexisting underlying dementia. A form of dementia with parkinsonism, *dementia with Lewy bodies* **(Chap. 434)**, is characterized by a fluctuating course, prominent visual hallucinations, parkinsonism, and an attentional deficit that clinically resembles hyperactive delirium; patients with this condition are particularly vulnerable to delirium. Delirium in the elderly often reflects an insult to a brain that is vulnerable due to an underlying neurodegenerative condition. Therefore, the development of delirium sometimes heralds the onset of a previously unrecognized brain disorder, and after the acute delirious episode has cleared, careful screening for an underlying condition should occur in the outpatient setting.

EPIDEMIOLOGY

Delirium is common, but its reported incidence has varied widely with the criteria used to define this disorder. Estimates of delirium in hospitalized patients range from 10% to >50%, with higher rates reported for elderly patients and patients undergoing hip surgery. Older patients in the ICU have especially high rates of delirium that approach 75%. The

condition is not recognized in up to one-third of delirious inpatients, and the diagnosis is especially problematic in the ICU environment, where cognitive dysfunction is often difficult to appreciate in the setting of serious systemic illness and sedation. Delirium in the ICU should be viewed as an important manifestation of organ dysfunction not unlike liver, kidney, or heart failure. Outside the acute hospital setting, delirium occurs in nearly one-quarter of patients in nursing homes and in 50–80% of those at the end of life. These estimates emphasize the remarkably high frequency of this cognitive syndrome in older patients, a population that continues to grow.

An episode of delirium was previously viewed as a transient condition that carried a benign prognosis. It is now recognized as a disorder with substantial morbidity and mortality, and that often represents the first manifestation of a serious underlying illness. Estimates of in-hospital mortality rates among delirious patients range from 25% to 33%, similar to mortality rates due to sepsis. Patients with an in-hospital episode of delirium have a fivefold higher mortality rate in the months after their illness compared with age matched nondelirious hospitalized patients. Delirious hospitalized patients also have a longer length of stay, are more likely to be discharged to a nursing home, have a higher frequency of readmission, and are more likely to experience subsequent episodes of delirium and cognitive decline; as a result, this condition has an enormous economic cost.

PATHOGENESIS

The pathogenesis and anatomy of delirium are incompletely understood. The attentional deficit that serves as the neuropsychological hallmark of delirium has a diffuse localization within the brainstem, thalamus, prefrontal cortex, and parietal lobes. Rarely, focal lesions such as ischemic strokes have led to delirium in otherwise healthy persons; right parietal and medial dorsal thalamic lesions have been reported most commonly, pointing to the importance of these areas in delirium pathogenesis. In most cases, however, delirium results from widespread disturbances in cortical and subcortical regions of the brain. Electroencephalogram (EEG) usually reveals symmetric slowing, a nonspecific finding that supports diffuse cerebral dysfunction.

Multiple neurotransmitter abnormalities, proinflammatory factors, and specific genes likely play a role in the pathogenesis of delirium. Deficiency of acetylcholine may play a key role, and medications with anticholinergic properties can commonly precipitate delirium. As noted earlier, patients with preexisting dementia are particularly susceptible to episodes of delirium. Alzheimer's disease **(Chap. 431)**, dementia with Lewy bodies **(Chap. 434)**, and Parkinson's disease dementia **(Chap. 435)** are all associated with cholinergic deficiency due to degeneration of acetylcholine-producing neurons in the basal forebrain. In addition, other neurotransmitters are also likely to be involved in this diffuse cerebral disorder. For example, increases in dopamine can lead to delirium, and patients with Parkinson's disease treated with dopaminergic medications can develop a delirium-like state that features visual hallucinations, fluctuations, and confusion.

Not all individuals exposed to the same insult will develop signs of delirium. A low dose of an anticholinergic medication may have no cognitive effects on a healthy young adult but produce a florid delirium in an elderly person with known underlying dementia, although even healthy young persons develop delirium with very high doses of anticholinergic medications. This concept of delirium developing as the result of an insult in predisposed individuals is currently the most widely accepted pathogenic construct. Therefore, if a previously healthy individual with no known history of cognitive illness develops delirium in the setting of a relatively minor insult such as elective surgery or hospitalization, an unrecognized underlying neurologic illness such as a neurodegenerative disease, multiple previous strokes, or another diffuse cerebral cause should be considered. In this context, delirium can be viewed as a "stress test for the brain" whereby exposure to known inciting factors such as systemic infection and offending drugs can unmask a decreased cerebral reserve and herald a serious underlying and potentially treatable illness. New blood-based biomarkers for specific dementias may soon be available to help predict people at risk for delirium before surgical procedures or hospitalization.

APPROACH TO THE PATIENT

Delirium

Because the diagnosis of delirium is clinical and is made at the bedside, a careful history and physical examination are necessary in evaluating patients with possible confusional states. Screening tools can aid physicians and nurses in identifying patients with delirium, including the Confusion Assessment Method (CAM); the Nursing Delirium Screening Scale (NuDESC); the Organic Brain Syndrome Scale; the Delirium Rating Scale; and, in the ICU, the ICU version of the CAM and the Delirium Detection Score. Using the well-validated CAM, a diagnosis of delirium is made if there is (1) an acute onset and fluctuating course and (2) inattention accompanied by either (3) disorganized thinking or (4) an altered level of consciousness **(Table 27-1)**. These scales may not identify the full spectrum of patients with delirium, and all patients who are acutely confused should be presumed delirious regardless of their presentation due to the wide variety of possible clinical features. A course that fluctuates over hours or days and may worsen at night (termed *sundowning*) is typical but not essential for the diagnosis. Observation will usually reveal an altered level of consciousness or a deficit of attention. Other features that are sometimes present include alteration of sleep-wake cycles, thought disturbances such as hallucinations or delusions, autonomic instability, and changes in affect.

HISTORY

It may be difficult to elicit an accurate history in delirious patients who have altered levels of consciousness or impaired attention. Information from a collateral source such as a spouse or another family member is therefore invaluable. The three most important pieces of history are the patient's baseline cognitive function, the time course of the present illness, and current medications.

Premorbid cognitive function can be assessed through the collateral source or, if needed, via a review of outpatient records. Delirium by definition represents a change that is relatively acute and usually developing over hours to days, from a cognitive baseline. An acute confusional state is nearly impossible to diagnose without some knowledge of baseline cognitive function. Without

TABLE 27-1 The Confusion Assessment Method (CAM) Diagnostic Algorithm[a]

The diagnosis of delirium requires the presence of features 1 and 2 **and** *either* feature 3 or 4.
Feature 1. Acute Onset and Fluctuating Course
This feature is satisfied by positive responses to the following questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day, that is, tend to come and go, or did it increase and decrease in severity?
Feature 2. Inattention
This feature is satisfied by a positive response to the following question: Did the patient have difficulty focusing attention, for example, being easily distractible, or have difficulty keeping track of what was being said?
Feature 3. Disorganized Thinking
This feature is satisfied by a positive response to the following question: Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?
Feature 4. Altered Level of Consciousness
This feature is satisfied by any answer other than "alert" to the following question: Overall, how would you rate the patient's level of consciousness: alert (normal), vigilant (hyperalert), lethargic (drowsy, easily aroused), stupor (difficult to arouse), or coma (unarousable)?

[a]Information is usually obtained from a reliable reporter, such as a family member, caregiver, or nurse.

this information, many patients with dementia or longstanding depression may be mistaken as delirious during a single initial evaluation. Patients with a more hypoactive, apathetic presentation with psychomotor slowing may be identified as being different from baseline only through conversations with family members. A number of validated instruments have been shown to diagnose cognitive dysfunction accurately using a collateral source, including the modified Blessed Dementia Rating Scale and the Clinical Dementia Rating (CDR). Baseline cognitive impairment is common in patients with delirium. Even when no such history of cognitive impairment is elicited, there should still be a high suspicion for a previously unrecognized underlying neurologic disorder.

Establishing the time course of cognitive change is important not only to make a diagnosis of delirium but also to correlate the onset of the illness with potentially treatable etiologies such as recent medication changes or symptoms of systemic infection.

Medications remain a common cause of delirium, especially compounds with anticholinergic or sedative properties. It is estimated that nearly one-third of all cases of delirium are secondary to medications, especially in the elderly. Medication histories should include all prescription as well as over-the-counter and herbal substances taken by the patient and any recent changes in dosing or formulation, including substitution of generics for brand-name medications.

Other important elements of the history include screening for symptoms of organ failure or systemic infection, which often contributes to delirium in the elderly. A history of illicit drug use, alcoholism, or toxin exposure is common in younger delirious patients. Finally, asking the patient and collateral source about other symptoms that may accompany delirium, such as depression, may help identify potential therapeutic targets.

PHYSICAL EXAMINATION

The general physical examination in a delirious patient should include careful screening for signs of infection such as fever, tachypnea, pulmonary consolidation, heart murmur, and meningismus. The patient's fluid status should be assessed; both dehydration and fluid overload with resultant hypoxemia have been associated with delirium, and each is usually easily rectified. The appearance of the skin can be helpful, showing jaundice in hepatic encephalopathy, cyanosis in hypoxemia, or needle tracks in patients using intravenous drugs.

The neurologic examination requires a careful assessment of mental status. Patients with delirium often present with a fluctuating course; therefore, the diagnosis can be missed when one relies on a single time point of evaluation. For patients who worsen in the evening (sundowning), assessment only during morning rounds may be falsely reassuring.

An altered level of consciousness ranging from hyperarousal to lethargy to coma is present in most patients with delirium and can be assessed easily at the bedside. In a patient with a relatively normal level of consciousness, a screen for an attentional deficit is in order, because this deficit is the classic neuropsychological hallmark of delirium. Attention can be assessed while taking a history from the patient. Tangential speech, a fragmentary flow of ideas, or inability to follow complex commands often signifies an attentional problem. There are formal neuropsychological tests to assess attention, but a simple bedside test of digit span forward is quick and fairly sensitive. In this task, patients are asked to repeat successively longer random strings of digits beginning with two digits in a row, said to the patient at one per second intervals. Healthy adults can repeat a string of five to seven digits before faltering; a digit span of four or less usually indicates an attentional deficit unless hearing or language barriers are present, and many patients with delirium have digit spans of three or fewer digits.

More formal neuropsychological testing can be helpful in assessing a delirious patient, but it is usually too cumbersome and time-consuming in the inpatient setting. A Mini-Mental State Examination (MMSE) provides information regarding orientation, language, and visuospatial skills **(Chap. 29)**; however, performance of many tasks on the MMSE, including the spelling of "world" backward and serial subtraction of digits, will be impaired by delirious patients' attentional deficits, rendering the test unreliable.

The remainder of the screening neurologic examination should focus on identifying new focal neurologic deficits. Focal strokes or mass lesions in isolation are rarely the cause of delirium, but patients with underlying extensive cerebrovascular disease or neurodegenerative conditions may not be able to cognitively tolerate even relatively small new insults. Patients should be screened for other signs of neurodegenerative conditions such as parkinsonism, which is seen not only in idiopathic Parkinson's disease but also in other dementing conditions including Alzheimer's disease, dementia with Lewy bodies, and progressive supranuclear palsy. The presence of multifocal myoclonus or asterixis on the motor examination is nonspecific but usually indicates a metabolic or toxic etiology of the delirium.

ETIOLOGY

Some etiologies can be easily discerned through a careful history and physical examination, whereas others require confirmation with laboratory studies, imaging, or other ancillary tests. A large, diverse group of insults can lead to delirium, and the cause in many patients is multifactorial. Common etiologies are listed in **Table 27-2**.

Prescribed, over-the-counter, and herbal medications all can precipitate delirium. Drugs with anticholinergic properties, narcotics, and benzodiazepines are particularly common offenders, but nearly any compound can lead to cognitive dysfunction in a predisposed patient. Whereas an elderly patient with baseline dementia may become delirious upon exposure to a relatively low dose of a medication, in less susceptible individuals, delirium occurs only with very high doses of the same medication. This observation emphasizes the importance of correlating the timing of recent medication changes, including dose and formulation, with the onset of cognitive dysfunction.

In younger patients, illicit drugs and toxins are common causes of delirium. In addition to more classic drugs of abuse, the availability of "bath salts," synthetic cannabis **(Chap. 455)**, methylenedioxymethamphetamine (MDMA, ecstasy), γ-hydroxybutyrate (GHB), and the phencyclidine (PCP)-like agent ketamine has led to an increase in delirious young persons presenting to acute care settings **(Chap. 457)**. Many common prescription drugs such as oral narcotics and benzodiazepines are often abused and readily available on the street. Alcohol abuse leading to high serum levels causes confusion, but more commonly, it is withdrawal from alcohol that leads to a hyperactive delirium **(Chap. 453)**. Alcohol and benzodiazepine withdrawal should be considered in all cases of delirium, including in the elderly, because even patients who drink only a few servings of alcohol every day can experience relatively severe withdrawal symptoms upon hospitalization.

Metabolic abnormalities such as electrolyte disturbances of sodium, calcium, magnesium, or glucose can cause delirium, and mild derangements can lead to substantial cognitive disturbances in susceptible individuals. Other common metabolic etiologies include liver and renal failure, hypercarbia and hypoxemia, vitamin deficiencies of thiamine and B_{12}, autoimmune disorders including central nervous system (CNS) vasculitis, and endocrinopathies such as thyroid and adrenal disorders.

Systemic infections often cause delirium, especially in the elderly. A common scenario involves the development of an acute cognitive decline in the setting of a urinary tract infection in a patient with baseline dementia. Pneumonia, skin infections such as cellulitis, and frank sepsis also lead to delirium. This so-called septic encephalopathy, often seen in the ICU, is probably due to the release of proinflammatory cytokines and their diffuse cerebral effects. CNS infections such as meningitis, encephalitis, and abscess are less common etiologies of delirium, as are cases of autoimmune or

TABLE 27-2 Differential Diagnosis of Delirium

Toxins
Prescription medications: especially those with anticholinergic properties, narcotics, and benzodiazepines
Drugs of abuse: alcohol intoxication and alcohol withdrawal, opiates, ecstasy, LSD, GHB, PCP, ketamine, cocaine, "bath salts," marijuana and its synthetic forms
Poisons: inhalants, carbon monoxide, ethylene glycol, pesticides
Metabolic Conditions
Electrolyte disturbances: hypoglycemia, hyperglycemia, hyponatremia, hypernatremia, hypercalcemia, hypocalcemia, hypomagnesemia
Hypothermia and hyperthermia
Pulmonary failure: hypoxemia and hypercarbia
Liver failure/hepatic encephalopathy
Renal failure/uremia
Cardiac failure
Vitamin deficiencies: B_{12}, thiamine, folate, niacin
Dehydration and malnutrition
Anemia
Infections
Systemic infections: urinary tract infections, pneumonia, skin and soft tissue infections, sepsis
CNS infections: meningitis, encephalitis, brain abscess
Endocrine Conditions
Hyperthyroidism, hypothyroidism
Hyperparathyroidism
Adrenal insufficiency
Cerebrovascular Disorders
Global hypoperfusion states
Hypertensive encephalopathy
Focal ischemic strokes and hemorrhages (rare): especially nondominant parietal and thalamic lesions
Autoimmune Disorders
CNS vasculitis
Cerebral lupus
Neurologic paraneoplastic and autoimmune encephalitis
Seizure-Related Disorders
Nonconvulsive status epilepticus
Intermittent seizures with prolonged postictal states
Neoplastic Disorders
Diffuse metastases to the brain
Gliomatosis cerebri
Carcinomatous meningitis
CNS lymphoma
Hospitalization
Terminal end-of-life delirium

Abbreviations: CNS, central nervous system; GHB, γ-hydroxybutyrate; LSD, lysergic acid diethylamide; PCP, phencyclidine.

paraneoplastic encephalitis; however, in light of the high morbidity and mortality rates associated with these conditions when they are not treated, clinicians must always maintain a high index of suspicion.

In some susceptible individuals, exposure to the unfamiliar environment of a hospital itself can contribute to delirium. This etiology usually occurs as part of a multifactorial delirium and should be considered a diagnosis of exclusion after all other causes have been thoroughly investigated. Many primary prevention and treatment strategies for delirium involve relatively simple methods to address the aspects of the inpatient setting that are most confusing.

Cerebrovascular etiologies of delirium are usually due to global hypoperfusion in the setting of systemic hypotension from heart failure, septic shock, dehydration, or anemia. Focal strokes in the right parietal lobe and medial dorsal thalamus rarely can lead to a delirious state. A more common scenario involves a new focal stroke or hemorrhage causing confusion in a patient who has decreased cerebral reserve. In these individuals, it is sometimes difficult to distinguish between cognitive dysfunction resulting from the new neurovascular insult itself and delirium due to the infectious, metabolic, and pharmacologic complications that can accompany hospitalization after stroke.

Because a fluctuating course often is seen in delirium, intermittent seizures may be overlooked when one is considering potential etiologies. Both nonconvulsive status epilepticus and recurrent focal or generalized seizures followed by postictal confusion can cause delirium; EEG remains essential for this diagnosis and should be considered whenever the etiology of delirium remains unclear following initial workup. Seizure activity spreading from an electrical focus in a mass or infarct can explain global cognitive dysfunction caused by relatively small lesions.

It is extremely common for patients to experience delirium at the end of life in palliative care settings. This condition must be identified and treated aggressively because it is an important cause of patient and family discomfort at the end of life. It should be remembered that these patients also may be suffering from more common etiologies of delirium such as systemic infection.

LABORATORY AND DIAGNOSTIC EVALUATION

A cost-effective approach allows the history and physical examination to guide further tests. No single algorithm will fit all delirious patients due to the staggering number of potential etiologies, but one stepwise approach is detailed in **Table 27-3**. If a clear precipitant such as an offending medication is identified, further testing may not be required. If, however, no likely etiology is uncovered with initial evaluation, an aggressive search for an underlying cause should be initiated.

Basic screening labs, including a complete blood count, electrolyte panel, and tests of liver and renal function, should be obtained in all patients with delirium. In elderly patients, screening for systemic infection, including chest radiography, urinalysis and culture, and possibly blood cultures, is important. In younger individuals, serum and urine drug and toxicology screening may be appropriate earlier in the workup. Additional laboratory tests addressing other autoimmune, endocrinologic, metabolic, and infectious etiologies should be reserved for patients in whom the diagnosis remains unclear after initial testing.

Multiple studies have demonstrated that brain imaging in patients with delirium is often unhelpful. If, however, the initial workup is unrevealing, most clinicians quickly move toward imaging of the brain to exclude structural causes. A noncontrast computed tomography (CT) scan can identify large masses and hemorrhages but is otherwise unlikely to help determine an etiology of delirium. The ability of magnetic resonance imaging (MRI) to identify most acute ischemic strokes as well as to provide neuroanatomic detail that gives clues to possible infectious, inflammatory, neurodegenerative, and neoplastic conditions makes it the test of choice. Because MRI techniques are limited by availability, speed of imaging, patient's cooperation, and contraindications, many clinicians begin with CT scanning and proceed to MRI if the etiology of delirium remains elusive.

Lumbar puncture (LP) must be obtained immediately after neuroimaging for all patients in whom CNS infection is suspected. Spinal fluid examination can also be useful in identifying autoimmune, other inflammatory, and neoplastic conditions. As a result, LP should be considered in any delirious patient with a negative workup. EEG remains invaluable if seizures are considered or if there is no cause readily identified.

TABLE 27-3 Stepwise Evaluation of a Patient with Delirium

Initial Evaluation
History with special attention to medications (including over-the-counter and herbals)
General physical examination and neurologic examination
Complete blood count
Electrolyte panel including calcium, magnesium, phosphorus
Liver function tests, including albumin
Renal function tests
First-Tier Further Evaluation Guided by Initial Evaluation
Systemic infection screen
Urinalysis and culture
Chest radiograph
Blood cultures
Electrocardiogram
Arterial blood gas
Serum and/or urine toxicology screen (perform earlier in young persons)
Brain imaging with MRI with diffusion and gadolinium (preferred) or CT
Suspected CNS infection or other inflammatory disorder: lumbar puncture after brain imaging
Suspected seizure-related etiology: electroencephalogram (EEG) (if high suspicion, should be performed immediately)
Second-Tier Further Evaluation
Vitamin levels: B_{12}, folate, thiamine
Endocrinologic laboratories: thyroid-stimulating hormone (TSH) and free T_4; cortisol
Serum ammonia
Sedimentation rate
Autoimmune serologies: antinuclear antibodies (ANA), complement levels; p-ANCA, c-ANCA, consider paraneoplastic/autoimmune encephalitis serologies
Infectious serologies: rapid plasmin reagin (RPR); fungal and viral serologies if high suspicion; HIV antibody
Lumbar puncture (if not already performed)
Brain MRI with and without gadolinium (if not already performed)

Abbreviations: c-ANCA, cytoplasmic antineutrophil cytoplasmic antibody; CNS, central nervous system; CT, computed tomography; MRI, magnetic resonance imaging; p-ANCA, perinuclear antineutrophil cytoplasmic antibody.

FIGURE 27-1 Delirium management and prevention: a checklist for hospitalized patients. Effective management of delirium relies on broad efforts to promote wakefulness (***A***) and sleep (***B***). CPO, continuous pulse oximetry.

TREATMENT

Delirium

Management of delirium begins with treatment of the underlying inciting factor (e.g., patients with systemic infections should be given appropriate antibiotics, and underlying electrolyte disturbances should be judiciously corrected). These treatments often lead to prompt resolution of delirium. Blindly targeting the symptoms of delirium pharmacologically only serves to prolong the time patients remain in the confused state and may mask important diagnostic information.

Relatively simple methods of supportive care can be highly effective (Fig. 27-1). Reorientation by the nursing staff and family combined with visible clocks, calendars, and outside-facing windows can reduce confusion. Sensory isolation should be prevented by providing glasses and hearing aids to patients who need them. Sundowning can be addressed to a large extent through vigilance to appropriate sleep-wake cycles. During the day, a well-lit room should be accompanied by activities or exercises to prevent napping. At night, a quiet, dark environment with limited interruptions by staff can assure proper rest; melatonin can be considered before bed to promote sleep. These sleep-wake cycle interventions are especially important in the ICU setting as the usual constant 24-h activity commonly provokes delirium. Attempting to mimic the home environment as much as possible also has been shown to help treat and even prevent delirium. Visits from friends and family throughout the day minimize the anxiety associated with the constant flow of new faces of staff and physicians. Allowing hospitalized patients to have access to home bedding, clothing, and nightstand objects makes the hospital environment less foreign and therefore less confusing. Simple standard nursing practices such as maintaining proper nutrition and volume status as well as managing pain, incontinence, and skin breakdown also help alleviate discomfort and resulting confusion.

In some instances, patients pose a threat to their own safety or to the safety of staff members, and acute management is required. Bed alarms and personal sitters are more effective and much less disorienting than physical restraints. Chemical restraints should be avoided, but when necessary, very-low-dose typical or atypical antipsychotic medications administered on an as-needed basis can be used, recognizing that clinical trials have consistently shown that these medications are ineffective in treating delirium. Therefore, they should be reserved for patients who display severe agitation and significant potential to harm themselves or staff. The association of antipsychotic use in the elderly with increased mortality rates underscores the importance of using these medications judiciously and only as a last resort. Benzodiazepines often worsen

confusion through their sedative properties. Although many clinicians use benzodiazepines to treat acute confusion, their use should be limited to cases in which delirium is caused by alcohol or benzodiazepine withdrawal.

PREVENTION

In light of the high morbidity associated with delirium and the tremendously increased health care costs that accompany it, development of an effective strategy to prevent delirium in hospitalized patients is extremely important. Successful identification of high-risk patients is the first step, followed by initiation of appropriate interventions. Increasingly, hospitals are using nursing or physician-administered tools to screen for high-risk individuals, triggering simple standardized protocols used to manage risk factors for delirium, including sleep-wake cycle reversal, immobility, visual impairment, hearing impairment, sleep deprivation, and dehydration. No specific medications have been definitively shown to be effective for delirium prevention, including trials of cholinesterase inhibitors and antipsychotic agents. Melatonin and its agonist ramelteon have shown some promising results in small preliminary trials. Recent studies in the ICU have focused both on identifying sedatives, such as dexmedetomidine, that are less likely to lead to delirium in critically ill patients and on developing protocols for daily awakenings in which infusions of sedative medications are interrupted and the patient is reorientated by the staff. All hospitals and health care systems should work toward decreasing the incidence of delirium and promptly recognizing and treating the disorder when it occurs.

28 Coma

S. Andrew Josephson, Allan H. Ropper, Stephen L. Hauser

Coma is among the most common neurologic emergencies encountered general medicine and requires an organized approach. It accounts for a substantial portion of admissions to emergency wards and occurs on all hospital services.

There exists a continuum of states of reduced alertness, the most severe form being coma, defined as a deep sleeplike state with eyes closed, from which the patient cannot be aroused. Stupor refers to a lower threshold for arousability, in which the patient can be transiently awakened by vigorous stimuli, accompanied by motor behavior that leads to avoidance or withdrawal from noxious stimuli. Drowsiness simulates light sleep and is characterized by easy arousal that may persist for brief periods. Stupor and drowsiness are usually accompanied by some degree of confusion when the patient is alerted **(Chap. 27)**. A precise narrative description of the level of arousal and of the type of responses evoked by various stimuli as observed at the bedside is preferable to use of ambiguous terms such as lethargy, semicoma, or obtundation.

Several conditions that render patients unresponsive and simulate coma are considered separately because of their special significance. The *vegetative state* signifies an awake-appearing but nonresponsive state, usually encountered in a patient who has emerged from coma. In the vegetative state, the eyelids may open periodically, giving the appearance of wakefulness. Respiratory and autonomic functions are retained. Yawning, coughing, swallowing, and limb and head movements persist, but there are few, if any, meaningful responses to the external and internal environment. There are typically accompanying signs that indicate extensive damage in both cerebral hemispheres, e.g., decerebrate or decorticate limb posturing and absent responses to visual stimuli (see below). In the closely related but less severe *minimally conscious state*, the patient displays rudimentary vocal or motor behaviors, often spontaneous, but sometimes in response to touch, visual stimuli, or command. Cardiac arrest with cerebral hypoperfusion and head trauma are the most common causes of the vegetative and minimally conscious states **(Chap. 307)**.

The prognosis for regaining meaningful mental faculties once the vegetative state has supervened for several months is poor, and after a year, almost nil; hence the term *persistent vegetative state*. Most reports of dramatic recovery, when investigated carefully, are found to yield to the usual rules for prognosis, but there have been rare instances in which recovery has occurred to a severely disabled condition and, in rare childhood cases, to an even better state. Patients in the minimally conscious state carry a better prognosis for some recovery compared to those in a persistent vegetative state, but even in these patients, dramatic recovery after 12 months is unusual.

The possibility of incorrectly attributing meaningful behavior to patients in the vegetative and minimally conscious states creates problems and anguish for families and physicians. The question of whether some of these patients have the capability for cognition has been investigated by functional MRI and electroencephalogram (EEG) studies that have demonstrated cerebral activation that is temporally consistent in response to verbal and other stimuli, as discussed in more detail below. This finding suggests at a minimum that some of these patients could in the future be able to communicate their needs using technological advances and that further research could shed light on treatment approaches targeting areas of the brain and their connections that seem to be preserved in individual patients.

Several syndromes that affect alertness are prone to be misinterpreted as stupor or coma, and clinicians should be aware of these pitfalls when diagnosing coma at the bedside. Akinetic mutism refers to a partially or fully awake state in which the patient remains virtually immobile and mute but can form impressions and think, as demonstrated by later recounting of events. This condition results from damage in the regions of the medial thalamic nuclei or the frontal lobes (particularly lesions situated deeply or on the orbitofrontal surfaces) or from extreme hydrocephalus. The term *abulia* describes a milder form of akinetic mutism characterized by mental and physical slowness and diminished ability to initiate activity. It is also usually the result of damage to the medial frontal lobes and their connections **(Chap. 30)**.

Catatonia is a hypomobile and mute syndrome that occurs usually as part of a major psychosis, typically schizophrenia or major depression. Catatonic patients make few voluntary or responsive movements, although they blink, swallow, and may not appear distressed. There are nevertheless signs that the patient is responsive, although it takes a careful examination to demonstrate these features. For example, eyelid elevation is actively resisted, blinking occurs in response to a visual threat, and the eyes move concomitantly with head rotation, all of which are inconsistent with the presence of a brain lesion causing unresponsiveness. The limbs may retain postures in which they have been placed by the examiner ("waxy flexibility," or catalepsy). With recovery from catatonia, patients often have some memory of events that occurred during their stupor. Catatonia is superficially similar to akinetic mutism, but clinical evidence of cerebral damage such as hyperreflexia and hypertonicity of the limbs is lacking in the former. The special problem of coma in brain death is discussed below.

The locked-in state describes a type of pseudocoma in which an awake but paralyzed patient has no means of producing speech or volitional limb movement but retains voluntary vertical eye movements and lid elevation, thus allowing the patient to communicate. The pupils are normally reactive. The usual cause is an infarction (e.g., basilar artery thrombosis) or hemorrhage of the bilateral ventral pons that transects all descending motor (corticospinal and corticobulbar) pathways. Another awake but de-efferented state occurs as a result of total paralysis of the musculature in severe cases of neuromuscular weakness such as in Guillain-Barré syndrome (Chap. 447), critical illness neuropathy (Chap. 307), or pharmacologic neuromuscular blockade.

THE ANATOMY AND PHYSIOLOGY OF COMA

Almost all instances of coma can be traced to either (1) widespread abnormalities of the cerebral hemispheres or (2) reduced activity of the thalamocortical alerting system, the reticular activating system (RAS), which is an assemblage of neurons located diffusely in the upper brainstem and thalamus. The proper functioning of this system, its ascending projections to the cortex, and the cortex itself are required to maintain alertness and coherence of thought. In addition to structural damage to either or both of these systems, suppression of reticulocerebral function commonly occurs by drugs, toxins, or metabolic derangements such as hypoglycemia, anoxia, uremia, and hepatic failure, or by seizures; these types of metabolic causes of coma are far more common than structural injuries.

Coma Due to Cerebral Mass Lesions and Herniation Syndromes The skull prevents outward expansion of the brain, and infoldings of the dura create compartments that restrict displacement of brain tissue within the cranium. The two cerebral hemispheres are separated by the falx and the anterior and posterior fossae by the tentorium. Herniation refers to displacement of brain tissue by an intracerebral or overlying mass into a contiguous compartment that it normally does not occupy. Coma from mass lesions, and many of its associated signs, are attributable to these tissue shifts, and certain clinical features are characteristic of specific configurations of herniation (Fig. 28-1).

In the most common form of herniation, brain tissue is displaced from the supratentorial to the infratentorial compartment through the tentorial opening, referred to as transtentorial herniation. The cause is often a mass hemispheral lesion, with accompanying contralateral hemiparesis. Uncal transtentorial herniation refers to impaction of the anterior medial temporal gyrus (the uncus) into the tentorial opening just anterior to and adjacent to the midbrain (Fig. 28-1*A*). The uncus can compress the third nerve as the nerve traverses the subarachnoid space, causing enlargement of the ipsilateral pupil as the first sign (the fibers subserving parasympathetic pupillary function are located peripherally in the nerve). The coma that typically follows is due to lateral displacement of the midbrain (and therefore the RAS) against the opposite tentorial edge by the displaced parahippocampal gyrus (Fig. 28-2), compressing the opposite cerebral peduncle and producing a Babinski sign and ipsilateral hemiparesis (the Kernohan-Woltman sign). Herniation may also compress the anterior and posterior cerebral arteries as they pass over the tentorial reflections, with resultant brain infarction. These distortions may also entrap portions of the ventricular system, causing hydrocephalus.

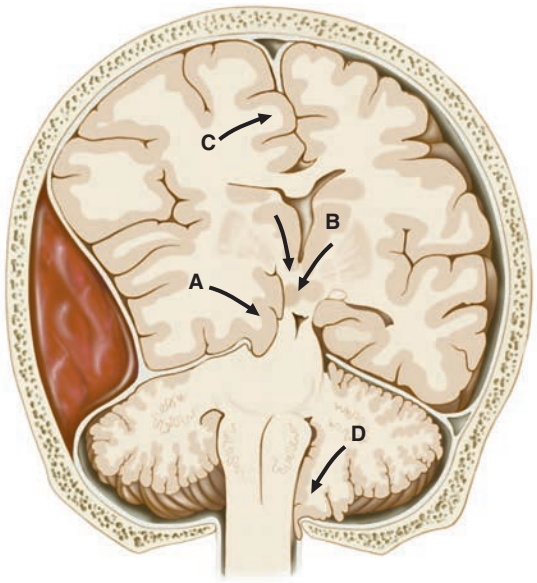

FIGURE 28-1 Types of cerebral herniation: (***A***) uncal; (***B***) central; (***C***) transfalcial; and (***D***) foraminal.

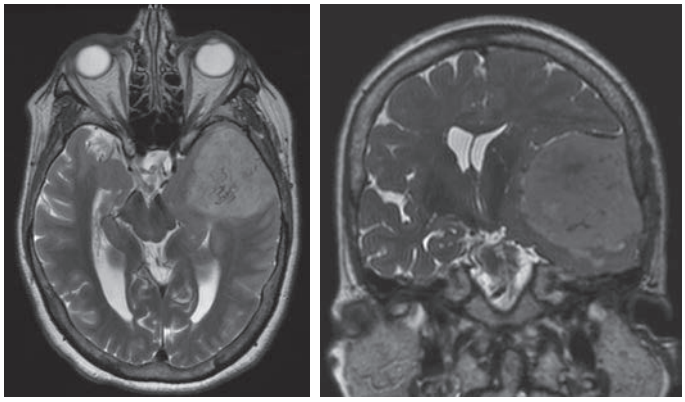

A ***B***

FIGURE 28-2 Axial (A) and coronal (B) T2-weighted magnetic resonance images from a stuporous patient with a left third nerve palsy from a large left-sided meningioma. A. The upper midbrain is compressed and displaced horizontally away from the mass, and there is transtentorial herniation of the medial temporal lobe structures, including the uncus. **B.** The lateral ventricle opposite to the mass has become enlarged as a result of compression of the third ventricle.

Central transtentorial herniation denotes a symmetric downward movement of the thalamic structures through the tentorial opening with compression of the upper midbrain (Fig. 28-1*B*). Miotic pupils and drowsiness are the heralding signs, in contrast to a unilaterally enlarged pupil of the uncal syndrome. Both uncal and central transtentorial herniations cause progressive compression of the brainstem and RAS, with initial damage to the midbrain, then the pons, and finally the medulla. The result is an approximate sequence of neurologic signs that corresponds to each affected level, with respiratory centers in the brainstem often spared until late in the herniation syndrome. Other forms of herniation include transfalcial herniation (displacement of the cingulate gyrus under the falx and across the midline, Fig. 28-1*C*) and foraminal herniation (downward forcing of the cerebellar tonsils into the foramen magnum, Fig. 28-1*D*), which causes early compression of the medulla, respiratory arrest, and death.

Coma Due to Metabolic, Drug, and Toxic Disorders Many systemic metabolic abnormalities cause coma by interrupting the delivery of energy substrates (e.g., oxygen, glucose) or by altering neuronal excitability (drugs and alcohol, anesthesia, and epilepsy). These are the most common causes of coma in large case series. The metabolic abnormalities that produce coma may, in milder forms, induce a confusional state (metabolic encephalopathy) in which clouded consciousness and coma are in a continuum.

Cerebral neurons are dependent on cerebral blood flow (CBF) and the delivery of oxygen and glucose. Brain stores of glucose are able to provide energy for ~2 min after blood flow is interrupted, and oxygen stores last 8–10 s after the cessation of blood flow. Simultaneous hypoxia and ischemia exhaust glucose more rapidly. The EEG rhythm in these circumstances becomes diffusely slowed, typical of metabolic encephalopathies, and as substrate delivery worsens, eventually brain electrical activity ceases.

Unlike hypoxia-ischemia, which first causes a metabolic encephalopathy due to reduced energy substrate but ultimately causes neuronal destruction, most metabolic disorders such as hypoglycemia, hyponatremia, hyperosmolarity, hypercapnia, hypercalcemia, and hepatic and renal failure cause no or only minor neuropathologic changes in the

brain. The reversible effects of these conditions are not fully understood but may result from impaired energy supplies, changes in ion fluxes across neuronal membranes, and neurotransmitter abnormalities. In hepatic encephalopathy (HE), high ammonia concentrations lead to increased synthesis of glutamine in astrocytes and osmotic swelling of the cells, mitochondrial energy failure, production of reactive nitrogen and oxygen species, increases in the inhibitory neurotransmitter GABA, and synthesis of putative "false" neurotransmitters. Over time, development of a diffuse astrocytosis is typical of chronic HE. Which, if any, of these is responsible for coma is not known.

The mechanism of the encephalopathy of renal failure is also uncertain and likely to be multifactorial; unlike ammonia, urea does not produce central nervous system (CNS) depression. Contributors to uremic encephalopathy may include accumulation of neurotoxic substances such as creatinine, guanidine, and related compounds; depletion of catecholamines; altered glutamate and GABA tone; increases in brain calcium; inflammation with disruption of the blood-brain barrier; and frequent coexisting vascular disease.

Coma and seizures are common accompaniments of large shifts in sodium and water balance in the brain. These changes in osmolarity arise from systemic medical disorders, including diabetic ketoacidosis, the nonketotic hyperosmolar state, and hyponatremia from any cause (e.g., water intoxication, excessive secretion of antidiuretic hormone, or atrial natriuretic peptides). Sodium levels <125 mmol/L, especially if achieved quickly, induce confusion, and levels <119 mmol/L are typically associated with coma and convulsions. In hyperosmolar coma, the serum osmolarity is generally >350 mosmol/L. Hypercapnia depresses the level of consciousness in proportion to the rise in carbon dioxide (CO_2) in the blood. In all of these metabolic encephalopathies, the degree of neurologic change depends on the rapidity with which the serum changes occur. The pathophysiology of other metabolic encephalopathies such as those due to hypercalcemia, hypothyroidism, vitamin B_{12} deficiency, and hypothermia are incompletely understood but must reflect derangements of CNS biochemistry, membrane function, or neurotransmitters.

Comas due to drugs and toxins are typically reversible and leave no residual damage provided there has not been hypoxia or severe hypotension. Many drugs and toxins are capable of depressing nervous system function. Some produce coma by affecting both the RAS and the cerebral cortex. The combination of cortical and brainstem signs, which occurs occasionally in certain drug overdoses, may lead to an incorrect diagnosis of structural brainstem disease. Overdose of medications that have atropinic actions produces signs such as dilated pupils, tachycardia, and dry skin; opiate overdose produces pinpoint pupils <1 mm in diameter. Some drug intoxications, typified by barbiturates, can mimic all of the signs of brain death; thus, toxic etiologies should be excluded prior to making a diagnosis of brain death.

Epileptic Coma Generalized electrical seizures are associated with coma, even in the absence of motor convulsions (nonconvulsive status epilepticus). As a result, EEG monitoring is often used in the evaluation of unexplained coma to exclude this treatable etiology. The self-limited coma that follows a seizure, the postictal state, may be due to exhaustion of energy reserves or effects of locally toxic molecules that are the by-product of seizures. The postictal state produces continuous, generalized slowing of the background EEG activity similar to that of metabolic encephalopathies. It typically lasts for a few minutes but in some cases can be prolonged for hours or even rarely for days.

Coma Due to Widespread Structural Damage to the Cerebral Hemispheres This category, comprising several unrelated disorders, results from extensive bilateral structural cerebral damage. The clinical appearance simulates a metabolic encephalopathy. Hypoxia-ischemia is perhaps the best characterized form of this type of injury, in which it is not possible initially to distinguish the acute reversible effects of oxygen deprivation of the brain from the subsequent effects of anoxic neuronal damage. Similar cerebral damage may be produced by disorders that occlude widespread small blood vessels throughout the brain; examples include thrombotic thrombocytopenic purpura, hyperviscosity, and cerebral malaria. Diffuse white matter damage from cranial trauma or inflammatory demyelinating diseases can cause a similar coma syndrome.

APPROACH TO THE PATIENT

Coma

A video examination of the comatose patient is shown in Chap. V4. Acute respiratory and cardiovascular problems should be attended to prior to neurologic assessment. In most instances, a complete medical evaluation, except for vital signs, funduscopy, and examination for nuchal rigidity, may be deferred until the neurologic evaluation has established the severity and nature of coma. **The approach to the patient with coma from cranial trauma is discussed in Chap. 443.**

HISTORY

The cause of coma may be immediately evident as in cases of trauma, cardiac arrest, or observed drug ingestion. In the remainder, certain points are useful: (1) the circumstances and rapidity with which neurologic symptoms developed; (2) antecedent symptoms (confusion, weakness, headache, fever, seizures, dizziness, double vision, or vomiting); (3) the use of medications, drugs, or alcohol; and (4) chronic liver, kidney, lung, heart, or other medical disease. Direct interrogation of family, observers, and emergency medical technicians on the scene, in person or by telephone, is an important part of the evaluation when possible.

GENERAL PHYSICAL EXAMINATION

Signs of head trauma raise the possibility of coexisting spinal cord injury, and in such cases, immobilization of the cervical spine is essential to prevent further injury. Fever suggests a systemic infection, bacterial meningitis, encephalitis, heat stroke, neuroleptic malignant syndrome, malignant hyperthermia due to anesthetics, or anticholinergic drug intoxication. Only rarely is fever attributable to a lesion that has disturbed hypothalamic temperature-regulating centers ("central fever"), and this diagnosis should only be considered after an exhaustive search for other causes fails to reveal an explanation for fever. A slight elevation in temperature may follow vigorous convulsions. Hypothermia is observed with alcohol, barbiturate, sedative, or phenothiazine intoxication; hypoglycemia; peripheral circulatory failure; or extreme hypothyroidism. Hypothermia itself causes coma when the temperature is <31°C (87.8°F) regardless of the underlying etiology; less dramatically low body temperatures can also cause coma in some instances. Tachypnea may indicate systemic acidosis or pneumonia. Aberrant respiratory patterns that reflect brainstem disorders are discussed below. Marked hypertension suggests hypertensive encephalopathy, cerebral hemorrhage, large cerebral infarction, or head injury. Hypotension is characteristic of coma from alcohol or barbiturate intoxication, internal hemorrhage or myocardial infarction causing poor delivery of blood to the brain, sepsis, profound hypothyroidism, or Addisonian crisis. The funduscopic examination can detect increased intracranial pressure (ICP) (papilledema), subarachnoid hemorrhage (subhyaloid hemorrhages), and hypertensive encephalopathy (exudates, hemorrhages, vessel-crossing changes, papilledema). Cutaneous petechiae suggest thrombotic thrombocytopenic purpura, meningococcemia, or a bleeding diathesis associated with an intracerebral hemorrhage. Cyanosis and reddish or anemic skin coloration are other indications of an underlying systemic disease or carbon monoxide as responsible for the coma.

NEUROLOGIC EXAMINATION

The patient should first be observed without intervention by the examiner. Spontaneously moving about the bed, reaching up toward the face, crossing legs, yawning, swallowing, coughing, and moaning reflect a drowsy state that is close to normal awakeness. Lack of restless movements on one side or an outturned leg suggests hemiplegia. Subtle, intermittent twitching movements of a foot, finger, or

facial muscle may be the only sign of seizures. Multifocal myoclonus usually indicates a metabolic disorder, particularly uremia, anoxia, drug intoxication, or rarely a prion disease **(Chap. 438)**. In a drowsy and confused patient, bilateral asterixis is a sign of metabolic encephalopathy or drug intoxication.

Decorticate rigidity and decerebrate rigidity, or "posturing," describe stereotyped arm and leg movements occurring spontaneously or elicited by sensory stimulation. Flexion of the elbows and wrists and supination of the arm (decorticate posturing) classically suggest bilateral damage rostral to the midbrain, whereas extension of the elbows and wrists with pronation (decerebrate posturing) indicates damage to motor tracts caudal to the midbrain. However, these localizations have been adapted from animal work and cannot be applied with precision to coma in humans. In fact, acute and widespread disorders of any type, regardless of location, frequently cause limb extension.

LEVEL OF AROUSAL

A sequence of increasingly intense stimuli is first used to determine the threshold for arousal and the motor response of each side of the body. The results of testing may vary from minute to minute, and serial examinations are useful. Tickling the nostrils with a cotton wisp is a moderate stimulus to arousal—all but deeply stuporous and comatose patients will move the head away and arouse to some degree. An even greater degree of responsiveness is present if the patient uses his hand to remove an offending stimulus. Pressure on bony prominences and pinprick stimulation, when necessary, are humane forms of noxious stimuli; pinching the skin causes ecchymoses and is generally not performed but may be useful in eliciting abduction withdrawal movements of the limbs. Posturing in response to noxious stimuli indicates severe damage to the corticospinal system, whereas abduction-avoidance movement of a limb is usually purposeful and denotes an intact corticospinal system. Posturing may also be unilateral and coexist with purposeful limb movements, reflecting incomplete damage to the motor system.

BRAINSTEM REFLEXES

Assessment of brainstem function is essential to localization of the lesion in coma **(Fig. 28-3)**. Patients with preserved brainstem reflexes typically have a bihemispheric localization to coma, including toxic or drug intoxication, whereas patients with abnormal brainstem reflexes either have a lesion in the brainstem or a herniation syndrome from a cerebral mass lesion impacting the brainstem secondarily. The most important brainstem reflexes are pupillary size and reaction to light, spontaneous and elicited eye movements, corneal responses, and the respiratory pattern.

Pupillary Signs Pupillary reactions are examined with a bright, diffuse light. Reactive and round pupils of midsize (2.5–5 mm) essentially exclude upper midbrain damage, either primary or secondary to compression from herniation. A response to light may be difficult to appreciate in pupils <2 mm in diameter, and bright room lighting may mute pupillary reactivity. One enlarged (>6 mm) and poorly reactive pupil signifies compression of the third nerve from the effects of a cerebral mass above. Enlargement of the pupil contralateral to a hemispheral mass may occur but is infrequent. An oval and slightly eccentric pupil is a transitional sign that accompanies early midbrain–third nerve compression. The most extreme pupillary sign, bilaterally dilated and unreactive pupils, indicates severe midbrain damage, usually from compression by a supratentorial mass. Ingestion of drugs with anticholinergic activity, the use of mydriatic eye drops, nebulizer treatments, and direct ocular trauma are other causes of pupillary enlargement.

Reactive and bilaterally small (1–2.5 mm) but not pinpoint pupils are seen in metabolic encephalopathies or in deep bilateral hemispheral lesions such as hydrocephalus or thalamic hemorrhage. Even smaller reactive pupils (<1 mm) characterize opioid overdoses but also occur with extensive pontine hemorrhage. The response to naloxone and the presence of reflex eye movements (see below) assist in distinguishing between these. Unilateral miosis in coma has been attributed to dysfunction of sympathetic efferents originating in the posterior hypothalamus and descending in the tegmentum of the brainstem to the cervical cord. It is an occasional finding in patients with a large cerebral hemorrhage that affects the thalamus.

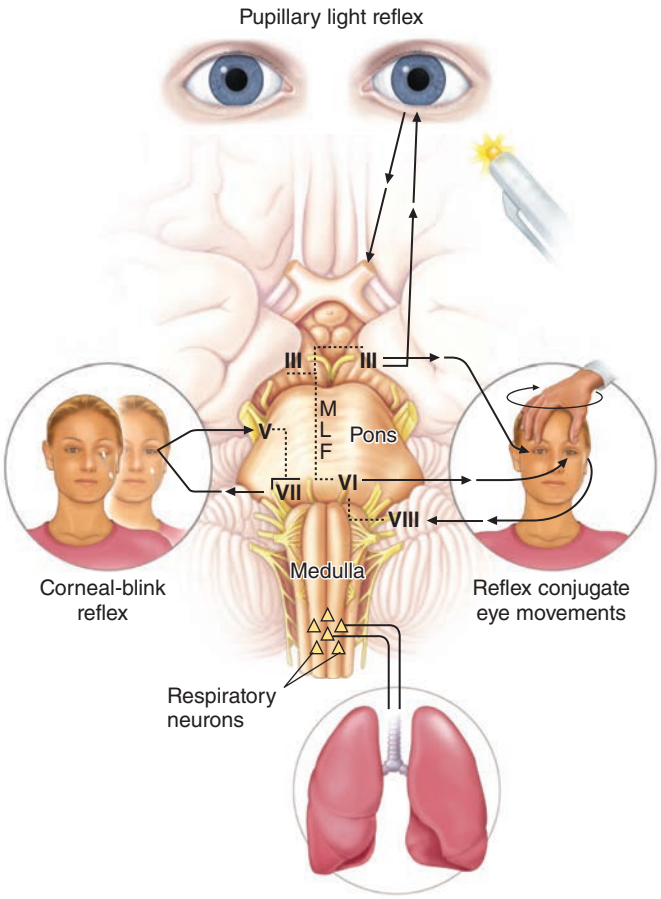

FIGURE 28-3 Examination of brainstem reflexes in coma. Midbrain and third nerve function are tested by pupillary reaction to light, pontine function by spontaneous and reflex eye movements and corneal responses, and medullary function by respiratory and pharyngeal responses. Reflex conjugate, horizontal eye movements are dependent on the medial longitudinal fasciculus (MLF) interconnecting the sixth and contralateral third nerve nuclei. Head rotation (oculocephalic reflex) or caloric stimulation of the labyrinths (oculovestibular reflex) elicits contraversive eye movements (for details, see text).

Ocular Movements The eyes are first observed by elevating the lids and observing the resting position and spontaneous movements of the globes. Horizontal divergence of the eyes at rest is normal in drowsiness. As coma deepens, the ocular axes may become parallel again.

Spontaneous eye movements in coma often take the form of conjugate horizontal roving. This finding alone exonerates extensive damage in the midbrain and pons and has the same significance as normal reflex eye movements (see below). Conjugate horizontal ocular deviation to one side indicates damage to the frontal lobe on the same side or less commonly the pons on the opposite side. This phenomenon is summarized by the following maxim: *The eyes look toward a hemispheral lesion and away from a brainstem lesion.* Seizures involving the frontal lobe drive the eyes to the opposite side, simulating a pontine destructive lesion. The eyes may occasionally turn paradoxically away from the side of a deep hemispheral lesion ("wrong-way eyes"). The eyes turn down and inward with thalamic and upper midbrain lesions, typically thalamic hemorrhage. "Ocular bobbing" describes brisk downward and slow upward movements of the eyes associated with loss of horizontal eye movements and is

diagnostic of bilateral pontine damage, usually from thrombosis of the basilar artery. "Ocular dipping" is a slower, arrhythmic downward movement followed by a faster upward movement in patients with normal reflex horizontal gaze; it usually indicates diffuse cortical anoxic damage.

The oculocephalic reflexes, elicited by moving the head from side to side or vertically and observing eye movements in the direction opposite to the head movement, depend on the integrity of the ocular motor nuclei and their interconnecting tracts that extend from the midbrain to the pons and medulla (Fig. 28-3). The movements, called somewhat inaccurately "doll's eyes," are normally suppressed in the awake patient with intact frontal lobes. The ability to elicit them therefore reflects both reduced cortical influence on the brainstem and intact brainstem pathways. The opposite, an absence of reflex eye movements, usually signifies damage within the brainstem but can result from overdoses of certain drugs. In this circumstance, normal pupillary size and light reaction distinguishes most drug-induced comas from structural brainstem damage. Oculocephalic maneuvers should not be attempted in patients with neck trauma, as vigorous head movements can precipitate or worsen a spinal cord injury.

Thermal, or "caloric," stimulation of the vestibular apparatus (oculovestibular response) provides a more intense stimulus for the oculocephalic reflex but provides essentially the same information. The test is performed by irrigating the external auditory canal with cold water in order to induce convection currents in the labyrinths. After a brief latency, the result is tonic deviation of both eyes to the side of cold-water irrigation. In comatose patients, nystagmus in the opposite direction may not occur. The acronym "COWS" has been used to remind generations of medical students of the direction of nystagmus—cold water opposite, warm water same—but since nystagmus is often absent in the opposite direction due to frontal lobe dysfunction in coma, this mnemonic does not often hold true.

The corneal reflex, elicited by touching the cornea with a wisp of cotton and observing bilateral lid closure, depends on the integrity of pontine pathways between the fifth (afferent) and both seventh (efferent) cranial nerves; it is a useful test of pontine function. CNS-depressant drugs diminish or eliminate the corneal responses soon after reflex eye movements are paralyzed but before the pupils become unreactive to light. The corneal response may be lost for a time on the side of an acute hemiplegia.

Respiratory Patterns These are of less localizing value in comparison to other brainstem signs. Shallow, slow, but regular breathing suggests metabolic or drug-induced depression of the medullary respiratory centers. Cheyne-Stokes respiration in its typical cyclic form, ending with a brief apneic period, signifies bihemispheral damage or metabolic suppression and commonly accompanies light coma. Rapid, deep (Kussmaul) breathing usually implies metabolic acidosis but may also occur with pontomesencephalic lesions. Agonal gasps are the result of lower brainstem (medullary) damage and are recognized as the terminal respiratory pattern of severe brain damage. Other cyclic breathing patterns have been described but are of lesser significance.

LABORATORY STUDIES AND IMAGING

The studies that are most useful in the diagnosis of coma are chemical-toxicologic analysis of blood and urine, cranial CT or MRI, EEG, and cerebrospinal fluid (CSF) examination. Arterial blood gas analysis is helpful in patients with lung disease and acid-base disorders. The metabolic aberrations commonly encountered in clinical practice are usually revealed by measurement of electrolytes, glucose, calcium, magnesium, osmolarity, and renal (blood urea nitrogen) and hepatic (NH_3) function. Toxicologic analysis may be necessary in cases of acute coma, when the diagnosis is not immediately clear. However, the presence of exogenous drugs or toxins, especially alcohol, does not exclude the possibility that other factors, particularly head trauma, are contributing to the clinical state. An ethanol level of 43 mmol/L (0.2 g/dL) in nonhabituated patients generally causes impaired mental activity; a level of >65 mmol/L (0.3 g/dL) is associated with stupor. The development of tolerance may allow some chronic alcoholics to remain awake at levels >87 mmol/L (0.4 g/dL).

The availability of cranial CT and MRI has focused attention on causes of coma that are detectable by imaging (e.g., hemorrhage, tumor, or hydrocephalus). Resorting primarily to this approach, although at times expedient, is imprudent because most cases of coma (and confusion) are metabolic or toxic in origin. Furthermore, a normal CT scan does not exclude an anatomic lesion as the cause of coma; for example, early bilateral hemisphere infarction, acute brainstem infarction, encephalitis, meningitis, mechanical shearing of axons as a result of closed head trauma, sagittal sinus thrombosis, hypoxic injury, and subdural hematoma isodense to adjacent brain are some of the disorders that may not be detected. Sometimes imaging results can be misleading such as when small subdural hematomas or old strokes are found, but the patient's coma is due to intoxication. Additional imaging with CT angiography or MRI can be obtained if acute posterior circulation stroke is considered.

The EEG **(Chap. 425)** provides clues in metabolic or drug-induced states but is rarely diagnostic in these disorders. However, it is the essential test to reveal coma due to nonconvulsive seizures and shows fairly characteristic patterns in herpesvirus encephalitis and prion disease. The EEG may be further helpful in disclosing generalized slowing of the background activity, a reflection of the severity of an encephalopathy. Predominant high-voltage slowing (δ or triphasic waves) in the frontal regions is typical of metabolic coma, as from hepatic failure, and widespread fast (β) activity implicates overdose with sedative drugs (e.g., benzodiazepines). A special pattern of "alpha coma," defined by widespread, variable 8- to 12-Hz activity, superficially resembles the normal α rhythm of waking but, unlike normal α activity, is not altered by environmental stimuli. Alpha coma results from pontine or diffuse cortical damage and is associated with a poor prognosis. A unique EEG pattern in adults of "extreme delta brush" is characteristic of a specific (anti–*N*-methyl-D-aspartate [NMDA] receptor) form of autoimmune encephalitis. Normal α activity on the EEG, which is suppressed by stimulating the patient, also alerts the clinician to the locked-in syndrome, hysteria, or catatonia.

Lumbar puncture should be performed if no cause is readily apparent, as examination of the CSF remains indispensable in the diagnosis of various forms of meningitis and encephalitis. An imaging study should be performed prior to lumbar puncture to exclude a large intracranial mass lesion, which could lead to herniation with lumbar puncture. Blood cultures and administration of antibiotics should precede the imaging study if infectious meningitis is suspected **(Chap. 138)**.

DIFFERENTIAL DIAGNOSIS OF COMA

(Table 28-1) The causes of coma can be divided into three broad categories: those without focal neurologic signs (e.g., metabolic and toxic encephalopathies); those with prominent focal signs (e.g., stroke, cerebral hemorrhage); and meningitis syndromes, characterized by fever or stiff neck and an excess of cells in the spinal fluid (e.g., bacterial meningitis, subarachnoid hemorrhage, encephalitis). Causes of sudden coma include drug ingestion, cerebral hemorrhage, trauma, cardiac arrest, epilepsy, and basilar artery occlusion. Coma that appears subacutely is usually related to a preexisting medical or neurologic problem or, less often, to secondary brain swelling surrounding a mass such as tumor or cerebral infarction.

The diagnosis of coma due to cerebrovascular disease can be difficult **(Chap. 426)**. The most common diseases in this category are (1) basal ganglia and thalamic hemorrhage (acute but not instantaneous onset, vomiting, headache, hemiplegia, and characteristic eye signs); (2) pontine hemorrhage (sudden onset, pinpoint pupils, loss of reflex eye movements and corneal responses, ocular bobbing, posturing, and hyperventilation); (3) cerebellar hemorrhage (occipital headache, vomiting, gaze paresis, and inability to stand and walk); (4) basilar artery thrombosis (neurologic prodrome or transient ischemic attack warning spells, diplopia, dysarthria, vomiting, eye movement and corneal response abnormalities, and asymmetric limb paresis); and

TABLE 28-1 Differential Diagnosis of Coma

1. Diseases that cause no focal brainstem or lateralizing neurologic signs (CT scan is often normal)
   a. Intoxications: alcohol, sedative drugs, opiates, etc.
   b. Metabolic disturbances: anoxia, hyponatremia, hypernatremia, hypercalcemia, diabetic acidosis, nonketotic hyperosmolar hyperglycemia, hypoglycemia, uremia, hepatic coma, hypercarbia, Addisonian crisis, hypo- and hyperthyroid states, profound nutritional deficiency
   c. Severe systemic infections: pneumonia, septicemia, typhoid fever, malaria, Waterhouse-Friderichsen syndrome
   d. Shock from any cause
   e. Status epilepticus, nonconvulsive status epilepticus, postictal states
   f. Hyperperfusion syndromes including hypertensive encephalopathy, eclampsia, posterior reversible encephalopathy syndrome (PRES)
   g. Severe hyperthermia, hypothermia
   h. Concussion
   i. Acute hydrocephalus
2. Diseases that cause focal brainstem or lateralizing cerebral signs (CT scan is typically abnormal)
   a. Hemispheral hemorrhage (basal ganglionic, thalamic) or infarction (large middle cerebral artery territory) with secondary brainstem compression
   b. Brainstem infarction due to basilar artery thrombosis or embolism
   c. Brain abscess, subdural empyema
   d. Epidural and subdural hemorrhage, brain contusion
   e. Brain tumor with surrounding edema
   f. Cerebellar and pontine hemorrhage and infarction
   g. Widespread traumatic brain injury
   h. Metabolic coma (see above) in the setting of preexisting focal damage
3. Diseases that cause meningeal irritation with or without fever, and with an excess of white blood cells or red blood cells in the CSF
   a. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, trauma
   b. Infectious meningitis and meningoencephalitis
   c. Paraneoplastic and autoimmune encephalitis
   d. Carcinomatous and lymphomatous meningitis

(5) subarachnoid hemorrhage (precipitous coma after sudden severe headache and vomiting). The most common stroke, infarction in the territory of the middle cerebral artery, does not cause coma, but edema surrounding large infarctions may expand over several days and cause coma from mass effect.

The syndrome of acute hydrocephalus accompanies many intracranial diseases, particularly subarachnoid hemorrhage. It is characterized by headache and sometimes vomiting that may progress quickly to coma with extensor posturing of the limbs, bilateral Babinski signs, small unreactive pupils, and impaired oculocephalic movements in the vertical direction. At times, the coma may be featureless without lateralizing signs, although papilledema is often present.

BRAIN DEATH

Brain death is a state of irreversible cessation of all cerebral and brainstem function with preservation of cardiac activity and maintenance of respiratory and somatic function by artificial means. It is the only type of brain damage recognized as morally, ethically, and legally equivalent to death. Criteria have been advanced for the diagnosis of brain death, and it is essential to adhere to consensus standards as multiple studies have shown variability in local practice. Given the implications of the diagnosis, clinicians must be thorough and precise in determining brain death. It is advisable to delay clinical testing for at least 24 h if a cardiac arrest has caused brain death or if the inciting disease is not known. Some centers advocate a brief period of observation between two examiners' tests during which the clinical signs of brain death are sustained.

Established criteria contain two essential elements, after assuring that no confounding factors (e.g., hypothermia, drug intoxication) are present: (1) widespread cortical destruction that is reflected by deep coma and unresponsiveness to all forms of stimulation; and (2) global brainstem damage as demonstrated by absent pupillary light reaction, absent corneal reflexes, loss of oculovestibular reflexes, and destruction of the medulla, manifested by complete and irreversible apnea. Diabetes insipidus is often present but may only develop hours or days after the other clinical signs of brain death appear. The pupils are usually midsized but may be enlarged. Loss of deep tendon reflexes is not required because the spinal cord remains functional. Occasionally, other reflexes that originate from the spine may be present and should not preclude a diagnosis of brain death.

Demonstration that apnea is due to medullary damage requires that the P_{CO_2} be high enough to stimulate respiration during a test of spontaneous breathing. Apnea testing can be done by the use of preoxygenation with 100% oxygen prior to and following removal of the ventilator. CO_2 tension increases ~0.3–0.4 kPa/min (2–3 mmHg/min) during apnea. Apnea is confirmed if no respiratory effort has been observed in the presence of a sufficiently elevated P_{CO_2}. The apnea test is usually stopped if there is cardiovascular instability and alternative means of testing can be employed.

An isoelectric EEG may be used as an optional confirmatory test for total cerebral damage. Radionuclide brain scanning, cerebral angiography, or transcranial Doppler measurements may be used to demonstrate the absence of blood flow when a confirmatory study is desired.

It is largely accepted in Western society that the ventilator can be disconnected from a brain-dead patient and that organ donation is subsequently possible. Good communication between the physician and the family is important with appropriate preparation of the family for brain death testing and diagnosis.

TREATMENT

Coma

The immediate goal in a comatose patient is prevention of further nervous system damage. Hypotension, hypoglycemia, hypercalcemia, hypoxia, hypercapnia, and hyperthermia should be corrected rapidly. Hyponatremia should be corrected slowly to avoid injury from osmotic demyelination (Chap. 307). An oropharyngeal airway is adequate to keep the pharynx open in a drowsy patient who is breathing normally. Tracheal intubation is indicated if there is apnea, upper airway obstruction, hypoventilation, or emesis, or if the patient is at risk for aspiration. Mechanical ventilation is required if there is hypoventilation or a need to induce hypocapnia in order to lower ICP. **The management of raised ICP is discussed in Chap. 307.** IV access is established and naloxone and dextrose are administered if opioid overdose or hypoglycemia are possibilities; thiamine is given along with glucose to avoid provoking Wernicke's encephalopathy in malnourished patients. In cases of suspected ischemic stroke including basilar thrombosis with brainstem ischemia, IV tissue plasminogen activator or mechanical embolectomy is often used after cerebral hemorrhage has been excluded and when the patient presents within established time windows for these interventions (Chap. 427). Physostigmine may awaken patients with anticholinergic-type drug overdose but should be used only with careful monitoring; many physicians believe that it should only be used to treat anticholinergic overdose–associated cardiac arrhythmias. The use of benzodiazepine antagonists offers some prospect of improvement after overdose; however, these drugs are not commonly used empirically in part due to their tendency to provoke seizures. Certain other toxic and drug-induced comas have specific treatments such as fomepizole for ethylene glycol ingestion.

Administration of hypotonic IV solutions should be monitored carefully in any serious acute brain illness because of the potential for exacerbating brain swelling. Cervical spine injuries must not be overlooked, particularly before attempting intubation or evaluation of oculocephalic responses. Fever and meningismus indicate an urgent need for examination of the CSF to diagnose meningitis. Whenever acute bacterial meningitis is suspected, antibiotics including at least vancomycin and a third-generation cephalosporin are typically administered rapidly along with dexamethasone (see Chap. 138).

PROGNOSIS

Some patients, especially children and young adults, may have ominous early clinical findings such as abnormal brainstem reflexes and yet recover; early prognostication outside of brain death therefore is unwise. Metabolic comas have a far better prognosis than traumatic ones. Systems for estimating prognosis in adults should be taken as approximations, and medical judgments must be tempered by factors such as age, underlying systemic disease, and general medical condition. In an attempt to collect prognostic information from large numbers of patients with head injury, the Glasgow Coma Scale was devised; it has predictive value in cases of brain trauma **(see Chap. 443)**. For anoxic coma, clinical signs such as the pupillary and motor responses after 1 day, 3 days, and 1 week have predictive value; however, some prediction rules are less reliable in the setting of therapeutic hypothermia, and therefore, serial examinations and multimodal prognostication approaches are advised in this setting. For example, the absence of the cortical responses of the somatosensory evoked potentials has been shown to be a strong indicator of poor outcome following hypoxic injury.

The poor outcome of persistent vegetative and minimally conscious states has already been mentioned, but reports of a small number of patients displaying cortical activation on functional MRI in response to salient stimuli have begun to alter the perception of such individuals. In one series, about 10% of vegetative patients (mainly following traumatic brain injury) could activate their frontal or temporal lobes in response to requests by an examiner to imagine certain visuospatial tasks. Another series demonstrated that up to 15% of patients with various forms of acute brain injury and absence of behavioral responses to motor commands showed EEG activation in response to these commands. It is prudent to avoid generalizations from these findings, but the need for future studies of novel techniques to help communication and possibly recovery is needed.

29 Dementia

William W. Seeley, Gil D. Rabinovici, Bruce L. Miller

Dementia, a syndrome with many causes, affects nearly 6 million people in the United States and results in a total annual health care cost in excess of $300 billion. Dementia is defined as an acquired deterioration in cognitive abilities that impairs the successful performance of activities of daily living. Episodic memory, the ability to recall events specific in time and place, is the cognitive function most commonly lost; 10% of persons age >70 years and 20–40% of individuals age >85 years have clinically identifiable memory loss. In addition to memory, dementia may erode other mental faculties, including language, visuospatial, praxis, calculation, judgment, and problem-solving abilities. Neuropsychiatric and social deficits also arise in many dementia syndromes, manifesting as depression, apathy, anxiety, hallucinations, delusions, agitation, insomnia, sleep disturbances, compulsions, or disinhibition. The clinical course may be slowly progressive, as in Alzheimer's disease (AD); static, as in anoxic encephalopathy; or may fluctuate from day to day or minute to minute, as in dementia with Lewy bodies (DLB). Most patients with AD, the most prevalent form of dementia, begin with episodic memory impairment, but in other dementias, such as frontotemporal dementia (FTD), memory loss is not typically a presenting feature. **Focal cerebral disorders are discussed in Chap. 30 and illustrated in a video library in Chap. V2; detailed discussions of AD can be found in Chap. 431; FTD and related disorders in Chap. 432; vascular dementia in Chap. 433; DLB in Chap. 434; Huntington's disease (HD) in Chap. 436; and prion diseases in Chap. 438.**

FUNCTIONAL ANATOMY OF THE DEMENTIAS

Dementia syndromes result from the disruption of specific large-scale neuronal networks; the location and severity of synaptic and neuronal loss combine to produce the clinical features **(Chap. 30)**. Behavior, mood, and attention are modulated by ascending noradrenergic, serotonergic, and dopaminergic pathways, whereas cholinergic signaling is critical for attention and memory functions. The dementias differ in the relative neurotransmitter deficit profiles; accordingly, accurate diagnosis guides effective pharmacologic therapy.

AD typically begins in the entorhinal region of the medial temporal lobe, spreads to the hippocampus and other limbic structures, and moves through the basal temporal areas and then into the lateral and posterior temporal and parietal neocortex, eventually causing a more widespread degeneration. Vascular dementia is associated with focal damage in a variable patchwork of cortical and subcortical regions or white matter tracts that disconnects nodes within distributed networks. In keeping with its anatomy, AD typically presents with episodic memory loss accompanied later by aphasia, executive dysfunction, or navigational problems. In contrast, dementias that begin in frontal or subcortical regions, such as FTD or HD, are less likely to begin with memory problems and more likely to present with difficulties with judgment, mood, executive control, movement, and behavior.

Lesions of frontal-striatal[1] pathways produce specific and predictable effects on behavior. The dorsolateral prefrontal cortex has connections with a central band of the caudate nucleus. Lesions of either the caudate or dorsolateral prefrontal cortex, or their connecting white matter pathways, may result in executive dysfunction, manifesting as poor organization and planning, decreased cognitive flexibility, and impaired working memory. The lateral orbital frontal cortex connects with the ventromedial caudate, and lesions of this system cause impulsiveness, distractibility, and disinhibition. The anterior cingulate cortex and adjacent medial prefrontal cortex project to the nucleus accumbens, and interruption of this system produces apathy, poverty of speech, emotional blunting, or even akinetic mutism. All corticostriatal systems also include topographically organized projections through the globus pallidus and thalamus, and damage to these nodes can likewise reproduce the clinical syndrome associated with the corresponding cortical or striatal injuries. Involvement of brainstem nuclei and cerebellar structures can further contribute to cognitive, behavioral, and motor manifestations.

THE CAUSES OF DEMENTIA

The single strongest risk factor for dementia is increasing age. The prevalence of disabling memory loss increases with each decade over age 50 and is usually associated with the microscopic changes of AD at autopsy. Yet some centenarians have intact memory function and no evidence of clinically significant dementia. Whether dementia is an inevitable consequence of normal human aging remains controversial although the prevalence increases with every decade of life.

[1]The striatum comprises the caudate/putamen/nucleus accumbens.

TABLE 29-1 Differential Diagnosis of Dementia

Most Common Causes of Dementia	
Alzheimer's disease	Alcoholism[a]
Vascular dementia	PDD/LBD spectrum
Multi-infarct	Drug/medication intoxication[a]
Diffuse white matter disease (Binswanger's)	Limbic-predominant age-related TDP-43 encephalopathy
Less Common Causes of Dementia	
Vitamin deficiencies	Toxic disorders
Thiamine (B_1): Wernicke's encephalopathy[a]	Drug, medication, and narcotic poisoning[a]
B_{12} (subacute combined degeneration)[a]	Heavy metal intoxication[a]
Nicotinic acid (pellagra)[a]	Organic toxins
Endocrine and other organ failure	Psychiatric
Hypothyroidism[a]	Depression (pseudodementia)[a]
Adrenal insufficiency and Cushing's syndrome[a]	Schizophrenia[a]
Hypo- and hyperparathyroidism[a]	Conversion disorder[a]
Renal failure[a]	Degenerative disorders
Liver failure[a]	Huntington's disease
Pulmonary failure[a]	Multisystem atrophy
Chronic infections	Hereditary ataxias (some forms)
HIV	Frontotemporal lobar degeneration spectrum
Neurosyphilis[a]	Multiple sclerosis
Papovavirus (JC virus) (progressive multifocal leukoencephalopathy)	Adult Down's syndrome with Alzheimer's disease
Tuberculosis, fungal, and protozoal[a]	ALS-parkinsonism-dementia complex of Guam
Whipple's disease[a]	Prion (Creutzfeldt-Jakob and Gerstmann-Sträussler-Scheinker diseases)
Head trauma and diffuse brain damage	Miscellaneous
Chronic traumatic encephalopathy	Sarcoidosis[a]
Chronic subdural hematoma[a]	Vasculitis[a]
Postanoxia	CADASIL, etc.
Postencephalitis	Acute intermittent porphyria[a]
Normal-pressure hydrocephalus[a]	Recurrent nonconvulsive seizures[a]
Intracranial hypotension	Additional conditions in children or adolescents
Neoplastic	Pantothenate kinase–associated neurodegeneration
Primary brain tumor[a]	Subacute sclerosing panencephalitis
Metastatic brain tumor[a]	Metabolic disorders (e.g., Wilson's and Leigh's diseases, leukodystrophies, lipid storage diseases, mitochondrial mutations)
Autoimmune (paraneoplastic) encephalitis[a]	

[a]Potentially reversible dementia.

Abbreviations: ALS, amyotrophic lateral sclerosis; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; LBD, Lewy body disease; PDD, Parkinson's disease dementia.

The many causes of dementia are listed in **Table 29-1**. The frequency of each condition depends on the age group under study, access of the group to medical care, country of origin, and perhaps racial or ethnic background. AD is the most common cause of dementia in Western countries, accounting for more than half of all patients. Vascular disease is the second most frequent cause for dementia and is particularly common in elderly patients or populations with limited access to medical care, where vascular risk factors are undertreated. Often, vascular brain injury is mixed with neurodegenerative disorders, particularly AD, making it difficult, even for the neuropathologist, to estimate the contribution of cerebrovascular disease to the cognitive disorder in an individual patient. Dementias associated with Parkinson's disease (PD) are common and may develop years after onset of a parkinsonian disorder, as seen with PD-related dementia (PDD), or they can occur concurrently with or preceding the motor syndrome, as in DLB. Limbic-predominant aging-related TDP-43 encephalopathy (LATE) is common after age 70 and has been linked to declining episodic memory function. Chronic traumatic encephalopathy (CTE), a unique disease found in individuals with a history of repetitive head impacts (e.g., professional athletes in collision or fighting sports, military veterans exposed to multiple blasts), presents with changes in cognition, mood, behavior, or motor function. Mixed pathology is common, especially in older individuals. In patients under the age of 65, FTD rivals AD as the most common cause of dementia. Chronic intoxications, including those resulting from alcohol and prescription drugs, are an important and often treatable cause of dementia. Other disorders listed in Table 29-1 are uncommon but important because many are reversible. The classification of dementing illnesses into reversible and irreversible disorders is a useful approach to differential diagnosis. When effective treatments for the neurodegenerative conditions emerge, this dichotomy will become obsolete.

In a study of 1000 persons attending a memory disorders clinic, 19% had a potentially reversible cause of the cognitive impairment and 23% had a potentially reversible concomitant condition that may have contributed to the patient's impairment. The three most common potentially reversible diagnoses were depression, normal pressure hydrocephalus (NPH), and alcohol dependence; medication side effects are also common and should be considered in every patient (Table 29-1).

The term *rapidly progressive dementia (RPD)* is applied to illnesses that progress from initial symptom onset to dementia within a year or less; confusional states related to toxic/metabolic conditions are excluded. Although the prion proteinopathy Creutzfeldt-Jakob disease (CJD) **(Chap. 438)** is the classic cause of a rapidly progressive dementia, especially when associated with myoclonus, more often cases of RPD are due to AD or another neurodegenerative disorder, or to an autoimmune encephalitis.

Subtle cumulative decline in episodic memory is a common part of aging. This frustrating experience, often the source of jokes and humor, has historically been referred to as *benign forgetfulness of the elderly*. *Benign* means that it is not so progressive or serious that it impairs successful and productive daily functioning, although the distinction between benign and significant memory loss can be subtle. At age 85, the average person is able to learn and recall approximately one-half of the items (e.g., words on a list) that he or she could at age 18. The term *subjective cognitive decline* describes individuals who experience a subjective decline from their cognitive baseline but perform within normal limits for their age and educational attainment on formal neuropsychological testing. *Mild cognitive impairment (MCI)* is defined as a decline in cognition that is confirmed on objective cognitive testing but does not disrupt normal daily activities. MCI can be further subcategorized based on the presenting complaints and deficits (e.g., amnestic MCI, executive MCI). Factors that predict progression from MCI to an AD dementia include a prominent memory deficit, family history of dementia, presence of an apolipoprotein ε4 (Apo ε4) allele, small hippocampal volumes, an AD-like signature of cortical atrophy, low cerebrospinal fluid Aβ and elevated tau, or evidence of brain amyloid and tau deposition on positron emission tomography (PET) imaging.

The major degenerative dementias include AD, DLB, FTD and related disorders, HD, and prion diseases, including CJD. All are associated with the abnormal aggregation of a specific protein: $A\beta_{42}$ and tau in AD; α-synuclein in DLB; tau, TAR DNA-binding protein of 43 kDa (TDP-43), or the FET family of proteins (*fu*sed in sarcoma [FUS], Ewing sarcoma [EWS], and TBP-associated factor 15 [TAF15]) in FTD; huntingtin in HD; and misfolded prion protein (PrP^{sc}) in CJD **(Table 29-2)**.

The risk of developing dementia in late-life is associated with exposures and lifestyle factors that can operate across the life span. Modifiable risk factors include low education, hearing loss, traumatic brain injury, hypertension, diabetes mellitus, obesity, heavy alcohol use, smoking, depression, physical inactivity, and air pollution. Improved management of midlife vascular risk factors has been credited with a decreasing incidence of dementia observed in North America and Western Europe.

TABLE 29-2 The Molecular Basis for Degenerative Dementia

DEMENTIA	MOLECULAR BASIS	CAUSAL GENES (CHROMOSOME)	SUSCEPTIBILITY GENES	PATHOLOGIC FINDINGS
AD	Aβ/tau	*APP* (21), *PS-1* (14), *PS-2* (1) (<2% carry these mutations, most often in *PS-1*)	*Apo ε4* (19)	Amyloid plaques, neurofibrillary tangles, and neuropil threads
FTD	Tau	*MAPT* exon and intron mutations (17) (about 10% of familial cases)	H1 *MAPT* haplotype	Tau neuronal and glial inclusions varying in morphology and distribution
	TDP-43	*GRN* (10% of familial cases), *C9ORF72* (20%–30% of familial cases), rare *VCP*, very rare *TARDBP, TBK1, TIA1*		TDP-43 neuronal and glial inclusions varying in morphology and distribution
	FET	Very rare *FUS*		FET neuronal and glial inclusions varying in morphology and distribution
DLB	α-Synuclein	Very rare *SNCA* (4)	Unknown	α-Synuclein neuronal inclusions (Lewy bodies)
CJD	PrP^{SC}	*PRNP* (20) (up to 15% of patients carry these dominant mutations)	Codon 129 homozygosity for methionine or valine	PrP^{SC} deposition, panlaminar spongiosis

Abbreviations: AD, Alzheimer's disease; CJD, Creutzfeldt-Jakob disease; DLB, dementia with Lewy bodies; FET, FUS/EWS/TAF-15; FTD, frontotemporal dementia.

APPROACH TO THE PATIENT

Dementias

Three major issues should be kept at the forefront: (1) What is the clinical diagnosis? (2) What component of the dementia syndrome is treatable or reversible? (3) Can the physician help to alleviate the burden on caregivers? A broad overview of the approach to dementia is shown in **Table 29-3**. The major degenerative dementias can usually be distinguished by the initial symptoms; neuropsychological, neuropsychiatric, and neurologic findings; and neuroimaging features **(Table 29-4)**.

HISTORY

The history should concentrate on the onset, duration, and tempo of progression. An acute or subacute onset of confusion may be due to delirium **(Chap. 27)** and should trigger a search for intoxication, infection, or metabolic derangement. An elderly person with slowly progressive memory loss over several years is likely to suffer from AD. Nearly 75% of patients with AD begin with memory symptoms, but other early symptoms include anxiety or depression as well as difficulty managing money, driving, shopping, following instructions, finding words, or navigating. Personality change, disinhibition, and weight gain or compulsive eating suggest FTD, not AD. FTD is also suggested by prominent apathy, compulsivity, loss of empathy for others, or progressive loss of speech fluency or single-word comprehension with relative sparing of memory and visuospatial abilities. The diagnosis of DLB is suggested by early visual hallucinations; parkinsonism; proneness to delirium or sensitivity to psychoactive medications; rapid eye movement (REM) behavior disorder (RBD; dramatic, sometimes violent, limb movements during dreaming **[Chap. 31]**); or Capgras syndrome, the delusion that a familiar person has been replaced by an impostor.

A history of stroke with irregular stepwise progression suggests vascular dementia. Vascular dementia is also commonly seen in the setting of hypertension, atrial fibrillation, peripheral vascular disease, smoking, and diabetes. In patients suffering from cerebrovascular disease, it can be difficult to determine whether the dementia is due to AD, vascular disease, or a mixture of the two because many of the risk factors for vascular dementia, including diabetes, high cholesterol, elevated homocysteine, and low exercise, are also risk factors for AD. Moreover, many patients with a major vascular contribution to their dementia lack a history of stepwise decline. Rapid progression with motor rigidity and myoclonus suggests CJD **(Chap. 438)**. Seizures may indicate strokes or neoplasm but also occur in AD, particularly early-age-of-onset AD. Gait disturbance is common in vascular dementia, PD/DLB, or NPH. A history of high-risk sexual behaviors or intravenous drug use should trigger a search for central nervous system (CNS) infection, especially HIV or syphilis. A history of recurrent head trauma could indicate chronic subdural hematoma, CTE, intracranial hypotension, or NPH. Subacute onset of severe amnesia and psychosis with mesial temporal T2/fluid-attenuated inversion recovery (FLAIR) hyperintensities on MRI should raise concern for autoimmune (paraneoplastic) encephalitis, sometimes in long-term smokers or other patients at risk for cancer. The spectrum of autoimmune etiologies producing

TABLE 29-3 Evaluation of the Patient with Dementia

ROUTINE EVALUATION	OPTIONAL FOCUSED TESTS	OCCASIONALLY HELPFUL TESTS
History	Psychometric testing	EEG
Physical examination	Chest x-ray	Parathyroid function
Laboratory tests	Lumbar puncture	Adrenal function
Thyroid function (TSH)	Liver function	Urine heavy metals
Vitamin B_{12}	Renal function	RBC sedimentation rate
Complete blood count	Urine toxin screen	Angiogram
Electrolytes	HIV	Brain biopsy
CT/MRI	Apolipoprotein E	SPECT
	RPR or VDRL	PET
		Autoantibodies
Diagnostic Categories		
REVERSIBLE CAUSES	**IRREVERSIBLE/ DEGENERATIVE DEMENTIAS**	**PSYCHIATRIC DISORDERS**
Examples	Examples	Depression
Hypothyroidism	Alzheimer's	Schizophrenia
Thiamine deficiency	Frontotemporal dementia	Conversion reaction
Vitamin B_{12} deficiency	Huntington's	
Normal pressure hydrocephalus	Dementia with Lewy bodies	
Subdural hematoma	Vascular	
Chronic infection	Leukoencephalopathies	
Brain tumor	Parkinson's	
Drug intoxication		
Autoimmune encephalopathy		
Associated Treatable Conditions		
	Depression	Agitation
	Seizures	Caregiver "burnout"
	Insomnia	Drug side effects

Abbreviations: CT, computed tomography; EEG, electroencephalogram; MRI, magnetic resonance imaging; PET, positron emission tomography; RBC, red blood cell; RPR, rapid plasma reagin (test); SPECT, single-photon emission computed tomography; TSH, thyroid-stimulating hormone; VDRL, venereal disease research laboratory (test for syphilis).

TABLE 29-4 Clinical Differentiation of the Major Dementias

DISEASE	FIRST SYMPTOM	MENTAL STATUS	NEUROPSYCHIATRY	NEUROLOGY	IMAGING
AD	Memory loss	Episodic memory loss	Irritability, anxiety, depression	Initially normal	Entorhinal cortex and hippocampal atrophy
FTD	Apathy, poor judgment/ insight, speech/language, hyperorality	Frontal/executive and/or language; spares drawing	Apathy, disinhibition, overeating, compulsivity	May have vertical gaze palsy, axial rigidity, dystonia, alien hand, or MND	Frontal, insular, and/or temporal atrophy; usually spares posterior parietal lobe
DLB	Visual hallucinations, REM sleep behavior disorder, delirium, Capgras syndrome, parkinsonism	Drawing and frontal/ executive, spares memory, delirium-prone	Visual hallucinations, depression, sleep disorder, delusions	Parkinsonism	Posterior parietal atrophy, hippocampi larger than in AD
CJD	Dementia, mood, anxiety, movement disorders	Variable, frontal/ executive, focal cortical, memory	Depression, anxiety, psychosis in some	Myoclonus, rigidity, parkinsonism	Cortical ribboning and basal ganglia or thalamus hyperintensity on diffusion/ FLAIR MRI
Vascular	Often but not always sudden, variable, apathy, falls, focal weakness	Frontal/executive, cognitive slowing, can spare memory	Apathy, delusions, anxiety	Usually motor slowing, spasticity, can be normal	Cortical and/or subcortical infarctions, confluent white matter disease

Abbreviations: AD, Alzheimer's disease; CBD, cortical basal degeneration; CJD, Creutzfeldt-Jakob disease; DLB, dementia with Lewy bodies; FLAIR, fluid-attenuated inversion recovery; FTD, frontotemporal dementia; MND, motor neuron disease; MRI, magnetic resonance imaging; REM, rapid eye movement.

RPD has rapidly expanded, and includes antibodies targeting leucine-rich glioma-inactivated 1 (LGI1; faciobrachial dystonic seizures); contactin-associated protein-like 2 (Caspr2; insomnia, ataxia, myotonia); *N-methyl*-D-*aspartate* (NMDA)-receptor (psychosis, insomnia, dyskinesias); and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-receptor (limbic encephalitis with relapses), among others **(Chap. 94)**. Alcohol abuse creates risk for malnutrition and thiamine deficiency. Veganism, bowel irradiation, an autoimmune diathesis, a remote history of gastric surgery, and chronic therapy with histamine H2-receptor antagonists for dyspepsia or gastroesophageal reflux predispose to B_{12} deficiency. Certain occupations, such as working in a battery or chemical factory, might indicate heavy metal intoxication. Careful review of medication intake, especially for sedatives and analgesics, may raise the issue of chronic drug intoxication. An autosomal dominant family history is found in HD and in familial forms of AD, FTD, DLB, or prion disorders. A history of mood disorder, the recent death of a loved one, or depressive signs such as insomnia or weight loss, raise the possibility of depression-related cognitive impairment.

PHYSICAL AND NEUROLOGIC EXAMINATION

A thorough general and neurologic examination is essential to identify signs of nervous system involvement and search for clues suggesting a systemic disease that might be responsible for the cognitive disorder. Typical AD spares motor systems until late in the course. In contrast, patients with FTD often develop axial rigidity, supranuclear gaze palsy, or a motor neuron disease reminiscent of amyotrophic lateral sclerosis (ALS). In DLB, the initial symptoms may include a parkinsonian syndrome (resting tremor, cogwheel rigidity, bradykinesia, festinating gait), but DLB often starts with visual hallucinations or cognitive impairment, and symptoms referable to the lower brainstem (RBD, gastrointestinal, or autonomic problems) may arise years or even decades before parkinsonism or dementia. Corticobasal syndrome (CBS) features asymmetric akinesia and rigidity, dystonia, myoclonus, alien limb phenomena, pyramidal signs, and prefrontal deficits such as nonfluent aphasia with or without motor speech impairment, executive dysfunction, apraxia, or a behavioral disorder. Progressive supranuclear palsy (PSP) is associated with unexplained falls, axial rigidity, dysphagia, and vertical gaze deficits. CJD is suggested by the presence of diffuse rigidity, an akinetic mute state, and prominent, often startle-sensitive, myoclonus.

Hemiparesis or other focal neurologic deficits suggest vascular dementia or brain tumor. Dementia with a myelopathy and peripheral neuropathy suggests vitamin B_{12} deficiency. Peripheral neuropathy could also indicate another vitamin deficiency, heavy metal intoxication, thyroid dysfunction, Lyme disease, or vasculitis. Dry cool skin, hair loss, and bradycardia suggest hypothyroidism. Fluctuating confusion associated with repetitive stereotyped movements may indicate ongoing limbic, temporal, or frontal seizures. In the elderly, hearing impairment or visual loss may produce confusion and disorientation misinterpreted as dementia. Profound bilateral sensorineural hearing loss in a younger patient with short stature or myopathy, however, should raise concern for a mitochondrial disorder.

COGNITIVE AND NEUROPSYCHIATRIC EXAMINATION

Brief screening tools such as the Mini-Mental State Examination (MMSE), the Montreal Cognitive Assessment (MOCA), the Tablet Based Cognitive Assessment Tool, and Cognistat can be used to capture dementia and follow progression. None of these tests is highly sensitive to early-stage dementia or reliably discriminates between dementia syndromes. The MMSE is a 30-point test of cognitive function, with each correct answer being scored as 1 point. It includes tests of: orientation (e.g., identify season/date/month/year/floor/hospital/town/state/country); registration (e.g., name and restate 3 objects); recall (e.g., remember the same three objects 5 minutes later); and language (e.g., name pencil and watch; repeat "no ifs ands or buts"; follow a 3-step command; obey a written command; and write a sentence and copy a design). In most patients with MCI and some with clinically apparent AD, bedside screening tests may be normal, and a more challenging and comprehensive set of neuropsychological tests will be required. When the etiology for the dementia syndrome remains in doubt, a specially tailored evaluation should be performed that includes tasks of working and episodic memory, executive function, language, and visuospatial and perceptual abilities. In AD, the early deficits involve episodic memory, category generation ("name as many animals as you can in 1 minute"), and visuoconstructive ability. Usually deficits in verbal or visual episodic memory are the first neuropsychological abnormalities detected, and tasks that require the patient to recall a long list of words or a series of pictures after a predetermined delay will demonstrate deficits in most patients. In FTD, the earliest deficits on cognitive testing involve executive control or language (speech or naming) functions, but some patients lack either finding despite profound social-emotional deficits. PDD or DLB patients have more severe deficits in executive and visuospatial function but do better on episodic memory tasks than patients with AD. Patients with vascular dementia often demonstrate a mixture of executive and visuospatial deficits, with prominent psychomotor slowing. In delirium, the most prominent deficits involve attention, working

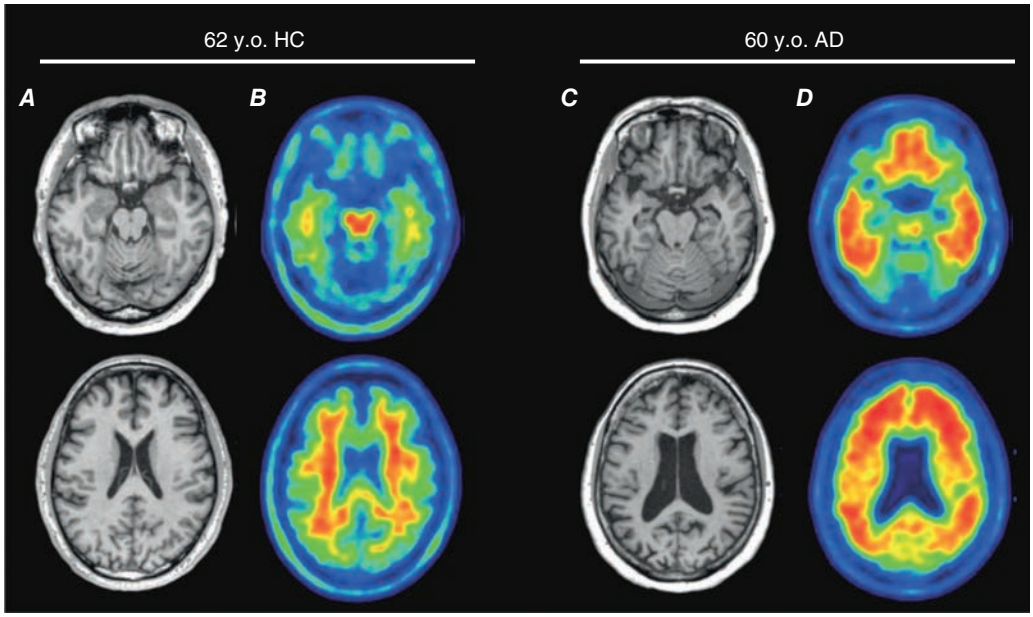

FIGURE 29-1 Alzheimer's disease (AD). Axial T1-weighted magnetic resonance images of a healthy 62-year-old (***A, B***) and a 60-year-old with AD (***C, D***). Note the diffuse atrophy, plus temporal lobe volume loss, in the patient with AD. Aβ positron emission tomography (PET) with [^{11}C]PIB (***B*** and ***D***) reveals extensive radiotracer retention in neocortex bilaterally in AD, consistent with the known distribution of amyloid plaques. HC, healthy control. *(Source: Gil Rabinovici, University of California, San Francisco and William Jagust, University of California, Berkeley.)*

memory, and executive function, making the assessment of other cognitive domains challenging and often uninformative.

A functional assessment should also be performed to help the physician determine the day-to-day impact of the disorder on the patient's memory, community affairs, hobbies, judgment, dressing, and eating. Knowledge of the patient's functional abilities will help the clinician and the family to organize a therapeutic approach.

Neuropsychiatric assessment is important for diagnosis, prognosis, and treatment. In the early stages of AD, mild depressive features, social withdrawal, and irritability or anxiety are the most prominent psychiatric changes, but patients often maintain core social graces into the middle or late stages, when delusions, agitation, and sleep disturbance may emerge. In FTD, dramatic personality change with apathy, overeating, compulsions, disinhibition, and loss of empathy are early and common. DLB is associated with visual hallucinations, delusions related to person or place identity, RBD, and excessive daytime sleepiness. Dramatic fluctuations occur not only in cognition but also in arousal. Vascular dementia can present with psychiatric symptoms such as depression, anxiety, delusions, disinhibition, or apathy.

LABORATORY TESTS

The choice of laboratory tests in the evaluation of dementia is complex and should be tailored to the individual patient. The physician must take measures to avoid missing a reversible or treatable cause, yet no single treatable etiology is common; thus a screen must use multiple tests, each of which has a low yield. Cost/benefit ratios are difficult to assess, and many laboratory screening algorithms for dementia discourage multiple tests. Nevertheless, even a test with only a 1–2% positive rate is worth undertaking if the alternative is missing a treatable cause of dementia. Table 29-3 lists most screening tests for dementia. The American Academy of Neurology recommends the routine measurement of a complete blood count; electrolytes; glucose; renal, liver, and thyroid functions; a vitamin B_{12} level; and a structural neuroimaging study (MRI or CT).

Neuroimaging studies, especially MRI, help to rule out primary and metastatic neoplasms, locate areas of infarction or inflammation, detect subdural hematomas, and suggest NPH or diffuse white matter disease. They also help to establish a regional pattern of atrophy. Support for the diagnosis of AD includes hippocampal atrophy in addition to posterior-predominant cortical atrophy **(Fig. 29-1)**. Focal frontal, insular, and/or anterior temporal atrophy suggests FTD **(Chap. 432)**. DLB often features less prominent atrophy, with greater involvement of the amygdala than the hippocampus. In CJD, magnetic resonance (MR) diffusion-weighted imaging reveals restricted diffusion within the cortical ribbon and/or basal ganglia in most patients. Extensive multifocal white matter abnormalities suggest a vascular etiology **(Fig. 29-2)**. Communicating hydrocephalus with vertex effacement (crowding of dorsal convexity gyri/sulci), gaping Sylvian fissures despite minimal cortical atrophy, and additional features shown in **Fig. 29-3** suggest NPH. Single-photon emission computed tomography (SPECT) and fluoro-deoxyglucose PET scanning show temporal-parietal hypoperfusion or hypometabolism in AD and frontotemporal deficits in FTD, but abnormalities in these patterns can be detected with MRI alone in many patients. Recently, amyloid- and tau-PET imaging have shown promise for the diagnosis of AD. There are currently

FIGURE 29-2 Diffuse white matter disease. Axial fluid-attenuated inversion recovery (FLAIR) magnetic resonance image through the lateral ventricles reveals multiple areas of hyperintensity (*arrows*) involving the periventricular white matter as well as the corona radiata and striatum. Although seen in some individuals with normal cognition, this appearance is more pronounced in patients with dementia of a vascular etiology.

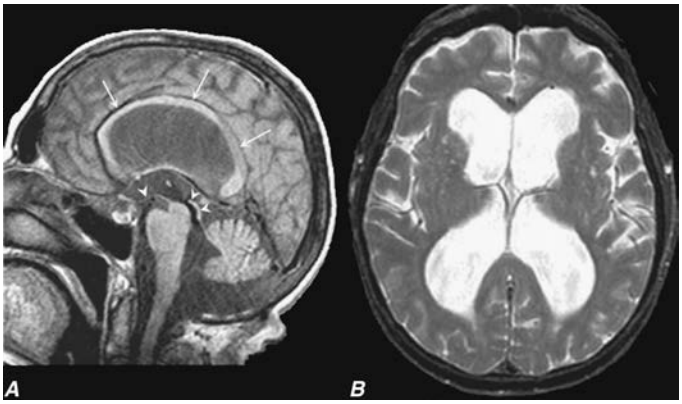

FIGURE 29-3 Normal pressure hydrocephalus. ***A.*** Sagittal T1-weighted MRI demonstrates dilation of the lateral ventricle and stretching of the corpus callosum (*arrows*), depression of the floor of the third ventricle (*single arrowhead*), and enlargement of the aqueduct (*double arrowheads*). Note the diffuse dilation of the lateral, third, and fourth ventricles with a patent aqueduct, typical of communicating hydrocephalus. ***B.*** Axial T2-weighted MRIs demonstrate dilation of the lateral ventricles. This patient underwent successful ventriculoperitoneal shunting.

three amyloid PET ligands (F18-florbetapir, F18-florbetaben, F18-flutametamol) and one tau PET ligand (F18-flortaucipir) approved by the US Food and Drug Administration for clinical use. Amyloid PET ligands bind to diffuse and neuritic amyloid plaques, as well as to vascular amyloid deposits (prominent in cerebral amyloid angiopathy), while tau PET ligands bind to the paired helical filaments of tau characteristic of neurofibrillary tangles in AD **(Chap. 431)**. Because amyloid plaques are also commonly found in cognitively normal older persons (~25% of individuals at age 65), the main clinical value of amyloid imaging is to exclude AD as the likely cause of dementia in patients who have negative scans. The spread of tau is more tightly linked to cognitive state **(Chap. 431)**, and thus may be more useful than amyloid imaging for "ruling in" AD, as well as for disease staging. Once disease-modifying therapies become available, CSF or molecular PET biomarkers will likely be used to identify treatment candidates. In the meantime, the prognostic value of detecting brain amyloid in an asymptomatic elder to assess preclinical disease and risk of future cognitive decline remains a topic of vigorous investigation.

Lumbar puncture need not be done routinely in the evaluation of dementia, but it is indicated when CNS infection or inflammation are credible diagnostic possibilities. Cerebrospinal fluid (CSF) levels of $A\beta_{42}$ and tau proteins show differing patterns with the various dementias, and the presence of low $A\beta_{42}$ (or a low $A\beta_{42}/A\beta_{40}$ ratio), mild-moderately elevated CSF total tau, and elevated CSF phosphorylated tau (at residues 181 or 217) is highly suggestive of AD. Novel fully automated CSF Aβ and tau assays perform comparably to amyloid and tau PET respectively, though, as with PET, their routine use in the diagnosis of dementia is debated. Blood-based biomarkers for AD show promise as a less invasive screening tool but remain under development **(Chap. 431)**. Formal psychometric testing helps to document the severity of cognitive disturbance, suggests psychogenic causes, and provides a more formal method for following the disease course. Electroencephalogram (EEG) is not routinely used but can help to suggest CJD (repetitive bursts of diffuse high-amplitude sharp waves, or "periodic complexes") or an underlying nonconvulsive seizure disorder (epileptiform discharges). Brain biopsy (including meninges) is not advised except to diagnose vasculitis, neoplasms, or unusual infections when the diagnosis is uncertain. Systemic disorders with CNS manifestations, such as sarcoidosis, can often be confirmed through biopsy of lymph node or solid organ rather than brain. MR angiography should be considered when cerebral vasculitis or cerebral venous thrombosis is a possible cause of the dementia.

GLOBAL CONSIDERATIONS

Vascular dementia **(Chap. 433)** is more common in Asia due to the higher prevalence of intracranial atherosclerosis. Rates of vascular dementia are also on the rise in developing countries as vascular risk factors such as hypertension, hypercholesterolemia, and diabetes mellitus become more widespread. CNS infections, HIV (and associated opportunistic infections), syphilis, cysticercosis, and tuberculosis, likewise represent major contributors to dementia in the developing world. Systemic infection with SARS-CoV-2 may, in some individuals, have lasting effects on cognition due to involvement of brain microvasculature or to immunologically mediated white matter injury (acute disseminated encephalomyelitis [ADEM]) **(Chap. 444)**. Some individuals complain of lasting fatigue, changes in mood, and cognitive difficulties, but the long-term prognosis for SARS-CoV-2-related cognitive impairment remains unknown. Isolated populations have also contributed to our understanding of neurodegenerative dementia. Kuru, the cannibalism-associated rapidly progressive dementia seen in tribal New Guinea, played a role in the discovery of human prion disease. Amyotrophic lateral sclerosis-parkinsonism-dementia complex of Guam (or, Lytico-bodig disease) is a poly-proteinopathy, often with tau, TDP-43, and alpha-synuclein aggregation. The root cause of the disease remains uncertain, but its incidence has declined sharply over the past 60 years.

TREATMENT

Dementia

The major goals of dementia management are to treat reversible causes and provide comfort and support to the patient and caregivers. Treatment of underlying causes includes thyroid replacement for hypothyroidism; vitamin therapy for thiamine or B_{12} deficiency or for elevated serum homocysteine; antimicrobials for opportunistic infections or antiretrovirals for HIV; ventricular shunting for NPH; or surgical, radiation, and/or chemotherapeutic treatment for CNS neoplasms. Removal of cognition-impairing drugs or medications is essential when appropriate. If the patient's cognitive complaints stem from a psychiatric disorder, vigorous treatment of the condition should be tried to eliminate the cognitive complaint or to confirm that it persists despite adequate resolution of the mood or anxiety symptoms. Patients with degenerative diseases may also be depressed or anxious, and those aspects of their condition often respond to therapy while not necessarily improving cognition. Antidepressants, such as selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) **(Chap. 452)**, which feature anxiolytic properties but few cognitive side effects, provide the mainstay of treatment when necessary. Anticonvulsants are used to control AD-associated seizures.

Agitation, hallucinations, delusions, and confusion are difficult to treat. These behavioral problems represent major causes for nursing home placement and institutionalization. Before treating these behaviors with medications, the clinician should aggressively seek out modifiable environmental or metabolic factors. Hunger, lack of exercise, toothache, constipation, urinary tract or respiratory infection, electrolyte imbalance, and drug toxicity all represent easily correctable causes that can be remedied without psychoactive drugs. Drugs such as phenothiazines and benzodiazepines may ameliorate the behavior problems but have untoward side effects such as sedation, rigidity, or dyskinesia; benzodiazepines can occasionally produce paradoxical disinhibition. Despite their unfavorable side effect profile, second-generation antipsychotics such as quetiapine (starting dose, 12.5–25 mg daily) can be used for patients with agitation, aggression, and psychosis, although the risk profile for these compounds is significant, including increased mortality in patients with dementia. When patients do not respond to treatment, it is usually a mistake to advance to higher doses or to use anticholinergic drugs (like diphenhydramine) or sedatives (such as barbiturates or benzodiazepines). It is important to recognize and treat depression; treatment can begin with a low dose of an

SSRI (e.g., escitalopram, starting dose 5 mg daily, target dose 5–10 mg daily) while monitoring for efficacy and toxicity. Sometimes apathy, visual hallucinations, depression, and other psychiatric symptoms respond to cholinesterase inhibitors, especially in DLB, obviating the need for other more toxic therapies.

Cholinesterase inhibitors are being used to treat AD (donepezil, rivastigmine, galantamine) and PDD (rivastigmine). Memantine is useful for some patients with moderate to severe AD; its major benefit relates to decreasing caregiver burden, most likely by decreasing resistance to dressing and grooming support. In moderate to severe AD, the combination of memantine and a cholinesterase inhibitor delayed nursing home placement in several studies, although other studies have not supported the efficacy of adding memantine to the regimen. Memantine should be used with great caution, or not at all, in patients with DLB, due to risk of worsening agitation and confusion. Therapies targeting the production, aggregation, and spread of misfolded proteins associated with dementia are under development. Recently the first drug in this class, the amyloid-beta targeting monoclonal antibody aducanumab, was approved by the United States Food & Drug Administration for treatment of Alzheimer's disease (Chap. 431). Other drugs under development target disease-associated neuroinflammation metabolic changes, synaptic loss, and neurotransmitter changes.

Proactive approaches reduce the occurrence of delirium in hospitalized patients. Frequent orientation, cognitive activities, sleep-enhancement measures, vision and hearing aids, and correction of dehydration are all valuable in decreasing the likelihood of delirium.

Nondrug behavior therapy has an important place in dementia management. The primary goals are to make the patient's life comfortable, uncomplicated, and safe. Preparing lists, schedules, calendars, and labels can be helpful in the early stages. It is also useful to stress familiar routines, walks, and simple physical exercises. For many demented patients, memory for events is worse than their ability to carry out routine activities, and they may still be able to take part in their favorite hobbies, sports, and social activities. Demented patients often object to losing control over familiar tasks such as driving, cooking, and handling finances. Attempts to help may be greeted with complaints, depression, or anger. Hostile responses on the part of the caregiver are counterproductive and sometimes even harmful. Reassurance, distraction, and calm positive statements are more productive when resistance is present. Eventually, tasks such as finances and driving must be assumed by others, and the patient will conform and adjust. Safety is an important issue that includes not only driving but controlling the kitchen, bathroom, and sleeping area environments, as well as stairways. These areas need to be monitored, supervised, and made as safe as possible. A move to a retirement complex, assisted-living center, or nursing home can initially increase confusion and agitation. Repeated reassurance, reorientation, and careful introduction to the new personnel will help to smooth the process. Providing activities that are known to be enjoyable to the patient can also help.

The clinician must pay special attention to frustration and depression among family members and caregivers. Caregiver guilt and burnout are common. Family members often feel overwhelmed and helpless and may vent their frustrations on the patient, each other, and health care providers. Caregivers should be encouraged to take advantage of day-care facilities and respite services. Education and counseling about dementia are important. Local and national support groups, such as the Alzheimer's Association (*www.alz.org*), can provide considerable help.

30 Aphasia, Memory Loss, and Other Cognitive Disorders

M.-Marsel Mesulam

The cerebral cortex of the human brain contains ~20 billion neurons spread over an area of 2.5 m^2. The primary sensory and motor areas constitute 10% of the cerebral cortex. The rest is subsumed by modality-selective, heteromodal, paralimbic, and limbic areas collectively known as the *association cortex* **(Fig. 30-1)**. The association cortex mediates the integrative processes that subserve cognition, emotion, and comportment. A systematic testing of these mental functions is necessary for the effective clinical assessment of the association cortex and its diseases. According to current thinking, there are no centers for "hearing words," "perceiving space," or "storing memories." Cognitive

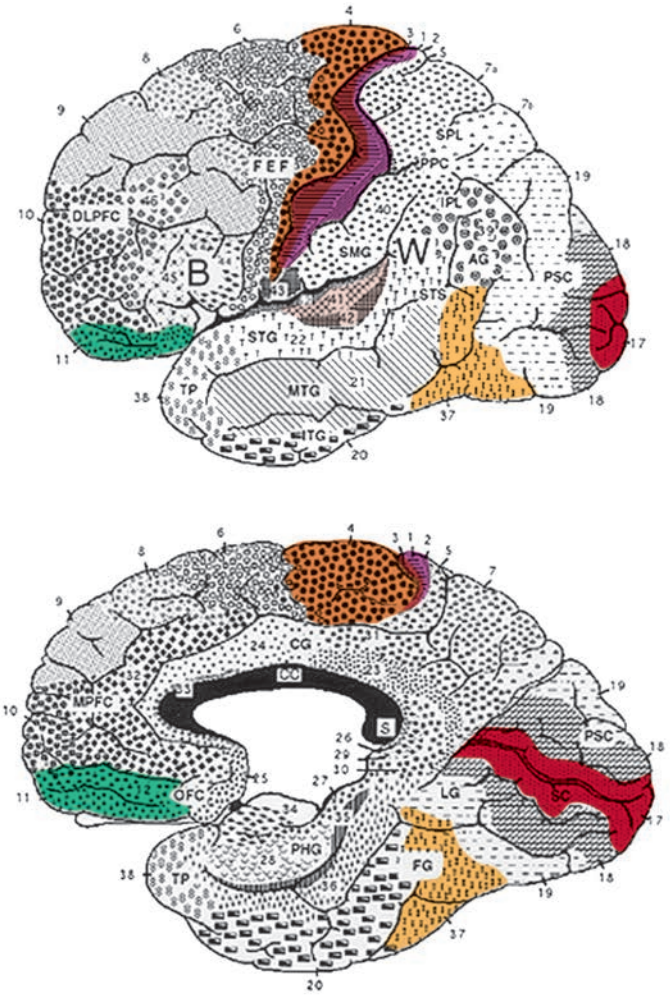

FIGURE 30-1 Lateral (*top*) and medial (*bottom*) views of the cerebral hemispheres. The numbers refer to the Brodmann cytoarchitectonic designations. Area 17 corresponds to the primary visual cortex, 41–42 to the primary auditory cortex, 1–3 to the primary somatosensory cortex, and 4 to the primary motor cortex. The rest of the cerebral cortex contains association areas. AG, angular gyrus; B, Broca's area; CC, corpus callosum; CG, cingulate gyrus; DLPFC, dorsolateral prefrontal cortex; FEF, frontal eye fields (premotor cortex); FG, fusiform gyrus; IPL, inferior parietal lobule; ITG, inferior temporal gyrus; LG, lingual gyrus; MPFC, medial prefrontal cortex; MTG, middle temporal gyrus; OFC, orbitofrontal cortex; PHG, parahippocampal gyrus; PPC, posterior parietal cortex; PSC, peristriate cortex; SC, striate cortex; SMG, supramarginal gyrus; SPL, superior parietal lobule; STG, superior temporal gyrus; STS, superior temporal sulcus; TP, temporopolar cortex; W, Wernicke's area.

and behavioral functions (domains) are coordinated by intersecting *large-scale neural networks* that contain interconnected cortical and subcortical components. Five anatomically defined *large-scale networks* are most relevant to clinical practice: (1) a left-dominant perisylvian network for language, (2) a right-dominant parietofrontal network for spatial orientation, (3) an occipitotemporal network for face and object recognition, (4) a limbic network for episodic memory and emotional modulation, and (5) a prefrontal network for the executive control of cognition and comportment. Investigations based on functional imaging have also identified a *default mode network*, which becomes activated when the person is not engaged in a specific task requiring attention to external events. The clinical consequences of damage to this network are not yet fully defined.

THE LEFT PERISYLVIAN NETWORK FOR LANGUAGE AND APHASIAS

The production and comprehension of words and sentences is dependent on the integrity of a distributed network located along the perisylvian region of the language-dominant (usually left) hemisphere. One hub, situated in the inferior frontal gyrus, is known as *Broca's area*. Damage to this region impairs fluency of verbal output and the grammatical structure of sentences. The location of a second hub, critical for language comprehension, is less clearly settled. Accounts of patients with focal cerebrovascular lesions identified *Wernicke's area*, located at the parietotemporal junction, as a critical hub for word and sentence comprehension. Occlusive or embolic strokes involving this area interfere with the ability to understand spoken or written language as well as the ability to express thoughts through meaningful words and statements. However, investigations of patients with the neurodegenerative syndrome of primary progressive aphasia (PPA) have shown that sentence comprehension is a widely distributed faculty jointly subserved by Broca's and Wernicke's areas, and that the areas critical for word comprehension are more closely associated with the anterior temporal lobe than with Wernicke's area. All components of the language network are interconnected with each other and with surrounding parts of the frontal, parietal, and temporal lobes. Damage to this network gives rise to language impairments known as aphasia. Aphasia should be diagnosed only when there are deficits in the formal aspects of language, such as word finding, word choice, comprehension, spelling, or grammar. Dysarthria, apraxia of speech, and mutism do not by themselves lead to a diagnosis of aphasia. In ~90% of right-handers and 60% of left-handers, aphasia occurs only after lesions of the left hemisphere.

CLINICAL EXAMINATION

The clinical examination of language should include the assessment of naming, spontaneous speech, comprehension, repetition, reading, and writing. A deficit of naming (*anomia*) is the single most common finding in aphasic patients. When asked to name a common object, the patient may fail to come up with the appropriate word, may provide a circumlocutious description of the object ("the thing for writing"), or may come up with the wrong word (*paraphasia*). If the patient offers an incorrect but related word ("pen" for "pencil"), the naming error is known as a *semantic paraphasia*; if the word approximates the correct answer but is phonetically inaccurate ("plentil" for "pencil"), it is known as a *phonemic paraphasia*. In most anomias, the patient cannot retrieve the appropriate name when shown an object but can point to the appropriate object when the name is provided by the examiner. This is known as a one-way (or retrieval-based) naming deficit. A two-way (comprehension-based or semantic) naming deficit exists if the patient can neither provide nor recognize the correct name. *Spontaneous speech* is described as "fluent" if it maintains appropriate output volume, phrase length, and melody or as "nonfluent" if it is sparse and halting and average utterance length is below four words. The examiner also should note the integrity of *grammar* as manifested by word order (syntax), tenses, suffixes, prefixes, plurals, and possessives. *Comprehension* can be tested by assessing the patient's ability to follow conversation, asking yes-no questions ("Can a dog fly?" "Does it snow in summer?"), asking the patient to point to appropriate objects ("Where is the source of illumination in this room?"), or asking for verbal definitions of single words. *Repetition* is assessed by asking the patient to repeat single words, short sentences, or strings of words such as "No ifs, ands, or buts." The testing of repetition with tongue twisters such as "hippopotamus" and "Irish constabulary" provides a better assessment of dysarthria and apraxia of speech than of aphasia. It is important to make sure that the number of words does not exceed the patient's attention span. Otherwise, the failure of repetition becomes a reflection of the narrowed attention span (auditory working memory) rather than an indication of an aphasic deficit caused by dysfunction of a hypothetical *phonological loop* in the language network. *Reading* should be assessed for deficits in reading aloud as well as comprehension. *Alexia* describes an inability to either read aloud or comprehend written words and sentences; *agraphia* (or dysgraphia) is used to describe an acquired deficit in spelling.

Aphasias can arise acutely in cerebrovascular accidents (CVAs) or gradually in neurodegenerative diseases. In CVAs, damage encompasses cerebral cortex as well as deep white matter pathways interconnecting otherwise unaffected cortical areas. The syndromes listed in Table 30-1 are most applicable to this group, where gray matter and white matter at the lesion site are abruptly and jointly destroyed. Progressive neurodegenerative diseases can have cellular, laminar, and regional specificity for the cerebral cortex, giving rise to a different set of aphasias that will be described separately.

Wernicke's Aphasia Comprehension is impaired for spoken and written words and sentences. Language output is fluent but is highly paraphasic and circumlocutious. Paraphasic errors may lead to strings of neologisms, which lead to "jargon aphasia." Speech contains few substantive nouns. The output is therefore voluminous but uninformative. For example, a patient attempts to describe how his wife accidentally threw away something important, perhaps his dentures: "We don't need it anymore, she says. And with it when that was downstairs was my teeth-tick … a … den … dentith … my dentist. And they happened

TABLE 30-1 Clinical Features of Aphasias and Related Conditions Commonly Seen in Cerebrovascular Accidents

	COMPREHENSION	REPETITION OF SPOKEN LANGUAGE	NAMING	FLUENCY
Wernicke's	Impaired	Impaired	Impaired	Preserved or increased
Broca's	Preserved (except grammar)	Impaired	Impaired	Decreased
Global	Impaired	Impaired	Impaired	Decreased
Conduction	Preserved	Impaired	Impaired	Preserved
Nonfluent (anterior) transcortical	Preserved	Preserved	Impaired	Impaired
Fluent (posterior) transcortical	Impaired	Preserved	Impaired	Preserved

to be in that bag … see? …Where my two … two little pieces of dentist that I use … that I … all gone. If she throws the whole thing away … visit some friends of hers and she can't throw them away."

Gestures and pantomime do not improve communication. The patient may not realize that his or her language is incomprehensible and may appear angry and impatient when the examiner fails to decipher the meaning of a severely paraphasic statement. In some patients, this type of aphasia can be associated with severe agitation and paranoia. The ability to follow commands aimed at axial musculature may be preserved. The dissociation between the failure to understand simple questions ("What is your name?") in a patient who rapidly closes his or her eyes, sits up, or rolls over when asked to do so is characteristic of Wernicke's aphasia and helps differentiate it from deafness, psychiatric disease, or malingering. Patients with Wernicke's aphasia cannot express their thoughts in meaning-appropriate words and cannot decode the meaning of words in any modality of input. This aphasia therefore has expressive as well as receptive components. Repetition, naming, reading, and writing also are impaired.

The lesion site most commonly associated with Wernicke's aphasia caused by CVAs is the posterior portion of the language network. An embolus to the inferior division of the middle cerebral artery (MCA), to the posterior temporal or angular branches in particular, is the most common etiology **(Chap. 426)**. Intracerebral hemorrhage, head trauma, and neoplasm are other causes of Wernicke's aphasia. A coexisting right hemianopia or superior quadrantanopia is common, and mild right nasolabial flattening may be found, but otherwise, the examination is often unrevealing. The paraphasic, neologistic speech in an agitated patient with an otherwise unremarkable neurologic examination may lead to the suspicion of a primary psychiatric disorder such as schizophrenia or mania, but the other components characteristic of acquired aphasia and the absence of prior psychiatric disease usually settle the issue. Prognosis for recovery of language function is guarded.

Broca's Aphasia Speech is nonfluent, labored, interrupted by many word-finding pauses, and usually dysarthric. It is impoverished in function words but enriched in meaning-appropriate nouns. Abnormal word order and the inappropriate deployment of *bound morphemes* (word endings used to denote tenses, possessives, or plurals) lead to a characteristic agrammatism. Speech is telegraphic and pithy but quite informative. In the following passage, a patient with Broca's aphasia describes his medical history: "I see … the dotor, dotor sent me … Bosson. Go to hospital. Dotor … kept me beside. Two, tee days, doctor send me home."

Output may be reduced to a grunt or single word ("yes" or "no"), which is emitted with different intonations in an attempt to express approval or disapproval. In addition to fluency, naming and repetition are impaired. Comprehension of spoken language is intact except for syntactically difficult sentences with a passive voice structure or embedded clauses, indicating that Broca's aphasia is not just an "expressive" or "motor" disorder and that it also may involve a comprehension deficit in decoding syntax. Patients with Broca's aphasia can be tearful, easily frustrated, and profoundly depressed. Insight into their condition is preserved, in contrast to Wernicke's aphasia. Even when spontaneous speech is severely dysarthric, the patient may be able to display a relatively normal articulation of words when singing. This dissociation has been used to develop specific therapeutic approaches (melodic intonation therapy) for Broca's aphasia. Additional neurologic deficits include right facial weakness, hemiparesis or hemiplegia, and a buccofacial apraxia characterized by an inability to carry out motor commands involving oropharyngeal and facial musculature (e.g., patients are unable to demonstrate how to blow out a match or suck through a straw). The cause is most often infarction of Broca's area (the inferior frontal convolution; "B" in Fig. 30-1) and surrounding anterior perisylvian and insular cortex due to occlusion of the superior division of the MCA **(Chap. 426)**. Mass lesions, including tumor, intracerebral hemorrhage, and abscess, also may be responsible. When the cause of Broca's aphasia is stroke, recovery of language function generally peaks within 2–6 months, after which time further progress is limited. Speech therapy is more successful than in Wernicke's aphasia.

Conduction Aphasia Speech output is fluent but contains many phonemic paraphasias, comprehension of spoken language is intact, and repetition is severely impaired. Naming elicits phonemic paraphasias, and spelling is impaired. Reading aloud is impaired, but reading comprehension is preserved. The responsible lesion, usually a CVA in the temporoparietal or dorsal perisylvian region, interferes with the function of the phonological loop interconnecting Broca's area with Wernicke's area. Occasionally, a transient Wernicke's aphasia may rapidly resolve into a conduction aphasia. The paraphasic and circumlocutious output in conduction aphasia interferes with the ability to express meaning, but this deficit is not nearly as severe as the one displayed by patients with Wernicke's aphasia. Associated neurologic signs in conduction aphasia vary according to the primary lesion site.

Transcortical Aphasias: Fluent and Nonfluent Clinical features of *fluent (posterior) transcortical aphasia* are similar to those of Wernicke's aphasia, but repetition is intact. The lesion site disconnects the intact core of the language network from other temporoparietal association areas. Associated neurologic findings may include hemianopia. Cerebrovascular lesions (e.g., infarctions in the posterior watershed zone) and neoplasms that involve the temporoparietal cortex posterior to Wernicke's area are common causes. The features of *nonfluent (anterior) transcortical aphasia* are similar to those of Broca's aphasia, but repetition is intact and agrammatism is less pronounced. The neurologic examination may be otherwise intact, but a right hemiparesis also can exist. The lesion site disconnects the intact language network from prefrontal areas of the brain and usually involves the anterior watershed zone between anterior and MCA territories or the supplementary motor cortex in the territory of the anterior cerebral artery.

Global and Isolation Aphasias *Global aphasia* represents the combined dysfunction of Broca's and Wernicke's areas and usually results from strokes that involve the entire MCA distribution in the left hemisphere. Speech output is nonfluent, and comprehension of language is severely impaired. Related signs include right hemiplegia, hemisensory loss, and homonymous hemianopia. *Isolation aphasia* represents a combination of the two transcortical aphasias. Comprehension is severely impaired, and there is no purposeful speech output. The patient may parrot fragments of heard conversations (*echolalia*), indicating that the neural mechanisms for repetition are at least partially intact. This condition represents the pathologic function of the language network when it is isolated from other regions of the brain. Broca's and Wernicke's areas tend to be spared, but there is damage to the surrounding frontal, parietal, and temporal cortex. Lesions are patchy and can be associated with anoxia, carbon monoxide poisoning, or complete watershed zone infarctions.

Anomic Aphasia This form of aphasia may be considered the "minimal dysfunction" syndrome of the language network. Articulation, comprehension, and repetition are intact, but confrontation naming, word finding, and spelling are impaired. Word-finding pauses are uncommon, so language output is fluent but paraphasic, circumlocutious, and uninformative. The lesion sites can be anywhere within the left hemisphere language network, including the middle and inferior temporal gyri. *Anomic aphasia is the single most common language disturbance seen in head trauma, metabolic encephalopathy, and Alzheimer's disease.*

Pure Word Deafness The most common causes are either bilateral or left-sided MCA strokes affecting the superior temporal gyrus. The net effect of the underlying lesion is to interrupt the flow of information from the auditory association cortex to the language network. Patients have no difficulty understanding written language and can express themselves well in spoken or written language. They have no difficulty interpreting and reacting to environmental sounds if the primary auditory cortex and auditory association areas of the right hemisphere are spared. Because auditory information cannot be conveyed to the language network, however, it cannot be decoded into neural word representations, and the patient reacts to speech as if it were in an alien tongue that cannot be deciphered. Patients cannot

repeat spoken language but have no difficulty naming objects. In time, patients with pure word deafness teach themselves lipreading and may appear to have improved. There may be no additional neurologic findings, but agitated paranoid reactions are common in the acute stages. Cerebrovascular lesions are the most common cause.

Pure Alexia Without Agraphia This is the visual equivalent of pure word deafness. The lesions (usually a combination of damage to the left occipital cortex and to a posterior sector of the corpus callosum—the splenium) interrupt the flow of visual input into the language network. There is usually a right hemianopia, but the core language network remains unaffected. The patient can understand and produce spoken language, name objects in the left visual hemifield, repeat, and write. However, the patient acts as if illiterate when asked to read even the simplest sentence because the visual information from the written words (presented to the intact left visual hemifield) cannot reach the language network. Objects in the left hemifield may be named accurately because they activate nonvisual associations in the right hemisphere, which in turn can access the language network through transcallosal pathways anterior to the splenium. Patients with this syndrome also may lose the ability to name colors, although they can match colors. This is known as a *color anomia*. The most common etiology of pure alexia is a vascular lesion in the territory of the posterior cerebral artery or an infiltrating neoplasm in the left occipital cortex that involves the optic radiations as well as the crossing fibers of the splenium. Because the posterior cerebral artery also supplies medial temporal components of the limbic system, a patient with pure alexia also may experience an amnesia, but this is usually transient because the limbic lesion is unilateral.

Apraxia and Aphemia *Apraxia* designates a complex motor deficit that cannot be attributed to pyramidal, extrapyramidal, cerebellar, or sensory dysfunction and that does not arise from the patient's failure to understand the nature of the task. *Apraxia of speech* is used to designate articulatory abnormalities in the duration, fluidity, and stress of syllables that make up words. It can arise with CVAs in the posterior part of Broca's area or in the course of frontotemporal lobar degeneration (FTLD) with tauopathy. *Aphemia* is a severe form of acute speech apraxia that presents with severely impaired fluency (often mutism). Recovery is the rule and involves an intermediate stage of hoarse whispering. Writing, reading, and comprehension are intact, and so this is not a true aphasic syndrome. CVAs in parts of Broca's area or subcortical lesions that undercut its connections with other parts of the brain may be present. Occasionally, the lesion site is on the medial aspects of the frontal lobes and may involve the supplementary motor cortex of the left hemisphere. *Ideomotor apraxia* is diagnosed when commands to perform a specific motor act ("cough," "blow out a match") or pantomime the use of a common tool (a comb, hammer, straw, or toothbrush) in the absence of the real object cannot be followed. The patient's ability to comprehend the command is ascertained by demonstrating multiple movements and establishing that the correct one can be recognized. Some patients with this type of apraxia can imitate the appropriate movement when it is demonstrated by the examiner and show no impairment when handed the real object, indicating that the sensorimotor mechanisms necessary for the movement are intact. Some forms of ideomotor apraxia represent a disconnection of the language network from pyramidal motor systems so that commands to execute complex movements are understood but cannot be conveyed to the appropriate motor areas. *Buccofacial apraxia* involves apraxic deficits in movements of the face and mouth. Ideomotor *limb apraxia* encompasses apraxic deficits in movements of the arms and legs. Ideomotor apraxia almost always is caused by lesions in the left hemisphere and is commonly associated with aphasic syndromes, especially Broca's aphasia and conduction aphasia. Because the handling of real objects is not impaired, ideomotor apraxia by itself causes no major limitation of daily living activities. Patients with lesions of the anterior corpus callosum can display ideomotor apraxia confined to the left side of the body, a sign known as *sympathetic dyspraxia*. A severe form of sympathetic dyspraxia, known as the *alien hand* syndrome, is characterized by additional features of motor disinhibition on the left hand. *Ideational apraxia* refers to a deficit in the sequencing of goal-directed movements in patients who have no difficulty executing the individual components of the sequence. For example, when the patient is asked to pick up a pen and write, the sequence of uncapping the pen, placing the cap at the opposite end, turning the point toward the writing surface, and writing may be disrupted, and the patient may be seen trying to write with the wrong end of the pen or even with the removed cap. These motor sequencing problems usually are seen in the context of confusional states and dementias rather than focal lesions associated with aphasic conditions. *Limb-kinetic apraxia* involves clumsiness in the use of tools or objects that cannot be attributed to sensory, pyramidal, extrapyramidal, or cerebellar dysfunction. This condition can emerge in the context of focal premotor cortex lesions or *corticobasal degeneration* and can interfere with the use of tools and utensils.

Gerstmann's Syndrome The combination of *acalculia* (impairment of simple arithmetic), *dysgraphia* (impaired writing), *finger anomia* (an inability to name individual fingers such as the index and thumb), and *right-left confusion* (an inability to tell whether a hand, foot, or arm of the patient or examiner is on the right or left side of the body) is known as Gerstmann's syndrome. In making this diagnosis, it is important to establish that the finger and left-right naming deficits are not part of a more generalized anomia and that the patient is not otherwise aphasic. When Gerstmann's syndrome arises acutely and in isolation, it is commonly associated with damage to the inferior parietal lobule (especially the angular gyrus) in the left hemisphere.

Pragmatics and Prosody *Pragmatics* refers to aspects of language that communicate attitude, affect, and the figurative rather than literal aspects of a message (e.g., "green thumb" does not refer to the actual color of the finger). One component of pragmatics, *prosody,* refers to variations of melodic stress and intonation that influence attitude and the inferential aspect of verbal messages. For example, the two statements "He *is* clever." and "He is *clever*?" contain an identical word choice and syntax but convey vastly different messages because of differences in the intonation with which the statements are uttered. Damage to right hemisphere regions corresponding to Broca's area impairs the ability to introduce meaning-appropriate prosody into spoken language. The patient produces grammatically correct language with accurate word choice, but the statements are uttered in a monotone that interferes with the ability to convey the intended stress and effect. Patients with this type of *aprosodia* give the mistaken impression of being depressed or indifferent. Other aspects of pragmatics, especially the ability to infer the figurative aspect of a message, become impaired by damage to the right hemisphere or frontal lobes.

Subcortical Aphasia Damage to subcortical components of the language network (e.g., the striatum and thalamus of the left hemisphere) also can lead to aphasia. The resulting syndromes contain combinations of deficits in the various aspects of language but rarely fit the specific patterns described in Table 30-1. In a patient with a CVA, an anomic aphasia accompanied by dysarthria or a fluent aphasia with hemiparesis should raise the suspicion of a subcortical lesion site.

CLINICAL PRESENTATION AND DIAGNOSIS OF PPA Aphasias caused by CVAs start suddenly and display maximal deficits at the onset. These are the "classic" aphasias described above. Aphasias caused by neurodegenerative diseases have an insidious onset and relentless progression. The neuropathology can be selective not only for gray matter but also for specific layers and cell types. The clinico-anatomic patterns are therefore different from those described in Table 30-1.

Several neurodegenerative syndromes, such as typical Alzheimer-type (amnestic; **Chap. 431**) and frontotemporal (behavioral; **Chap. 432**) dementias, can also include language impairments as the disease progresses. In these cases, the aphasia is an ancillary component of the overall syndrome. A diagnosis of primary progressive aphasia (PPA) is justified only if the language disorder (i.e., aphasia) arises in relative isolation, becomes the primary concern that brings the patient to medical attention, and remains the most salient deficit for 1–2 years. PPA

can be caused by either FTLD or Alzheimer's disease (AD) pathology. Rarely, an identical syndrome can be caused by Creutzfeldt-Jacob disease (CJD) but with a more rapid progression **(Chap. 438)**.

LANGUAGE IN PPA The impairments of language in PPA have slightly different patterns from those seen in CVA-caused aphasias. For example, the full syndrome of Wernicke's aphasia is almost never seen in PPA, confirming the view that sentence comprehension and word comprehension are controlled by different regions of the language network. Three major subtypes of PPA can be recognized.

Agrammatic PPA The *agrammatic variant* is characterized by consistently low fluency and impaired grammar but intact word comprehension. It most closely resembles Broca's aphasia or anterior transcortical aphasia but usually lacks the right hemiparesis or dysarthria and may have more profound impairments of grammar. Peak sites of neuronal loss (gray matter atrophy) include the left inferior frontal gyrus where Broca's area is located. The neuropathology is usually a FTLD with tauopathy but can also be an atypical form of AD pathology.

Semantic PPA The *semantic variant* is characterized by preserved fluency and syntax but poor single-word comprehension and profound two-way naming impairments. This kind of aphasia is not seen with CVAs. It differs from Wernicke's aphasia or posterior transcortical aphasia because speech is usually informative and repetition is intact. Comprehension of sentences is relatively preserved if the meaning is not too dependent on words that fail to be understood allowing the patient to surmise the gist of the conversation through contextual cues. Such patients may appear unimpaired in the course of casual small talk but become puzzled upon encountering an undecipherable word such as "pumpkin" or "umbrella." Peak atrophy sites are located in the left anterior temporal lobe, indicating that this part of the brain plays a critical role in the comprehension of words, especially words that denote concrete objects. This is a part of the brain that was not included within the classic language network, probably because it is not a common site for focal CVAs. The neuropathology is frequently an FTLD with abnormal precipitates of the 43-kDa transactive response DNA-binding protein TDP-43 of type C.

Logopenic PPA The *logopenic variant* is characterized by preserved syntax and comprehension but frequent and severe word-finding pauses, anomia, circumlocutions, and simplifications during spontaneous speech. Repetition is usually impaired. Peak atrophy sites are located in the temporoparietal junction and posterior temporal lobe, partially overlapping with traditional location of Wernicke's area. However, the comprehension impairment of *Wernicke's aphasia* is absent probably because the underlying deep white matter, frequently damaged by CVAs, remains relatively intact in PPA. The repetition impairment suggests that parts of Wernicke's area are critical for phonological loop functionality. In contrast to Broca's aphasia or agrammatic PPA, the interruption of fluency is variable so that speech may appear entirely normal if the patient is allowed to engage in small talk. Logopenic PPA resembles the anomic aphasia of Table 30-1 but usually has longer and more frequent word-finding pauses. When repetition is impaired, the aphasia resembles the *conduction aphasia* in Table 30-1. Of all PPA subtypes, this is the one most commonly associated with the pathology of AD, but FTLD can also be the cause. In addition to these three major subtypes, there is also a *mixed* type of PPA where grammar, fluency, and word comprehension are jointly impaired. This is most like the global aphasia of Table 30-1. Rarely, PPA can present with patterns reminiscent of *pure word deafness* or *Gerstmann's syndrome*.

THE PARIETOFRONTAL NETWORK FOR SPATIAL ORIENTATION

Adaptive spatial orientation is subserved by a large-scale network containing three major cortical components. The *cingulate cortex* provides access to a motivational mapping of the extrapersonal space, the *posterior parietal cortex* to a sensorimotor representation of salient extrapersonal events, and the *frontal eye fields* to motor strategies for attentional behaviors **(Fig. 30-2)**. Subcortical components of this network include the striatum and the thalamus. Damage to this network can undermine the distribution of attention within the extrapersonal space, giving rise to hemispatial neglect, simultanagnosia, and object finding failures. The integration of egocentric (self-centered) with allocentric (object-centered) coordinates can also be disrupted, giving rise to impairments in route finding, the ability to avoid obstacles, and the ability to dress.

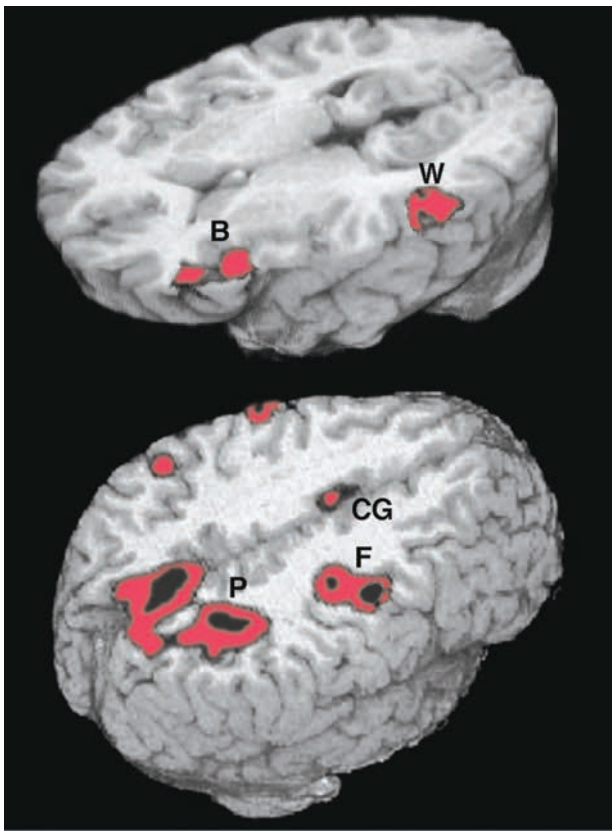

FIGURE 30-2 Functional magnetic resonance imaging of language and spatial attention in neurologically intact subjects. The red and black areas show regions of task-related significant activation. (*Top*) The subjects were asked to determine if two words were synonymous. This language task led to the simultaneous activation of the two components of the language network, Broca's area (B) and Wernicke's area (W). The activations are exclusively in the left hemisphere. (*Bottom*) The subjects were asked to shift spatial attention to a peripheral target. This task led to the simultaneous activation of the three epicenters of the attentional network: the posterior parietal cortex (P), the frontal eye fields (F), and the cingulate gyrus (CG). The activations are predominantly in the right hemisphere. *(Courtesy of Darren Gitelman, MD.)*

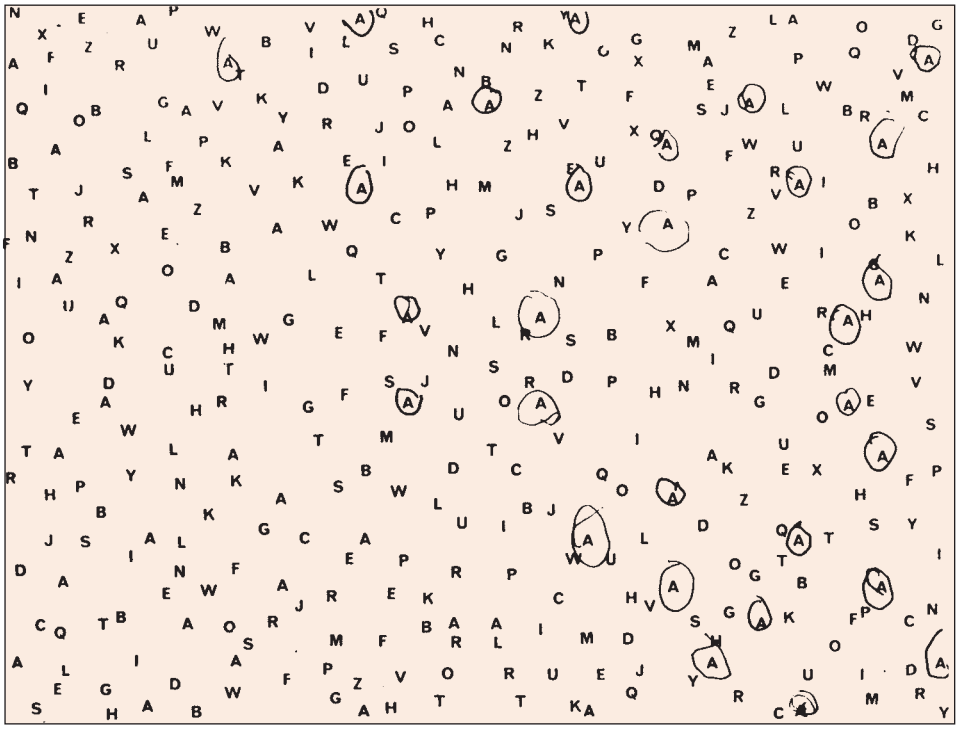
HEMISPATIAL NEGLECT

Contralesional hemispatial neglect represents one outcome of damage to the cortical or subcortical components of this network. *The traditional view that hemispatial neglect always denotes a parietal lobe lesion is inaccurate*. According to one model of spatial cognition, the right hemisphere directs attention within the *entire* extrapersonal space, whereas the left hemisphere directs attention mostly within the contralateral right hemispace. Consequently, left hemisphere lesions do not give rise to much contralesional neglect because the global attentional mechanisms of the right hemisphere can compensate for the loss of the *contralaterally* directed attentional functions of the left hemisphere. Right hemisphere lesions, however, give rise to severe contralesional left hemispatial neglect because the unaffected left hemisphere does not contain ipsilateral attentional mechanisms. This model is consistent with clinical experience, which shows that contralesional neglect is more common, more severe, and longer lasting after damage to the right hemisphere than after damage to the left hemisphere. Severe neglect for the right hemispace is rare, even in left-handers with left hemisphere lesions.

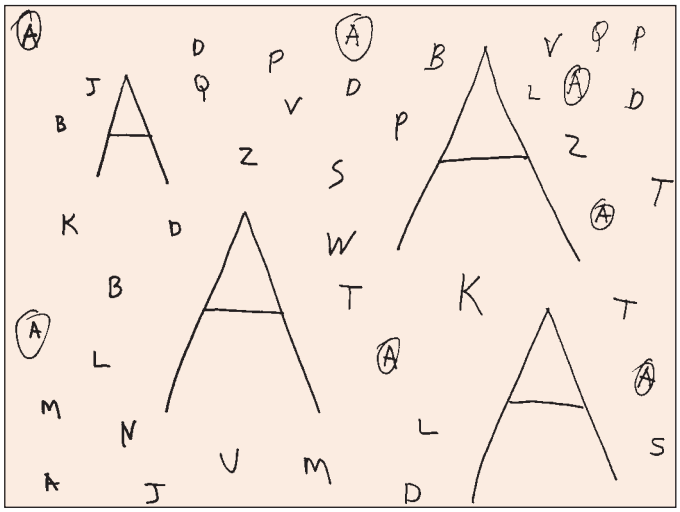
Clinical Examination Patients with severe neglect may fail to dress, shave, or groom the left side of the body; fail to eat food placed on the left side of the tray; and fail to read the left half of sentences. When asked to copy a simple line drawing, the patient fails to copy detail on the left, and when the patient is asked to write, there is a tendency to leave an unusually wide margin on the left. Two bedside tests that are useful in assessing neglect are *simultaneous bilateral stimulation* and *visual target cancellation*. In the former, the examiner provides either unilateral or simultaneous bilateral stimulation in the visual, auditory, and tactile modalities. After right hemisphere injury, patients who have no difficulty detecting unilateral stimuli on either side experience the bilaterally presented stimulus as coming only from the right. This phenomenon is known as *extinction* and is a manifestation of the sensory-representational aspect of hemispatial neglect. In the target detection task, targets (e.g., A's) are interspersed with foils (e.g., other letters of the alphabet) on a 21.5- to 28.0-cm (8.5–11 in.) sheet of paper, and the patient is asked to circle all the targets. A failure to detect targets on the left is a manifestation of the exploratory (motor) deficit in hemispatial neglect **(Fig. 30-3*A*)**. Hemianopia is not by itself sufficient to cause the target detection failure because the patient is free to turn the head and eyes to the left. Target detection failures therefore reflect a distortion of spatial attention, not just of sensory input. Some patients with neglect also may deny the existence of hemiparesis and may even deny ownership of the paralyzed limb, a condition known as *anosognosia*.

BÁLINT'S SYNDROME, SIMULTANAGNOSIA, DRESSING APRAXIA, CONSTRUCTION APRAXIA, AND ROUTE-FINDING IMPAIRMENTS

Bilateral involvement of the network for spatial attention, especially its parietal components, leads to a state of severe spatial disorientation known as *Bálint's syndrome*. Bálint's syndrome involves deficits in the



A



B

FIGURE 30-3 ***A.*** A 47-year-old man with a large frontoparietal lesion in the right hemisphere was asked to circle all the A's. Only targets on the right are circled. This is a manifestation of left hemispatial neglect. ***B.*** A 70-year-old woman with a 2-year history of degenerative dementia was able to circle most of the small targets but ignored the larger ones. This is a manifestation of simultanagnosia.

orderly visuomotor scanning of the environment (*oculomotor apraxia*), accurate manual reaching toward visual targets (*optic ataxia*), and the ability to integrate visual information in the center of gaze with more peripheral information (*simultanagnosia*). A patient with simultanagnosia "misses the forest for the trees." For example, a patient who is shown a table lamp and asked to name the object may look at its circular base and call it an ashtray. Some patients with simultanagnosia report that objects they look at may vanish suddenly, probably indicating an inability to compute the oculomotor return to the original point of gaze after brief saccadic displacements. Movement and distracting stimuli greatly exacerbate the difficulties of visual perception. Simultanagnosia can occur without the other two components of Bálint's syndrome, especially in association with AD.

A modification of the letter cancellation task described above can be used for the bedside diagnosis of simultanagnosia. In this modification, some of the targets (e.g., A's) are made to be much larger than the others (7.5–10 cm vs 2.5 cm [3–4 in. vs 1 in.] in height), and all targets are embedded among foils. Patients with simultanagnosia display a counterintuitive but characteristic tendency to miss the larger targets **(Fig. 30-3*B*)**. This occurs because the information needed for the identification of the larger targets cannot be confined to the immediate line of gaze and requires the integration of visual information across multiple fixation points. The greater difficulty in the detection of the larger targets also indicates that poor acuity is not responsible for the impairment of visual function and that the problem is central rather than peripheral. The test shown in Fig. 30-3*B* is not by itself sufficient to diagnose simultanagnosia as some patients with a frontal network syndrome may omit the letters that appear incongruous for the size of the paper. This may happen because they lack the mental flexibility to realize that the two types of targets are symbolically identical despite being superficially different.

Bilateral parietal lesions can impair the integration of egocentric with allocentric spatial coordinates. One manifestation is *dressing apraxia*. A patient with this condition is unable to align the body axis with the axis of the garment and can be seen struggling as he or she holds a coat from its bottom or extends his or her arm into a fold of the garment rather than into its sleeve. Lesions that involve the posterior parietal cortex also lead to severe difficulties in copying simple line drawings. This is known as a *construction apraxia* and is much more severe if the lesion is in the right hemisphere. In some patients with right hemisphere lesions, the drawing difficulties are confined to the left side of the figure and represent a manifestation of hemispatial neglect; in others, there is a more universal deficit in reproducing contours and three-dimensional perspective. Impairments of route finding can be included in this group of disorders, which reflect an inability to orient the self with respect to external objects and landmarks.

Causes of Spatial Disorientation and the Posterior Cortical Atrophy Syndrome Cerebrovascular lesions and neoplasms in the right hemisphere are common causes of hemispatial neglect. Depending on the site of the lesion, a patient with neglect also may have hemiparesis, hemihypesthesia, and hemianopia on the left, but these are not invariant findings. The majority of these patients display considerable improvement of hemispatial neglect, usually within the first several weeks. Bálint's syndrome, dressing apraxia, and route-finding impairments are more likely to result from bilateral dorsal parietal lesions; common settings for acute onset include watershed infarction between the middle and posterior cerebral artery territories, hypoglycemia, and sagittal sinus thrombosis.

A progressive form of spatial disorientation, known as the *posterior cortical atrophy* (PCA) syndrome, most commonly represents a variant of AD with unusual concentrations of neurofibrillary degeneration in the parieto-occipital cortex and the superior colliculus **(Fig. 30-4)**. Lewy body disease (LBD), CJD, and FTLD (corticobasal degeneration type) are other possible causes. The patient displays progressive hemispatial neglect, Bálint's syndrome, and route-finding impairments, usually accompanied by dressing and construction apraxia.

THE OCCIPITOTEMPORAL NETWORK FOR FACE AND OBJECT RECOGNITION

A patient with *prosopagnosia* cannot recognize familiar faces, including, sometimes, the reflection of their own face in the mirror. This is not a perceptual deficit because prosopagnosic patients easily can tell whether two faces are identical. Furthermore, a prosopagnosic patient who cannot recognize a familiar face by visual inspection alone can use auditory cues to reach appropriate recognition if allowed to listen to the person's voice. The deficit in prosopagnosia is therefore modality-specific and reflects the existence of a lesion that prevents the activation of otherwise intact multimodal associative templates by relevant visual input. Prosopagnosic patients characteristically have no difficulty with the generic identification of a face as a face or a car as a car, but may not recognize the identity of an individual face or the make of an individual car. This reflects a visual recognition deficit for proprietary features that characterize individual members of an object class. When recognition problems become more generalized and extend to the generic identification of common objects, the condition is known as *visual object agnosia*. A patient with anomia cannot name the object but can describe its use. In contrast, a patient with visual agnosia is unable either to name a visually presented object or to describe its use. Face and object recognition disorders also can result from the simultanagnosia of Bálint's syndrome, in which case they are known as *apperceptive* agnosias as opposed to the *associative* agnosias that result from inferior temporal lobe lesions.

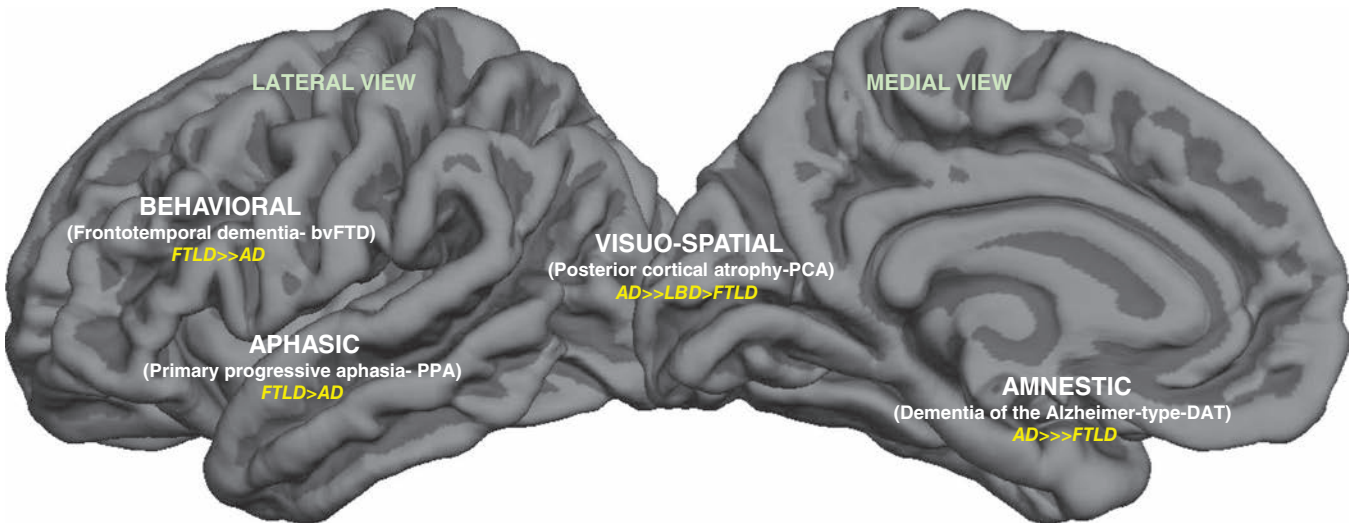


FIGURE 30-4 Four focal dementia syndromes and their most likely neuropathologic correlates. AD, Alzheimer's disease; bvFTD, behavioral variant frontotemporal dementia; DAT, amnestic dementia of the Alzheimer type; FTLD, frontotemporal lobar degeneration (tau or TDP-43 type); LBD, Lewy body disease; PCA, posterior cortical atrophy syndrome; PPA, primary progressive aphasia.

CAUSES AND RELATION TO SEMANTIC DEMENTIA

The characteristic lesions in prosopagnosia and visual object agnosia of acute onset consist of bilateral infarctions in the territory of the posterior cerebral arteries that involve the fusiform gyrus. Associated deficits can include visual field defects (especially superior quadrantanopias) and a centrally based color blindness known as achromatopsia. Rarely, the responsible lesion is unilateral. In such cases, prosopagnosia is associated with lesions in the right hemisphere, and object agnosia with lesions in the left. Degenerative diseases of anterior and inferior temporal cortex can cause progressive associative prosopagnosia and object agnosia. The combination of progressive associative agnosia and a fluent aphasia with word comprehension impairment is known as *semantic dementia*. Patients with semantic dementia fail to recognize faces and objects and cannot understand the meaning of words denoting objects. This needs to be differentiated from the semantic type of PPA where there is severe impairment in understanding words that denote objects and in naming faces and objects but a relative preservation of face and object recognition. The anterior temporal lobe atrophy is usually bilateral in semantic dementia whereas it tends to affect mostly the left hemisphere in semantic PPA. Acute onset of the semantic dementia syndrome can be associated with herpes simplex encephalitis.

LIMBIC NETWORK FOR EXPLICIT MEMORY AND AMNESIA

Limbic areas (e.g., the hippocampus, amygdala, and entorhinal cortex), paralimbic areas (e.g., the cingulate gyrus, insula, temporopolar cortex, and parts of orbitofrontal regions), the anterior and medial nuclei of the thalamus, the medial and basal parts of the striatum, and the hypothalamus collectively constitute a distributed network known as the *limbic system*. The behavioral affiliations of this network can be classified into two groups. One includes the coordination of emotion, motivation, affiliative behaviors, autonomic tone, and endocrine function. These functions are under the influence of the amygdala and anterior paralimbic areas. They make up the salience network. The two neurologic conditions that most frequently interfere with this group of limbic functions are temporal lobe epilepsy and behavioral variant frontotemporal dementia (bvFTD). An additional area of specialization for the limbic network and the one that is of most relevance to clinical practice is that of declarative (explicit) memory for recent episodes and experiences. This function is under the influence of the hippocampus, entorhinal cortex, posterior paralimbic areas, and limbic nuclei of the thalamus. This part of the limbic system is also known as the Papez circuit. A disturbance of explicit memory is known as an *amnestic state*. In the absence of deficits in motivation, attention, language, or visuospatial function, the clinical diagnosis of a persistent global amnestic state is always associated with bilateral damage to the limbic network, usually within the hippocampo-entorhinal complex or the thalamus. Damage to the limbic network does not necessarily destroy memories but interferes with their conscious recall in coherent form. The individual fragments of information remain preserved despite the limbic lesions and can sustain what is known as *implicit memory*. For example, patients with amnestic states can acquire new motor or perceptual skills even though they may have no conscious knowledge of the experiences that led to the acquisition of these skills.

The memory disturbance in the amnestic state is multimodal and includes retrograde and anterograde components. The *retrograde amnesia* involves an inability to recall experiences that occurred before the onset of the amnestic state. Relatively recent events are more vulnerable to retrograde amnesia than are more remote and more extensively consolidated events. A patient who comes to the emergency room complaining that he cannot remember his or her identity but can remember the events of the previous day almost certainly does not have a neurologic cause of memory disturbance. The second and most important component of the amnestic state is the *anterograde amnesia*, which indicates an inability to store, retain, and recall new knowledge. Patients with amnestic states cannot remember what they ate a few hours ago or the details of an important event they may have experienced in the recent past. In the acute stages, there also may be a tendency to fill in memory gaps with inaccurate, fabricated, and often implausible information. This is known as *confabulation*. Patients with the amnestic syndrome forget that they forget and tend to deny the existence of a memory problem when questioned. Confabulation is more common in cases where the underlying lesion also interferes with parts of the frontal network, as in the case of the Wernicke-Korsakoff syndrome or traumatic head injury.

CLINICAL EXAMINATION

A patient with an amnestic state is almost always disoriented, especially to time, and has little knowledge of current news. The anterograde component of an amnestic state can be tested with a list of four to five words read aloud by the examiner up to five times or until the patient can immediately repeat the entire list without an intervening delay. The next phase of the recall occurs after a period of 5–10 min during which the patient is engaged in other tasks. Amnestic patients fail this phase of the task and may even forget that they were given a list of words to remember. Accurate recognition of the words by multiple choice in a patient who cannot recall them indicates a less severe memory disturbance that affects mostly the retrieval stage of memory. The retrograde component of an amnesia can be assessed with questions related to autobiographical or historic events. The anterograde component of amnestic states is usually much more prominent than the retrograde component. In rare instances, occasionally associated with temporal lobe epilepsy or herpes simplex encephalitis, the retrograde component may dominate. Confusional states caused by toxic-metabolic encephalopathies and some types of frontal lobe damage lead to secondary memory impairments, especially at the stages of encoding and retrieval, even in the absence of limbic lesions. This sort of memory impairment can be differentiated from the amnestic state by the presence of additional impairments in the attention-related tasks described below in the section on the frontal lobes.

CAUSES, INCLUDING ALZHEIMER'S DISEASE

Neurologic diseases that give rise to an amnestic state include tumors (of the sphenoid wing, posterior corpus callosum, thalamus, or medial temporal lobe), infarctions (in the territories of the anterior or posterior cerebral arteries), head trauma, herpes simplex encephalitis, Wernicke-Korsakoff encephalopathy, autoimmune limbic encephalitis, and degenerative dementias such as AD and Pick's disease. The one common denominator of all these diseases is the presence of bilateral lesions within one or more components in the limbic network. Occasionally, unilateral left-sided hippocampal lesions can give rise to an amnestic state, but the memory disorder tends to be transient. Depending on the nature and distribution of the underlying neurologic disease, the patient also may have visual field deficits, eye movement limitations, or cerebellar findings.

The most common cause of progressive memory impairments in the elderly is AD. This is why a predominantly amnestic dementia is also known as a dementia of the Alzheimer type (DAT). A prodromal stage of DAT, when daily living activities are generally preserved, is known as amnestic mild cognitive impairment (MCI). The predilection of the entorhinal cortex and hippocampus for early neurofibrillary degeneration by typical AD pathology is responsible for the initially selective impairment of episodic memory. In time, additional impairments in language, attention, and visuospatial skills emerge as the neurofibrillary degeneration spreads to additional neocortical areas. Less frequently, amnestic dementias can also be caused by FTLD.

Transient global amnesia is a distinctive syndrome usually seen in late middle age. Patients become acutely disoriented and repeatedly ask who they are, where they are, and what they are doing. The spell is characterized by anterograde amnesia (inability to retain new information) and a retrograde amnesia for relatively recent events that occurred before the onset. The syndrome usually resolves within 24–48 h and is followed by the filling in of the period affected by the retrograde amnesia, although there is persistent loss of memory for the events that occurred during the ictus. Recurrences are noted in

~20% of patients. Migraine, temporal lobe seizures, and perfusion abnormalities in the posterior cerebral territory have been postulated as causes of transient global amnesia. The absence of associated neurologic findings occasionally may lead to the incorrect diagnosis of a psychiatric disorder.

THE PREFRONTAL NETWORK FOR EXECUTIVE FUNCTION AND BEHAVIOR

The frontal lobes can be subdivided into motor-premotor, dorsolateral prefrontal, medial prefrontal, and orbitofrontal components. The terms *frontal lobe syndrome* and *prefrontal cortex* refer only to the last three of these four components. These are the parts of the cerebral cortex that show the greatest phylogenetic expansion in primates, especially in humans. The dorsolateral prefrontal, medial prefrontal, and orbitofrontal areas, along with the subcortical structures with which they are interconnected (i.e., the head of the caudate and the dorsomedial nucleus of the thalamus), collectively make up a large-scale network that coordinates exceedingly complex aspects of human cognition and behavior. The prefrontal network overlaps with the salience network through the anterior cingulate gyrus and parts of the orbitofrontal region. Impairments of social conduct and empathy seen in neurodegenerative frontal dementias (such as bvFTD) are attributed to pathology of the prefrontal and salience networks.

The prefrontal network plays an important role in behaviors that require multitasking and the integration of thought with emotion. Cognitive operations impaired by prefrontal cortex lesions often are referred to as "executive functions." The most common clinical manifestations of damage to the prefrontal network take the form of two relatively distinct syndromes. In the *frontal abulic syndrome*, the patient shows a loss of initiative, creativity, and curiosity and displays a pervasive emotional blandness, apathy, and lack of empathy. In the *frontal disinhibition syndrome*, the patient becomes socially disinhibited and shows severe impairments of judgment, insight, foresight, and the ability to mind rules of conduct. The dissociation between intact intellectual function and a total lack of even rudimentary common sense is striking. Despite the preservation of all essential memory functions, the patient cannot learn from experience and continues to display inappropriate behaviors without appearing to feel emotional pain, guilt, or regret when those behaviors repeatedly lead to disastrous consequences. The impairments may emerge only in real-life situations when behavior is under minimal external control and may not be apparent within the structured environment of the medical office. Testing judgment by asking patients what they would do if they detected a fire in a theater or found a stamped and addressed envelope on the road is not very informative because patients who answer these questions wisely in the office may still act very foolishly in real-life settings. The physician must therefore be prepared to make a diagnosis of frontal lobe disease based on historic information alone even when the mental state is quite intact in the office examination.

CLINICAL EXAMINATION

The emergence of developmentally primitive reflexes, also known as frontal release signs, such as grasping (elicited by stroking the palm) and sucking (elicited by stroking the lips) are seen primarily in patients with large structural lesions that extend into the premotor components of the frontal lobes or in the context of metabolic encephalopathies. The vast majority of patients with prefrontal lesions and frontal lobe behavioral syndromes do not display these reflexes. Damage to the frontal lobe disrupts a variety of attention-related functions, including working memory (the transient online holding and manipulation of information), concentration span, the effortful scanning and retrieval of stored information, the inhibition of immediate but inappropriate responses, and mental flexibility. Digit span (which should be seven forward and five reverse) is decreased, reflecting poor working memory; the recitation of the months of the year in reverse order (which should take <15 s) is slowed as another indication of poor working memory; and the fluency in producing words starting with the letter a, f, or s that can be generated in 1 min (normally ≥12 per letter) is diminished even in nonaphasic patients, indicating an impairment in the ability to search and retrieve information from long-term stores. In "go–no go" tasks (where the instruction is to raise the finger upon hearing one tap but keep it still upon hearing two taps), the patient shows a characteristic inability to inhibit the response to the "no go" stimulus. Mental flexibility (tested by the ability to shift from one criterion to another in sorting or matching tasks) is impoverished; distractibility by irrelevant stimuli is increased; and there is a pronounced tendency for impersistence and perseveration. The ability for abstracting similarities and interpreting proverbs is also undermined.

The attentional deficits disrupt the orderly registration and retrieval of new information and lead to *secondary* deficits of explicit memory. The distinction of the underlying neural mechanisms is illustrated by the observation that severely amnestic patients who cannot remember events that occurred a few minutes ago may have intact if not superior working memory capacity as shown in tests of digit span. The use of the term *memory* to designate two completely different mental faculties is confusing. Working memory depends on the on-line holding of information for brief periods of time, whereas explicit memory depends on the off-line storage and subsequent retrieval of the information.

CAUSES: TRAUMA, NEOPLASM, AND FRONTOTEMPORAL DEMENTIA

The abulic syndrome tends to be associated with damage in dorsolateral or dorsomedial prefrontal cortex, and the disinhibition syndrome with damage in orbitofrontal or ventromedial cortex. These syndromes tend to arise almost exclusively after bilateral lesions. Unilateral lesions confined to the prefrontal cortex may remain silent until the pathology spreads to the other side; this explains why thromboembolic CVA is an unusual cause of the frontal lobe syndrome. When behavioral syndromes of the frontal network arise in conjunction with asymmetric disease, the lesion tends to be predominantly on the right side of the brain. Common settings for frontal lobe syndromes include head trauma, ruptured aneurysms, hydrocephalus, tumors (including metastases, glioblastoma, and falx or olfactory groove meningiomas), and focal degenerative diseases, especially FTLD. The most prominent neurodegenerative frontal syndrome is bvFTD. In many patients with bvFTD, the atrophy includes orbitofrontal cortex and also extends into the anterior temporal lobes, insula, and anterior cingulate cortex. Occasionally, atrophy predominantly in the right anterior temporal lobe presents with the bvFTD syndrome. The behavioral changes in these patients can range from apathy to shoplifting, compulsive gambling, sexual indiscretions, remarkable lack of common sense, new ritualistic behaviors, and alterations in dietary preferences, usually leading to increased taste for sweets or rigid attachment to specific food items. In many patients with AD, neurofibrillary degeneration eventually spreads to prefrontal cortex and gives rise to components of the frontal lobe syndrome, but almost always on a background of severe memory impairment. Rarely, the bvFTD syndrome can arise in isolation in the context of an atypical form of AD pathology.

Lesions in the caudate nucleus or in the dorsomedial nucleus of the thalamus (subcortical components of the prefrontal network) also can produce a frontal lobe syndrome affecting mostly executive functions. This is one reason why the changes in mental state associated with degenerative basal ganglia diseases such as Parkinson's disease and Huntington's disease display components of the frontal lobe syndrome. Bilateral multifocal lesions of the cerebral hemispheres, none of which are individually large enough to cause specific cognitive deficits such as aphasia and neglect, can collectively interfere with the connectivity and therefore integrating (executive) function of the prefrontal cortex. A frontal lobe syndrome, usually of the abulic form, is therefore the single most common behavioral profile associated with a variety of bilateral multifocal brain diseases, including metabolic encephalopathy, multiple sclerosis, and vitamin B_{12} deficiency, among others. Many patients with the clinical diagnosis of a frontal lobe syndrome tend to have lesions that do not involve prefrontal cortex but involve either the subcortical components of the prefrontal network or its connections with other parts of the brain. To avoid making a diagnosis of "frontal lobe syndrome" in a patient with no evidence of frontal cortex disease, it is advisable to use the diagnostic term *frontal network syndrome*, with the

understanding that the responsible lesions can lie anywhere within this distributed network. A patient with frontal lobe disease raises potential dilemmas in differential diagnosis: the abulia and blandness may be misinterpreted as depression, and the disinhibition as idiopathic mania or acting out. Appropriate intervention may be delayed while a treatable tumor keeps expanding.

CARING FOR PATIENTS WITH DEFICITS OF HIGHER CEREBRAL FUNCTION

Spontaneous improvement of cognitive deficits following stroke or trauma is common. It is most rapid in the first few weeks but may continue for up to 2 years, especially in young individuals with single brain lesions. Some of the initial deficits in such cases appear to arise from remote dysfunction (diaschisis) in brain regions that are interconnected with the site of initial injury. Improvement in these patients may reflect, at least in part, a normalization of the remote dysfunction. Other mechanisms may involve functional reorganization in surviving neurons adjacent to the injury or the compensatory use of homologous structures, e.g., the right superior temporal gyrus with recovery from Wernicke's aphasia. In contrast, neurodegenerative diseases show a progression of impairment but at rates that vary greatly from patient to patient.

Pharmacologic and Nonpharmacologic Interventions Some of the deficits described in this chapter are so complex that they may bewilder not only the patient and family but also the physician. The care of patients with such deficits requires a careful evaluation of the history, cognitive test results, and diagnostic procedures. Each piece of information needs to be interpreted cautiously and placed in context. A complaint of "poor memory," for example, may reflect an anomia; poor scores on a learning task may reflect a weakness of attention rather than explicit memory; a report of depression or indifference may reflect impaired prosody rather than a change in mood or empathy; jocularity may arise from poor insight rather than good mood. Although there are few well-controlled studies, several nonpharmacologic interventions have been used to treat higher cortical deficits. These include speech therapy for aphasias, behavioral modification for compartmental disorders, and cognitive training for visuospatial disorientation and amnestic syndromes. More practical interventions, usually delivered through occupational therapy, aim to improve daily living activities through assistive devices and modifications of the home environment. Determining driving competence is challenging, especially in the early stages of dementing diseases. An on-the-road driving test and reports from family members may help time decisions related to this very important activity. In neurodegenerative conditions such as PPA, transcranial magnetic (or direct current) stimulation has had mixed success in eliciting symptomatic improvement. The goal is to activate remaining neurons at sites of atrophy or in unaffected regions of the contralateral hemisphere. Depression and sleep disorders can intensify the cognitive disorders and should be treated with appropriate modalities. If neuroleptics become absolutely necessary for the control of agitation, atypical neuroleptics are preferable because of their lower extrapyramidal side effects. Treatment with neuroleptics in elderly patients with dementia requires weighing the potential benefits against the potentially serious side effects. This is especially relevant to the case of patients with Lewy body dementia, who can be unusually sensitive to side effects.

As in all other branches of medicine, a crucial step in patient care is to identify the underlying cause of the impairment. This is easily done in cases of CVA, head trauma, or encephalitis but becomes particularly challenging in the dementias because the same progressive clinical syndrome can be caused by one of several neuropathologic entities. The advent of imaging, blood, and cerebrospinal fluid biomarkers now makes it possible to address this question with reasonable success and to make specific diagnoses of AD, LBD, CJD, and FTLD. A specific etiologic diagnosis allows the physician to recommend medications or clinical trials that are the most appropriate for the underlying disease process. A clinical assessment that identifies the principal domain of behavioral and cognitive impairment followed by the judicious use of biomarker information to surmise the nature of the underlying disease allows a personalized approach to patients with higher cognitive impairment.

31 Sleep Disorders

Thomas E. Scammell, Clifford B. Saper, Charles A. Czeisler

Disturbed sleep is one of the most common health complaints that physicians encounter. More than one-half of adults in the United States experience at least intermittent sleep disturbance, and only 30% of adult Americans report consistently obtaining a sufficient amount of sleep. The National Academy of Medicine has estimated that 50–70 million Americans suffer from a chronic disorder of sleep and wakefulness, which can adversely affect daytime functioning as well as physical and mental health. A high prevalence of sleep disorders across all cultures is also now increasingly recognized, and these problems are expected to further increase in the years ahead as the global population ages. Over the last 30 years, the field of sleep medicine has emerged as a distinct specialty in response to the impact of sleep disorders and sleep deficiency on overall health. Nonetheless, over 80% of patients with sleep disorders remain undiagnosed and untreated—costing the U.S. economy over $400 billion annually in increased health care costs, lost productivity, accidents and injuries, and leading to the development of workplace-based sleep health education and sleep disorders screening programs designed to address this unmet medical need.

PHYSIOLOGY OF SLEEP AND WAKEFULNESS

Most adults need 7–9 h of sleep per night to promote optimal health, although the timing, duration, and internal structure of sleep vary among individuals. In the United States, adults tend to have one consolidated sleep episode each night, although in some cultures sleep may be divided into a mid-afternoon nap and a shortened night sleep. This pattern changes considerably over the life span, as infants and young children sleep considerably more than older people, while individuals >70 years of age sleep on average about an hour less than young adults.

The stages of human sleep are defined on the basis of characteristic patterns in the electroencephalogram (EEG), the electrooculogram (EOG—a measure of eye-movement activity), and the surface electromyogram (EMG) measured on the chin, neck, and legs. The continuous recording of these electrophysiologic parameters to define sleep and wakefulness is termed *polysomnography*.

Polysomnographic profiles define two basic states of sleep: (1) rapid eye movement (REM) sleep and (2) non–rapid eye movement (NREM)

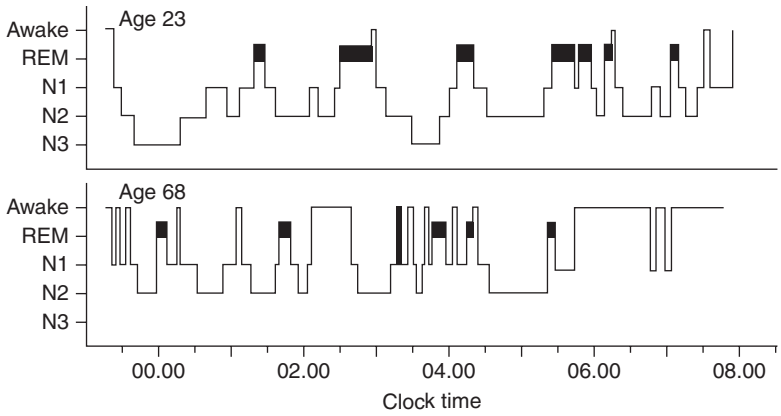

FIGURE 31-1 Wake-sleep architecture. Alternating stages of wakefulness, the three stages of non–rapid eye movement sleep (N1–N3), and rapid eye movement (REM) sleep (*solid bars*) occur over the course of the night for representative young and older adult men. Characteristic features of sleep in older people include reduction of N3 slow-wave sleep, frequent spontaneous awakenings, early sleep onset, and early morning awakening.

sleep. NREM sleep is further subdivided into three stages: N1, N2, and N3, characterized by an increasing threshold for arousal and slowing of the cortical EEG. REM sleep is characterized by a low-amplitude, mixed-frequency EEG, similar to NREM stage N1 sleep, and an EOG pattern of REMs that tend to occur in flurries or bursts. EMG activity is absent in nearly all skeletal muscles except those involved in respiration, reflecting the brainstem-mediated muscle paralysis that is characteristic of REM sleep.

ORGANIZATION OF HUMAN SLEEP

Normal nocturnal sleep in adults displays a consistent organization from night to night **(Fig. 31-1)**. After sleep onset, sleep usually progresses through NREM stages N1–N3 sleep within 45–60 min. NREM stage N3 sleep (also known as slow-wave sleep) predominates in the first third of the night and comprises 15–25% of total nocturnal sleep time in young adults. Sleep deprivation increases the rapidity of sleep onset and both the intensity and amount of slow-wave sleep.

The first REM sleep episode usually occurs in the second hour of sleep. NREM and REM sleep alternate through the night with an average period of 90–110 min (the "ultradian" sleep cycle). Overall, in a healthy young adult, REM sleep constitutes 20–25% of total sleep, and NREM stages N1 and N2 constitute 50–60%.

Age has a profound impact on sleep state organization (Fig. 31-1). N3 sleep is most intense and prominent during childhood, decreasing with puberty and across the second and third decades of life. In older adults, N3 sleep may be completely absent, and the remaining NREM sleep typically becomes more fragmented, with frequent awakenings from NREM sleep. It is the increased frequency of awakenings, rather than a decreased ability to fall back asleep, that accounts for the increased wakefulness during the sleep episode in older people. While REM sleep may account for 50% of total sleep time in infancy, the percentage falls off sharply over the first postnatal year as a mature REM-NREM cycle develops; thereafter, REM sleep occupies about 25% of total sleep time.

Sleep deprivation degrades cognitive performance, particularly on tests that require continual vigilance. Paradoxically, older people are less vulnerable than young adults to the neurobehavioral performance impairment induced by acute sleep deprivation, maintaining their reaction time and sustaining vigilance with fewer lapses of attention. However, it is more difficult for older adults to obtain recovery sleep after staying awake all night, as the ability to sleep during the daytime declines with age.

After sleep deprivation, NREM sleep generally recovers first, followed by REM sleep. However, because REM sleep tends to be most prominent in the second half of the night, sleep truncation (e.g., by an alarm clock) results in selective REM sleep deprivation. This may increase REM sleep pressure to the point where the first REM sleep may occur much earlier in the nightly sleep episode. Because several disorders (see below) also cause sleep fragmentation, it is important that the patient have sufficient sleep opportunity (at least 8 h per night) for several nights prior to a diagnostic polysomnogram.

There is growing evidence that inadequate sleep in humans is associated with glucose intolerance that may contribute to the development of diabetes, obesity, and the metabolic syndrome, as well as impaired immune responses, accelerated atherosclerosis, and increased risk of cardiac disease, cognitive impairment, Alzheimer's disease, and stroke. For these reasons, the National Academy of Medicine declared sleep deficiency and sleep disorders "an unmet public health problem."

WAKE AND SLEEP ARE REGULATED BY BRAIN CIRCUITS

Two principal neural systems govern the expression of sleep and wakefulness. The ascending arousal system, illustrated in *green* in **Fig. 31-2**, consists of clusters of nerve cells extending from the upper pons to the hypothalamus and basal forebrain that activate the cerebral cortex, thalamus (which is necessary to relay sensory information to the cortex), and other forebrain regions. The ascending arousal neurons use monoamines (norepinephrine, dopamine, serotonin, and histamine), glutamate, or acetylcholine as neurotransmitters to activate their target neurons. Some basal forebrain neurons use γ-aminobutyric acid (GABA) to inhibit cortical inhibitory interneurons, thus promoting arousal. Additional wake-promoting neurons in the hypothalamus use the peptide neurotransmitter orexin (also known as hypocretin, shown in Fig. 31-2 in *blue*) to reinforce activity in the other arousal cell groups.

Damage to the arousal system at the level of the rostral pons and lower midbrain causes coma, indicating that the ascending arousal influence from this level is critical in maintaining wakefulness. Injury to the hypothalamic branch of the arousal system causes profound sleepiness but usually not coma. Specific loss of the orexin neurons produces the sleep disorder narcolepsy (see below). Isolated damage to the thalamus causes loss of the content of wakefulness, known as a persistent vegetative state, but wake-sleep cycles are largely preserved.

The arousal system is turned off during sleep by inhibitory inputs from cell groups in the sleep-promoting system, shown in Fig. 31-2 in *red*. These neurons in the preoptic area and pons use GABA to inhibit the arousal system. Additional neurons in the lateral hypothalamus containing the peptide melanin-concentrating hormone promote REM sleep. Many sleep-promoting neurons are themselves inhibited by inputs from the arousal system. This mutual inhibition between the arousal- and sleep-promoting systems forms a neural circuit akin to what electrical engineers call a "flip-flop switch." A switch of this type tends to promote rapid transitions between the on (wake) and off (sleep) states, while avoiding intermediate states. The relatively rapid transitions between waking and sleeping states, as seen in the EEG of humans and animals, is consistent with this model.

Neurons in the ventrolateral preoptic nucleus, one of the key sleep-promoting sites, are lost during normal human aging, correlating with reduced ability to maintain sleep (sleep fragmentation). The ventrolateral preoptic neurons are also injured in Alzheimer's disease, which may in part account for the poor sleep quality in those patients.

Transitions between NREM and REM sleep appear to be governed by a similar switch in the brainstem. GABAergic REM-Off neurons have been identified in the lower midbrain that inhibit REM-On neurons in the upper pons. The REM-On group contains both GABAergic neurons that inhibit the REM-Off group (thus satisfying the conditions for a REM sleep flip-flop switch) as well as glutamatergic neurons that project widely in the central nervous system (CNS) to cause the key phenomena associated with REM sleep. REM-On neurons that project to the medulla and spinal cord activate inhibitory (GABA and glycine-containing) interneurons, which in turn hyperpolarize the motor neurons, producing the paralysis of REM sleep. REM-On neurons that project to the forebrain may be important in producing dreams.

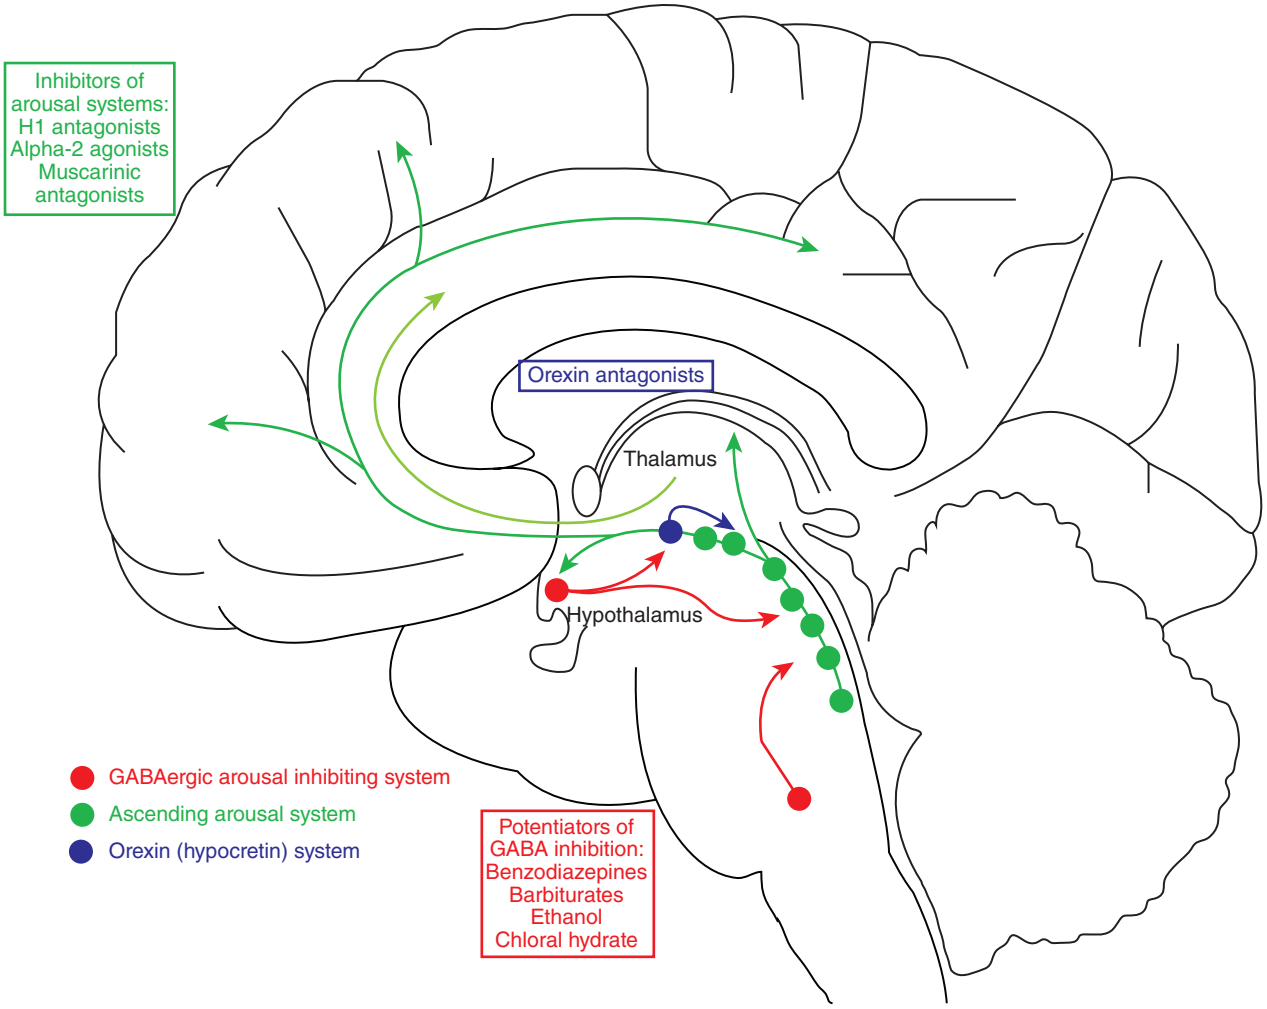

FIGURE 31-2 Relationship of drugs for insomnia with wake-sleep systems. The arousal system in the brain (*green*) includes monoaminergic, glutamatergic, and cholinergic neurons in the brainstem that activate neurons in the hypothalamus, thalamus, basal forebrain, and cerebral cortex. Orexin neurons (*blue*) in the hypothalamus, which are lost in narcolepsy, reinforce and stabilize arousal by activating other components of the arousal system. The sleep-promoting system (*red*) consists of GABAergic neurons in the preoptic area and brainstem that inhibit the components of the arousal system, thus allowing sleep to occur. Drugs used to treat insomnia include those that block the effects of arousal system neurotransmitters (*green* and *blue*) and those that enhance the effects of γ-aminobutyric acid (GABA) produced by the sleep system (*red*).

The REM sleep switch receives cholinergic input, which favors transitions to REM sleep, and monoaminergic (norepinephrine and serotonin) input that prevents REM sleep. As a result, drugs that increase monoamine tone (e.g., serotonin or norepinephrine reuptake inhibitors) tend to reduce the amount of REM sleep. Damage to the neurons that promote REM sleep paralysis can produce REM sleep behavior disorder, a condition in which patients act out their dreams (see below).

SLEEP-WAKE CYCLES ARE DRIVEN BY HOMEOSTATIC, ALLOSTATIC, AND CIRCADIAN INPUTS

The gradual increase in sleep drive with prolonged wakefulness, followed by deeper slow-wave sleep and prolonged sleep episodes, demonstrates that there is a *homeostatic* mechanism that regulates sleep. The neurochemistry of sleep homeostasis is only partially understood, but with prolonged wakefulness, adenosine levels rise in parts of the brain. Adenosine may act through A1 receptors to directly inhibit many arousal-promoting brain regions. In addition, adenosine promotes sleep through A2a receptors; blockade of these receptors by caffeine is one of the chief ways in which people fight sleepiness. Other humoral factors, such as prostaglandin D_2, have also been implicated in this process. Both adenosine and prostaglandin D_2 activate the sleep-promoting neurons in the ventrolateral preoptic nucleus.

Allostasis is the physiologic response to a challenge such as physical danger or psychological threat that cannot be managed by homeostatic mechanisms. These stress responses can severely impact the need for and ability to sleep. For example, insomnia is very common in patients with anxiety and other psychiatric disorders. Stress-induced insomnia is even more common, affecting most people at some time in their lives. Positron emission tomography (PET) studies in patients with chronic insomnia show hyperactivation of components of the ascending arousal system, as well as their limbic system targets in the forebrain (e.g., cingulate cortex and amygdala). The limbic areas are not only targets for the arousal system, but they also send excitatory outputs back to the arousal system, which contributes to a vicious cycle of anxiety about insomnia that makes it more difficult to sleep. Approaches to treating insomnia may employ drugs that either inhibit the output of the ascending arousal system (*green* and *blue* in Fig. 31-2) or potentiate the output of the sleep-promoting system (*red* in Fig. 31-2). However, behavioral approaches (cognitive behavioral therapy [CBT] and sleep hygiene) that may reduce forebrain limbic activity at bedtime are often the best long-term treatment.

Sleep is also regulated by a strong *circadian* timing signal, driven by the suprachiasmatic nuclei (SCN) of the hypothalamus, as described below. The SCN sends outputs to key sites in the hypothalamus, which impose 24-h rhythms on a wide range of behaviors and body systems, including the wake-sleep cycle.

PHYSIOLOGY OF CIRCADIAN RHYTHMICITY

The wake-sleep cycle is the most evident of many 24-h rhythms in humans. Prominent daily variations also occur in endocrine, thermoregulatory, cardiac, pulmonary, renal, immune, gastrointestinal, and neurobehavioral functions. In evaluating daily rhythms in humans,

it is important to distinguish between diurnal components passively evoked by periodic environmental or behavioral changes (e.g., the increase in blood pressure and heart rate that occurs upon assumption of the upright posture) and circadian rhythms actively driven by an endogenous oscillatory process (e.g., the circadian variations in adrenal cortisol and pineal melatonin secretion that persist across a variety of environmental and behavioral conditions).

At the cellular level, endogenous circadian rhythmicity is driven by self-sustaining feedback loops. While it is now recognized that most cells in the body have circadian clocks that regulate diverse physiologic processes, these clocks in different tissues, or even in different cells in the same tissue, when placed in isolation in a tissue explant are unable to maintain the long-term synchronization with each other that is required to produce useful 24-h rhythms aligned with the external light-dark cycle. The only tissue that maintains this rhythm in vitro is the SCN, whose neurons are interconnected with one another in such a way as to produce a near-24-h synchronous rhythm of neural activity even in prolonged slice culture. SCN neurons are located just above the optic chiasm in the hypothalamus, from which they receive visual input to synchronize them with the external world, and they have outputs to transmit that signal to the rest of the body. Bilateral destruction of the SCN results in a loss of most endogenous circadian rhythms including wake-sleep behavior and rhythms in endocrine and metabolic systems. The genetically determined period of this endogenous neural oscillator, which averages ~24.15 h in humans, is normally synchronized to the 24-h period of the environmental light-dark cycle through direct input from intrinsically photosensitive ganglion cells in the retina to the SCN. Humans are exquisitely sensitive to the resetting effects of light, particularly the shorter wavelengths (~460–500 nm) in the blue part of the visible spectrum. Small differences in circadian period contribute to variations in diurnal preference. Changes in homeostatic sleep regulation may underlie age-related changes in sleep-wake timing.

The timing and internal architecture of sleep are directly coupled to the output of the endogenous circadian pacemaker. Paradoxically, the endogenous circadian rhythm for wake propensity peaks just before the habitual bedtime, whereas that of sleep propensity peaks near the habitual wake time. These rhythms are thus timed to oppose the rise of sleep tendency throughout the usual waking day and the decline of sleep propensity during the habitual sleep episode, respectively, thus promoting consolidated sleep and wakefulness. Misalignment of the endogenous circadian pacemaker with the desired wake-sleep cycle can, therefore, induce insomnia, decrease alertness, and impair performance, posing health problems for night-shift workers and airline travelers.

BEHAVIORAL AND PHYSIOLOGIC CORRELATES OF SLEEP STATES AND STAGES

Polysomnographic staging of sleep correlates with behavioral changes during specific states and stages. During the transitional state (stage N1) between wakefulness and deeper sleep, individuals may respond to faint auditory or visual signals. Formation of short-term memories is inhibited at the onset of NREM stage N1 sleep, which may explain why individuals aroused from that transitional sleep stage frequently lack situational awareness. After sleep deprivation, such transitions may intrude upon behavioral wakefulness notwithstanding attempts to remain continuously awake (for example, see "Shift-Work Disorder," below).

Subjects awakened from REM sleep recall vivid dream imagery >80% of the time, especially later in the night. Less vivid imagery may also be reported after NREM sleep interruptions. Certain disorders may occur during specific sleep stages and are described below under "Parasomnias." These include sleepwalking, night terrors, and enuresis (bed wetting), which occur most commonly in children during deep (N3) NREM sleep, and REM sleep behavior disorder, which occurs mainly among older men who fail to maintain full paralysis during REM sleep, and often call out, thrash around, or even act out fragments of dreams.

All major physiologic systems are influenced by sleep. Blood pressure and heart rate decrease during NREM sleep, particularly during N3 sleep. During REM sleep, bursts of eye movements are associated with large variations in both blood pressure and heart rate mediated by the autonomic nervous system. Cardiac dysrhythmias may occur selectively during REM sleep. Respiratory function also changes. In comparison to relaxed wakefulness, respiratory rate becomes slower but more regular during NREM sleep (especially N3 sleep) and becomes irregular during bursts of eye movements in REM sleep. Decreases in minute ventilation during NREM sleep are out of proportion to the decrease in metabolic rate, resulting in a slightly higher P_{CO_2}.

Within the brain itself, neurotransmission is supported by ion gradients across the cell membranes of neurons and astrocytes. These ion flows are accompanied by increases in intracellular volume, so that during wake, there is very little extracellular space in the brain. During sleep, intracellular volume is reduced, resulting in increased extracellular space, which has higher calcium and lower potassium concentrations, supporting hyperpolarization and reduced firing of neurons. This expansion of the extracellular space during sleep increases diffusion of substances that accumulate extracellularly, like β-amyloid peptide, enhancing their clearance from the brain via cerebrospinal fluid (CSF) flow. Recent evidence suggests that lack of adequate sleep may contribute to extracellular accumulation of β-amyloid peptide, a key step in the pathogenesis of Alzheimer's disease.

Endocrine function also varies with sleep. N3 sleep is associated with secretion of growth hormone in men, while sleep in general is associated with augmented secretion of prolactin in both men and women. Sleep has a complex effect on the secretion of luteinizing hormone (LH): during puberty, sleep is associated with increased LH secretion, whereas sleep in postpubertal women inhibits LH secretion in the early follicular phase of the menstrual cycle. Sleep onset (and probably N3 sleep) is associated with inhibition of thyroid-stimulating hormone and of the adrenocorticotropic hormone–cortisol axis, an effect that is superimposed on the prominent circadian rhythms in the two systems.

The pineal hormone melatonin is secreted predominantly at night in both day- and night-active species, reflecting the direct modulation of pineal activity by the SCN via the sympathetic nervous system, which innervates the pineal gland. Melatonin secretion does not require sleep, but melatonin secretion is inhibited by ambient light, an effect mediated by the neural connection from the retina to the pineal gland via the SCN. In humans, sleep efficiency is highest when sleep coincides with endogenous melatonin secretion. When endogenous melatonin levels are low, such as during the biological day or at the desired bedtime in people with delayed sleep-wake phase disorder (DSWPD), administration of exogenous melatonin can hasten sleep onset and increase sleep efficiency, but it does not increase sleep efficiency if administered when endogenous melatonin levels are elevated. This may explain why melatonin is often ineffective in the treatment of patients with primary insomnia. On the other hand, patients with sympathetic denervation of the pineal gland, such as occurs in cervical spinal cord injury or in patients with Parkinson's disease, often have low melatonin levels, and administration of melatonin (3 mg 30 min before bedtime) may help them sleep.

Sleep is accompanied by alterations of thermoregulatory function. NREM sleep is associated with an increase in the firing of warm-responsive neurons in the preoptic area and a fall in body temperature; conversely, skin warming without increasing core body temperature has been found to increase NREM sleep. REM sleep is associated with reduced thermoregulatory responsiveness.

DISORDERS OF SLEEP AND WAKEFULNESS

APPROACH TO THE PATIENT

Sleep Disorders

Patients may seek help from a physician because of: (1) sleepiness or tiredness during the day; (2) difficulty initiating or maintaining sleep at night (insomnia); or (3) unusual behaviors during sleep itself (parasomnias).

Obtaining a careful history is essential. In particular, the duration, severity, and consistency of the symptoms are important, along with the patient's estimate of the consequences of the sleep disorder on waking function. Information from a bed partner or family member is often helpful because some patients may be unaware of symptoms such as heavy snoring or may underreport symptoms such as falling asleep at work or while driving. Physicians should inquire about when the patient typically goes to bed, when they fall asleep and wake up, whether they awaken during sleep, whether they feel rested in the morning, and whether they nap during the day. Depending on the primary complaint, it may be useful to ask about snoring, witnessed apneas, restless sensations in the legs, movements during sleep, depression, anxiety, and behaviors around the sleep episode. The physical examination may provide evidence of a small airway, large tonsils, or a neurologic or medical disorder that contributes to the main complaint.

It is important to remember that, rarely, seizures may occur exclusively during sleep, mimicking a primary sleep disorder; such sleep-related seizures typically occur during episodes of NREM sleep and may take the form of generalized tonic-clonic movements (sometimes with urinary incontinence or tongue biting) or stereotyped movements in partial complex epilepsy **(Chap. 418)**.

It is often helpful for the patient to complete a daily sleep log for 1–2 weeks to define the timing and amounts of sleep. When relevant, the log can also include information on levels of alertness, work times, and drug and alcohol use, including caffeine and hypnotics.

Polysomnography is necessary for the diagnosis of several disorders such as sleep apnea, narcolepsy, and periodic limb movement disorder (PLMD). A conventional polysomnogram performed in a clinical sleep laboratory allows measurement of sleep stages, respiratory effort and airflow, oxygen saturation, limb movements, heart rhythm, and additional parameters. A home sleep test usually focuses on just respiratory measures and is helpful in patients with a moderate to high likelihood of having obstructive sleep apnea. The multiple sleep latency test (MSLT) is used to measure a patient's propensity to sleep during the day and can provide crucial evidence for diagnosing narcolepsy and some other causes of sleepiness. The maintenance of wakefulness test is used to measure a patient's ability to sustain wakefulness during the daytime and can provide important evidence for evaluating the efficacy of therapies for improving sleepiness in conditions such as narcolepsy and obstructive sleep apnea.

EVALUATION OF DAYTIME SLEEPINESS

Up to 25% of the adult population has persistent daytime sleepiness that impairs an individual's ability to perform optimally in school, at work, while driving, and in other conditions that require alertness. Sleepy students often have trouble staying alert and performing well in school, and sleepy adults struggle to stay awake and focused on their work. More than half of Americans have fallen asleep while driving. An estimated 1.2 million motor vehicle crashes per year are due to drowsy drivers, causing about 20% of all serious crash injuries and deaths. One need not fall asleep to have a motor vehicle crash, as the inattention and slowed responses of drowsy drivers are major contributors. Twenty-four hours of continuous wakefulness impairs reaction time as much as a blood alcohol concentration of 0.10 g/dL (which is legally drunk in all 50 states).

Identifying and quantifying sleepiness can be challenging. First, patients may describe themselves as "sleepy," "fatigued," or "tired," and the meanings of these words may differ between patients. For clinical purposes, it is best to use the term "sleepiness" to describe a propensity to fall asleep, whereas "fatigue" is best used to describe a feeling of low physical or mental energy but without a tendency to actually sleep. Sleepiness is usually most evident when the patient is sedentary, whereas fatigue may interfere with more active pursuits. Sleepiness generally occurs with disorders that reduce the quality or quantity of sleep or that interfere with the neural mechanisms of arousal, whereas fatigue is more common in inflammatory disorders such as cancer, multiple sclerosis **(Chap. 444)**, fibromyalgia **(Chap. 373)**, chronic fatigue syndrome **(Chap. 450)**, or endocrine deficiencies such as hypothyroidism **(Chap. 383)** or Addison's disease **(Chap. 386)**. Second, sleepiness can affect judgment in a manner analogous to ethanol, such that patients may have limited insight into the condition and the extent of their functional impairment. Finally, patients may be reluctant to admit that sleepiness is a problem because they may have become unfamiliar with feeling fully alert, and because sleepiness is sometimes viewed pejoratively as reflecting poor motivation or bad sleep habits.

Table 31-1 outlines the diagnostic and therapeutic approach to the patient with a complaint of excessive daytime sleepiness.

To determine the extent and impact of sleepiness on daytime function, it is helpful to ask patients about the occurrence of sleep episodes during normal waking hours, both intentional and unintentional. Specific areas to be addressed include the occurrence of inadvertent sleep episodes while driving or in other safety-related settings, sleepiness while at work or school (and its impact on performance), and the effect of sleepiness on social and family life. Standardized questionnaires such as the Epworth Sleepiness Scale are often used clinically to measure sleepiness.

TABLE 31-1 Evaluation of the Patient with Excessive Daytime Sleepiness

FINDINGS ON HISTORY AND PHYSICAL EXAMINATION	DIAGNOSTIC EVALUATION	DIAGNOSIS	THERAPY
Difficulty waking in the morning, rebound sleep on weekends and vacations with improvement in sleepiness	Sleep log	Insufficient sleep	Sleep education and behavioral modification to increase amount of sleep
Obesity, snoring, hypertension	Polysomnogram or home sleep test	Obstructive sleep apnea **(Chap. 297)**	Continuous positive airway pressure; upper airway surgery (e.g., uvulopalatopharyngoplasty); dental appliance; weight loss
Cataplexy, hypnagogic hallucinations, sleep paralysis	Polysomnogram and multiple sleep latency test	Narcolepsy	Stimulants (e.g., modafinil, methylphenidate); REM sleep-suppressing antidepressants (e.g., venlafaxine); pitolisant; solriamfetol; sodium oxybate
Restless legs, kicking movements during sleep	Assessment for predisposing medical conditions (e.g., iron deficiency or renal failure)	Restless legs syndrome with or without periodic limb movements	Treatment of predisposing condition; dopamine agonists (e.g., pramipexole, ropinirole); gabapentin; pregabalin; opiates
Sedating medications, stimulant withdrawal, head trauma, systemic inflammation, Parkinson's disease and other neurodegenerative disorders, hypothyroidism, encephalopathy	Thorough medical history and examination including detailed neurologic examination	Sleepiness due to a drug or medical condition	Change medications, treat underlying condition, consider stimulants

Eliciting a history of daytime sleepiness is usually adequate, but objective quantification is sometimes necessary. The MSLT measures a patient's propensity to sleep under quiet conditions. An overnight polysomnogram should precede the MSLT to establish that the patient has had an adequate amount of good-quality nighttime sleep. The MSLT consists of five 20-min nap opportunities every 2 h across the day. The patient is instructed to try to fall asleep, and the major endpoints are the average latency to sleep and the occurrence of REM sleep during the naps. An average sleep latency across the naps of <8 min is considered objective evidence of excessive daytime sleepiness. REM sleep normally occurs only during nighttime sleep, and the occurrence of REM sleep in two or more of the MSLT daytime naps provides support for the diagnosis of narcolepsy.

For the safety of the individual and the general public, physicians have a responsibility to help manage issues around driving in patients with sleepiness. Legal reporting requirements vary between states and countries, but at a minimum, physicians should inform sleepy patients about their increased risk of having an accident and advise such patients not to drive a motor vehicle until the sleepiness has been treated effectively. This discussion is especially important for commercial drivers, and it should be documented in the patient's medical record.

INSUFFICIENT SLEEP

Insufficient sleep is probably the most common cause of excessive daytime sleepiness. The average adult needs 7.5–8 h of sleep, but on weeknights the average U.S. adult gets only 6.75 h of sleep. Only 30% of the U.S. adult population reports consistently obtaining sufficient sleep. Insufficient sleep is especially common among shift workers, individuals working multiple jobs, and people in lower socioeconomic groups. Most teenagers need ≥9 h of sleep, but many fail to get enough sleep because of circadian phase delay, plus social pressures to stay up late coupled with early school start times. Late evening light exposure, television viewing, video-gaming, social media, texting, and smartphone use often delay bedtimes, despite the fixed early wake times required for work or school. As is typical with any disorder that causes sleepiness, individuals with chronically insufficient sleep may feel inattentive, irritable, unmotivated, and depressed, and have difficulty with school, work, and driving. Individuals differ in their optimal amount of sleep, and it can be helpful to ask how much sleep the patient obtains on a quiet vacation when he or she can sleep without restrictions. Some patients may think that a short amount of sleep is normal or advantageous, and they may not appreciate their biological need for more sleep, especially if coffee and other stimulants mask the sleepiness. A 2-week sleep log documenting the timing of sleep and daily level of alertness is diagnostically useful and provides helpful feedback for the patient. Extending sleep to the optimal amount on a regular basis can resolve the sleepiness and other symptoms. As with any lifestyle change, extending sleep requires commitment and adjustments, but the improvements in daytime alertness make this change worthwhile.

SLEEP APNEA SYNDROMES

Respiratory dysfunction during sleep is a common, serious cause of excessive daytime sleepiness as well as of disturbed nocturnal sleep. At least 24% of middle-aged men and 9% of middle-aged women in the United States have a reduction or cessation of breathing dozens or more times each night during sleep, with 9% of men and 4% of women doing so more than a hundred times per night. These episodes may be due to an occlusion of the airway (*obstructive sleep apnea*), absence of respiratory effort (*central sleep apnea*), or a combination of these factors. Failure to recognize and treat these conditions appropriately may reduce daytime alertness and increase the risk of sleep-related motor vehicle crashes, depression, hypertension, myocardial infarction, diabetes, stroke, and mortality. Sleep apnea is particularly prevalent in overweight men and in the elderly, yet it is estimated to go undiagnosed in most affected individuals. This is unfortunate because several effective treatments are available. **Readers are referred to Chap. 297 for a comprehensive review of the diagnosis and treatment of patients with sleep apnea.**

NARCOLEPSY

Narcolepsy is characterized by difficulty sustaining wakefulness, poor regulation of REM sleep, and disturbed nocturnal sleep. All patients with narcolepsy have excessive daytime sleepiness. This sleepiness is usually moderate to severe, and in contrast to patients with disrupted sleep (e.g., sleep apnea), people with narcolepsy usually feel well rested upon awakening and then feel tired throughout much of the day. They may fall asleep at inappropriate times, but then feel refreshed again after a nap. In addition, they often experience symptoms related to an intrusion of REM sleep characteristics into wakefulness. REM sleep is characterized by dreaming and muscle paralysis, and people with narcolepsy can have: (1) sudden muscle weakness without a loss of consciousness, which is usually triggered by strong emotions (cataplexy; **Video 31-1**); (2) dream-like hallucinations at sleep onset (hypnagogic hallucinations) or upon awakening (hypnopompic hallucinations); and (3) muscle paralysis upon awakening (sleep paralysis). With severe cataplexy, an individual may be laughing at a joke and then suddenly collapse to the ground, immobile but awake for 1–2 min. With milder episodes, patients may have partial weakness of the face or neck. Narcolepsy is one of the more common causes of chronic sleepiness and affects about 1 in 2000 people in the United States. Narcolepsy typically begins between age 10 and 20; once established, the disease persists for life.

Narcolepsy is caused by loss of the hypothalamic neurons that produce the orexin neuropeptides (also known as hypocretins). Research in mice and dogs first demonstrated that a loss of orexin signaling due to null mutations of either the orexin neuropeptides or one of the orexin receptors causes sleepiness and cataplexy nearly identical to that seen in people with narcolepsy. Although genetic mutations rarely cause human narcolepsy, researchers soon discovered that patients with narcolepsy with cataplexy (now called type 1 narcolepsy) have very low or undetectable levels of orexins in their CSF, and autopsy studies showed a nearly complete loss of the orexin-producing neurons in the hypothalamus. The orexins normally promote long episodes of wakefulness and suppress REM sleep, and thus loss of orexin signaling results in frequent intrusions of sleep during the usual waking episode, with REM sleep and fragments of REM sleep at any time of day **(Fig. 31-3)**. Patients with narcolepsy but no cataplexy (type 2 narcolepsy) usually have normal orexin levels and may have other yet uncharacterized causes of their excessive daytime sleepiness.

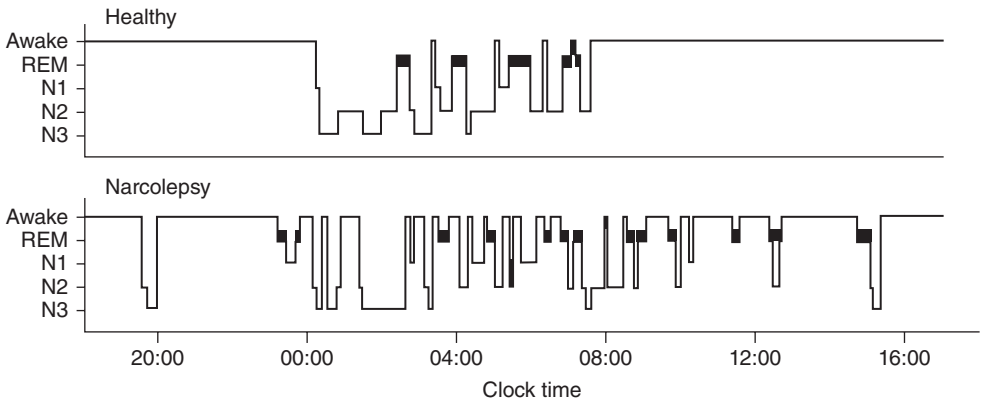

FIGURE 31-3 Polysomnographic recordings of a healthy individual and a patient with narcolepsy. The healthy individual has a long period or NREM sleep before entering REM sleep, but the individual with narcolepsy enters rapid eye movement (REM) sleep quickly at night and has moderately fragmented sleep. During the day, the healthy subject stays awake from 8:00 A.M. until midnight, but the patient with narcolepsy dozes off frequently, with many daytime naps that include REM sleep.

Extensive evidence suggests that an autoimmune process likely causes this selective loss of the orexin-producing neurons. Certain human leukocyte antigens (HLAs) can increase the risk of autoimmune disorders (Chap. 350), and narcolepsy has the strongest known HLA association. HLA DQB1*06:02 is found in >90% of people with type 1 narcolepsy, whereas it occurs in only 12–25% of the general population. Researchers now hypothesize that in people with DQB1*06:02, an immune response against influenza, *Streptococcus*, or other infections may also damage the orexin-producing neurons through a process of molecular mimicry. This mechanism may account for the eight- to twelvefold increase in new cases of narcolepsy among children in Europe who received a particular brand of H1N1 influenza A vaccine (Pandemrix). In support of this hypothesis, people with type 1 narcolepsy have heightened T cell responses against orexin peptides.

On rare occasions, narcolepsy can occur with neurologic disorders such as tumors or strokes that directly damage the orexin-producing neurons in the hypothalamus or their projections.

Diagnosis Narcolepsy is most commonly diagnosed by the history of chronic sleepiness plus cataplexy or other symptoms. Many disorders can cause feelings of weakness, but with true cataplexy patients will describe definite functional weakness (e.g., slurred speech, dropping a cup, slumping into a chair) that has consistent emotional triggers such as laughing at a joke, happy surprise at unexpectedly seeing a friend, or intense anger. Cataplexy occurs in about half of all narcolepsy patients and is diagnostically very helpful because it occurs in almost no other disorder. In contrast, occasional hypnagogic hallucinations and sleep paralysis occur in about 20% of the general population, and these symptoms are not as diagnostically specific.

When narcolepsy is suspected, the diagnosis should be firmly established with a polysomnogram followed the next day by an MSLT. The polysomnogram helps rule out other possible causes of sleepiness such as sleep apnea and establishes that the patient had adequate sleep the night before, and the MSLT provides essential, objective evidence of sleepiness plus REM sleep dysregulation. Across the five naps of the MSLT, most patients with narcolepsy will fall asleep in <8 min on average, and they will have episodes of REM sleep in at least two of the naps. Abnormal regulation of REM sleep is also manifested by the appearance of REM sleep within 15 min of sleep onset at night, which is rare in healthy individuals sleeping at their habitual bedtime. Stimulants should be stopped 1 week before the MSLT and antidepressants should be stopped 3 weeks prior, because these medications can affect the MSLT. In addition, patients should be encouraged to obtain a fully adequate amount of sleep each night for the week prior to the test to eliminate any effects of insufficient sleep.

TREATMENT

Narcolepsy

The treatment of narcolepsy is symptomatic. Most patients with narcolepsy feel more alert after sleep, and they should be encouraged to get adequate sleep each night and to take a 15- to 20-min nap in the afternoon. This nap may be sufficient for some patients with mild narcolepsy, but most also require treatment with wake-promoting medications. Modafinil is often used because it has fewer side effects than amphetamines and a relatively long half-life; for most patients, 200–400 mg each morning is very effective. Methylphenidate (10–20 mg bid) or dextroamphetamine (10 mg bid) are also effective, but sympathomimetic side effects, anxiety, and the potential for abuse can be concerns. These medications are available in slow-release formulations, extending their duration of action and allowing easier dosing. Solriamfetol, a norepinephrine–dopamine reuptake inhibitor (75–150 mg daily), and pitolisant, a selective histamine 3 (H_3) receptor antagonist (8.9–35.6 mg daily), also improve sleepiness and have relatively few side effects. Sodium oxybate (gamma hydroxybutyrate), given at bedtime and 3–4 h later, is often very valuable in improving alertness, but it can produce excessive sedation, nausea, and confusion.

Cataplexy is usually much improved with antidepressants that increase noradrenergic or serotonergic tone because these neurotransmitters strongly suppress REM sleep and cataplexy. Venlafaxine (37.5–150 mg each morning) and fluoxetine (10–40 mg each morning) are often quite effective. The tricyclic antidepressants, such as protriptyline (10–40 mg/d) or clomipramine (25–50 mg/d) are potent suppressors of cataplexy, but their anticholinergic effects, including sedation and dry mouth, make them less attractive.[1] Sodium oxybate, twice each night, is also very helpful in reducing cataplexy.

[1]No antidepressant has been approved by the US Food and Drug Administration (FDA) for treating narcolepsy.

EVALUATION OF INSOMNIA

Insomnia is the complaint of poor sleep and usually presents as difficulty initiating or maintaining sleep. People with insomnia are dissatisfied with their sleep and feel that it impairs their ability to function well in work, school, and social situations. Affected individuals often experience fatigue, decreased mood, irritability, malaise, and cognitive impairment.

Chronic insomnia, lasting >3 months, occurs in about 10% of adults and is more common in women, older adults, people of lower socioeconomic status, and individuals with medical, psychiatric, and substance abuse disorders. Acute or short-term insomnia affects over 30% of adults and is often precipitated by stressful life events such as a major illness or loss, change of occupation, medications, and substance abuse. If the acute insomnia triggers maladaptive behaviors such as increased nocturnal light exposure, frequently checking the clock, or attempting to sleep more by napping, it can lead to chronic insomnia.

Most insomnia begins in adulthood, but many patients may be predisposed and report easily disturbed sleep predating the insomnia, suggesting that their sleep is lighter than usual. Clinical studies and animal models indicate that insomnia is associated with activation during sleep of brain areas normally active only during wakefulness. The polysomnogram is rarely used in the evaluation of insomnia, as it typically confirms the patient's subjective report of long latency to sleep and numerous awakenings but usually adds little new information. Many patients with insomnia have increased fast (beta) activity in the EEG during sleep; this fast activity is normally present only during wakefulness, which may explain why some patients report feeling awake for much of the night. The MSLT is rarely used in the evaluation of insomnia because, despite their feelings of low energy, most people with insomnia do not easily fall asleep during the day, and on the MSLT, their average sleep latencies are usually longer than normal.

Many factors can contribute to insomnia, and obtaining a careful history is essential so one can select therapies targeting the underlying factors. The assessment should focus on identifying predisposing, precipitating, and perpetuating factors.

Psychophysiological Factors Many patients with insomnia have negative expectations and conditioned arousal that interfere with sleep. These individuals may worry about their insomnia during the day and have increasing anxiety as bedtime approaches if they anticipate a poor night of sleep. While attempting to sleep, they may frequently check the clock, which only heightens anxiety and frustration. They may find it easier to sleep in a new environment rather than their bedroom, as it lacks the negative associations.

Inadequate Sleep Hygiene Patients with insomnia sometimes develop counterproductive behaviors that contribute to their insomnia. These can include daytime napping that reduces sleep drive at night; an irregular sleep-wake schedule that disrupts their circadian rhythms; use of wake-promoting substances (e.g., caffeine, tobacco) too close to bedtime; engaging in alerting or stressful activities close to bedtime (e.g., arguing with a partner, work-related emailing and texting while in bed, sleeping with a smartphone or tablet at the bedside); and routinely using the bedroom for activities other than sleep or sex (e.g., email,

television, work), so the bedroom becomes associated with arousing or stressful feelings.

Psychiatric Conditions About 80% of patients with psychiatric disorders have sleep complaints, and about half of all chronic insomnia occurs in association with a psychiatric disorder. Depression is classically associated with early morning awakening, but it can also interfere with the onset and maintenance of sleep. Mania and hypomania can disrupt sleep and often are associated with substantial reductions in the total amount of sleep. Anxiety disorders can lead to racing thoughts and rumination that interfere with sleep and can be very problematic if the patient's mind becomes active midway through the night. Panic attacks can arise from sleep and need to be distinguished from other parasomnias. Insomnia is common in schizophrenia and other psychoses, often resulting in fragmented sleep, less deep NREM sleep, and sometimes reversal of the day-night sleep pattern.

Medications and Drugs of Abuse A wide variety of psychoactive drugs can interfere with sleep. Caffeine, which has a half-life of 6–9 h, can disrupt sleep for up to 8–14 h, depending on the dose, variations in metabolism, and an individual's caffeine sensitivity. Insomnia can also result from use of prescription medications too close to bedtime (e.g., antidepressants, stimulants, glucocorticoids, theophylline). Conversely, withdrawal of sedating medications such as alcohol, narcotics, or benzodiazepines can cause insomnia. Alcohol taken just before bed can shorten sleep latency, but it often produces rebound insomnia 2–3 h later as it wears off. This same problem with sleep maintenance can occur with short-acting medications such as alprazolam or zolpidem.

Medical Conditions A large number of medical conditions disrupt sleep. Pain from rheumatologic disorders or a painful neuropathy commonly disrupts sleep. Some patients may sleep poorly because of respiratory conditions such as asthma, chronic obstructive pulmonary disease, cystic fibrosis, congestive heart failure, or restrictive lung disease, and some of these disorders are worse at night due to circadian variations in airway resistance and postural changes in bed that can result in nocturnal dyspnea. Many women experience poor sleep with the hormonal changes of menopause. Gastroesophageal reflux is also a common cause of difficulty sleeping.

Neurologic Disorders Dementia **(Chap. 29)** is often associated with poor sleep, probably due to a variety of factors, including napping during the day, altered circadian rhythms, and perhaps a weakened output of the brain's sleep-promoting mechanisms. In fact, insomnia and nighttime wandering are some of the most common causes for institutionalization of patients with dementia, because they place a larger burden on caregivers. Conversely, in cognitively intact elderly men, fragmented sleep and poor sleep quality are associated with subsequent cognitive decline. Patients with Parkinson's disease may sleep poorly due to rigidity, dementia, and other factors. Fatal familial insomnia is a very rare neurodegenerative condition caused by mutations in the prion protein gene **(Chap. 438)**, and although insomnia is a common early symptom, most patients present with other obvious neurologic signs such as dementia, myoclonus, dysarthria, or autonomic dysfunction.

TREATMENT

Insomnia

Treatment of insomnia improves quality of life and can promote long-term health. With improved sleep, patients often report less daytime fatigue, improved cognition, and more energy. Treating the insomnia can also improve comorbid disease. For example, management of insomnia at the time of diagnosis of major depression often improves the response to antidepressants and reduces the risk of relapse. Sleep loss can heighten the perception of pain, so a similar approach is warranted in acute and chronic pain management.

The treatment plan should target all putative contributing factors: establish good sleep hygiene, treat medical disorders, use behavioral therapies for anxiety and negative conditioning, and use pharmacotherapy and/or psychotherapy for psychiatric disorders. Behavioral therapies should be the first-line treatment, followed by judicious use of sleep-promoting medications if needed.

TREATMENT OF MEDICAL AND PSYCHIATRIC DISEASE

If the history suggests that a medical or psychiatric disease contributes to the insomnia, then it should be addressed by, for example, treating the pain or depression, improving breathing, and switching or adjusting the timing of medications.

IMPROVE SLEEP HYGIENE

Attention should be paid to improving sleep hygiene and avoiding counterproductive, arousing behaviors before bedtime. Patients should establish a regular bedtime and wake time, even on weekends, to help synchronize their circadian rhythms and sleep patterns. The amount of time allocated for sleep should not be more than their actual total amount of sleep. In the 30 min before bedtime, patients should establish a relaxing "wind-down" routine that can include a warm bath, listening to music, meditation, or other relaxation techniques. The bedroom should be off-limits to computers, televisions, radios, smartphones, videogames, and tablets. If an e-reader is used, the light should be adjusted for evening use (dimmer and reduced blue light) if possible, because light itself, especially in the blue spectrum, suppresses melatonin secretion and is arousing. Once in bed, patients should try to avoid thinking about anything stressful or arousing such as problems with relationships or work. If they cannot fall asleep within 20 min, it often helps to get out of bed and read or listen to relaxing music in dim light as a form of distraction from any anxiety, but artificial light, including light from a television, cell phone, or computer, should be avoided.

Table 31-2 outlines some of the key aspects of good sleep hygiene to improve insomnia.

COGNITIVE BEHAVIORAL THERAPY

Cognitive behavioral therapy (CBT) uses a combination of the techniques above plus additional methods to improve insomnia. A trained therapist may use cognitive psychology techniques to reduce excessive worrying about sleep and to reframe faulty beliefs about the insomnia and its daytime consequences. The therapist may also teach the patient relaxation techniques, such as progressive muscle relaxation or meditation, to reduce autonomic arousal, intrusive thoughts, and anxiety.

MEDICATIONS FOR INSOMNIA

If insomnia persists after treatment of these contributing factors, pharmacotherapy is often used on a nightly or intermittent basis. A variety of sedatives can improve sleep.

Antihistamines, such as diphenhydramine, are the primary active ingredient in most over-the-counter sleep aids. These may be of

TABLE 31-2 Methods to Improve Sleep Hygiene in Insomnia Patients

HELPFUL BEHAVIORS	BEHAVIORS TO AVOID
Use the bed only for sleep and sex • If you cannot sleep within 20 min, get out of bed and read or do other relaxing activities in dim light before returning to bed	Avoid behaviors that interfere with sleep physiology, including: • Napping, especially after 3:00 PM • Attempting to sleep too early • Caffeine after lunchtime
Make quality sleep a priority • Go to bed and get up at the same time each day • Ensure a restful environment (comfortable bed, bedroom quiet and dark)	In the 2–3 h before bedtime, avoid: • Heavy eating • Smoking or alcohol • Vigorous exercise
Develop a consistent bedtime routine. For example: • Prepare for sleep with 20–30 min of relaxation (e.g., soft music, meditation, yoga, pleasant reading) • Take a warm bath	When trying to fall asleep, avoid: • Solving problems • Thinking about life issues • Reviewing events of the day

benefit when used intermittently but can produce tolerance and anticholinergic side effects such as dry mouth and constipation, which limit their use, particularly in the elderly.

Benzodiazepine receptor agonists (BzRAs) are an effective and well-tolerated class of medications for insomnia. BzRAs bind to the $GABA_A$ receptor and potentiate the postsynaptic response to GABA. $GABA_A$ receptors are found throughout the brain, and BzRAs may globally reduce neural activity and enhance the activity of specific sleep-promoting GABAergic pathways. Classic BzRAs include lorazepam, triazolam, and clonazepam, whereas newer agents such as zolpidem and zaleplon have more selective affinity for the α_1 subunit of the $GABA_A$ receptor.

Specific BzRAs are often chosen based on the desired duration of action. The most commonly prescribed agents in this family are zaleplon (5–20 mg), with a half-life of 1–2 h; zolpidem (5–10 mg) and triazolam (0.125–0.25 mg), with half-lives of 2–4 h; eszopiclone (1–3 mg), with a half-life of 5–8 h; and temazepam (15–30 mg), with a half-life of 8–20 h. Generally, side effects are minimal when the dose is kept low and the serum concentration is minimized during the waking hours (by using the shortest-acting effective agent). For chronic insomnia, intermittent use is recommended, unless the consequences of untreated insomnia outweigh concerns regarding chronic use.

The heterocyclic antidepressants (trazodone, amitriptyline,[2] and doxepin) are the most commonly prescribed alternatives to BzRAs due to their lack of abuse potential and low cost. Trazodone (25–100 mg) is used more commonly than the tricyclic antidepressants, because it has a much shorter half-life (5–9 h) and less anticholinergic activity.

The orexin receptor antagonists suvorexant (10–20 mg) and lemborexant (5–10 mg) can also improve insomnia by blocking the wake-promoting effects of the orexin neuropeptides. These have long half-lives and can produce morning sedation, and as they reduce orexin signaling, they can rarely produce hypnagogic hallucinations and sleep paralysis (see narcolepsy section above).

Medications for insomnia are now among the most commonly prescribed medications, but they should be used cautiously. All sedatives increase the risk of injurious falls and confusion in the elderly, and therefore if needed these medications should be used at the lowest effective dose. Morning sedation can interfere with driving and judgment, and when selecting a medication, one should consider the duration of action. Benzodiazepines carry a risk of addiction and abuse, especially in patients with a history of alcohol or sedative abuse. In patients with depression, all sedatives can worsen the depression. Like alcohol, some sleep-promoting medications can worsen sleep apnea. Sedatives can also produce complex behaviors during sleep, such as sleepwalking and sleep eating, especially at higher doses.

[2]Trazodone and amitriptyline have not been approved by the FDA for treating insomnia.

RESTLESS LEGS SYNDROME

Patients with restless legs syndrome (RLS) report an irresistible urge to move the legs. Many patients report a creepy-crawly or unpleasant deep ache within the thighs or calves, and those with more severe RLS may have discomfort in the arms as well. For most patients with RLS, these dysesthesias and restlessness are much worse in the evening and first half of the night. The symptoms appear with inactivity and can make sitting still in an airplane or when watching a movie a miserable experience. The sensations are temporarily relieved by movement, stretching, or massage. This nocturnal discomfort usually interferes with sleep, and patients may report daytime sleepiness as a consequence. RLS is very common, affecting 5–10% of adults, and is more common in women and older adults.

A variety of factors can cause RLS. Iron deficiency is the most common treatable cause, and iron replacement should be considered if the ferritin level is <75 ng/mL. RLS can also occur with peripheral neuropathies and uremia and can be worsened by pregnancy, caffeine, alcohol, antidepressants, lithium, neuroleptics, and antihistamines. Genetic factors contribute to RLS, and polymorphisms in a variety of genes (*BTBD9, MEIS1, MAP2K5/LBXCOR*, and *PTPRD*) have been linked to RLS, although as yet, the mechanism through which they cause RLS remains unknown. Roughly one-third of patients (particularly those with an early age of onset) have multiple affected family members.

RLS is treated by addressing the underlying cause such as iron deficiency if present. Otherwise, treatment is symptomatic, and dopamine agonists or alpha-2-delta calcium channel ligands are used most frequently. Agonists of dopamine $D_{2/3}$ receptors such as pramipexole (0.25–0.5 mg q7PM) or ropinirole (0.5–4 mg q7PM) are usually quite effective, but about 25% of patients taking dopamine agonists develop augmentation, a worsening of RLS such that symptoms begin earlier in the day and can spread to other body regions. Other possible side effects of dopamine agonists include nausea, morning sedation, and increases in rewarding behaviors such as sex and gambling. Alpha-2-delta calcium channel ligands such as gabapentin (300–600 mg q7PM) and pregabalin (150–450 mg q7PM) can also be quite effective; these are less likely to cause augmentation, and they can be especially helpful in patients with concomitant pain, neuropathy, or anxiety. Opioids and benzodiazepines may also be of therapeutic value. Most patients with restless legs also experience PLMD, although the reverse is not the case.

PERIODIC LIMB MOVEMENT DISORDER

PLMD involves rhythmic twitches of the legs that disrupt sleep. The movements resemble a triple flexion reflex with extensions of the great toe and dorsiflexion of the foot for 0.5–5.0 s, which recur every 20–40 s during NREM sleep, in episodes lasting from minutes to hours. PLMD is diagnosed by a polysomnogram that includes recordings of the anterior tibialis and sometimes other muscles. The EEG shows that the movements of PLMD frequently cause brief arousals that disrupt sleep and can cause insomnia and daytime sleepiness. PLMD can be caused by the same factors that cause RLS (see above), and the frequency of leg movements improves with the same medications used for RLS, including dopamine agonists. Genetic studies identified polymorphisms associated with both RLS and PLMD, suggesting that they may have a common pathophysiology.

PARASOMNIAS

Parasomnias are abnormal behaviors or experiences that arise from or occur during sleep. A variety of parasomnias can occur during NREM sleep, from brief confusional arousals to sleepwalking and night terrors. The presenting complaint is usually related to the behavior itself, but the parasomnias can disturb sleep continuity or lead to mild impairments in daytime alertness. Two main parasomnias occur in REM sleep: REM sleep behavior disorder (RBD) and nightmares.

Sleepwalking (Somnambulism) Patients affected by this disorder carry out automatic motor activities that range from simple to complex. Individuals may walk, urinate inappropriately, eat, exit the house, or drive a car with minimal awareness. It may be difficult to arouse the patient to wakefulness, and some individuals may respond to attempted awakening with agitation or violence. In general, it is safest to lead the patient back to bed, at which point he or she will often fall back asleep. Sleepwalking arises from NREM stage N3 sleep, usually in the first few hours of the night, and the EEG initially shows the slow cortical activity of deep NREM sleep even when the patient is moving about. Sleepwalking is most common in children and adolescents, when deep NREM sleep is most abundant. About 15% of children have occasional sleepwalking, and it persists in about 1% of adults. Episodes are usually isolated but may be recurrent in 1–6% of patients. The cause is unknown, although it has a familial basis in roughly one-third of cases. Sleepwalking can be worsened by stress, alcohol, and insufficient sleep, which subsequently causes an increase in deep NREM sleep. These should be addressed if present. Small studies have shown some efficacy of antidepressants and benzodiazepines;

relaxation techniques and hypnosis can also be helpful. Patients and their families should improve home safety (e.g., replace glass doors, remove low tables to avoid tripping) to minimize the chance of injury if sleepwalking occurs.

Sleep Terrors This disorder occurs primarily in young children during the first few hours of sleep during NREM stage N3 sleep. The child often sits up during sleep and screams, exhibiting autonomic arousal with sweating, tachycardia, large pupils, and hyperventilation. The individual may be difficult to arouse and rarely recalls the episode on awakening in the morning. Treatment usually consists of reassuring parents that the condition is self-limited and benign, and like sleepwalking, it may improve by avoiding insufficient sleep.

Sleep Enuresis Bedwetting, like sleepwalking and night terrors, is another parasomnia that occurs during sleep in the young. Before age 5 or 6 years, nocturnal enuresis should be considered a normal feature of development. The condition usually improves spontaneously by puberty, persists in 1–3% of adolescents, and is rare in adulthood. Treatment consists of bladder training exercises and behavioral therapy. Symptomatic pharmacotherapy is usually accomplished in adults with desmopressin (0.2 mg qhs), oxybutynin chloride (5 mg qhs), or imipramine (10–25 mg qhs). Important causes of nocturnal enuresis in patients who were previously continent for 6–12 months include urinary tract infections or malformations, cauda equina lesions, emotional disturbances, epilepsy, sleep apnea, and certain medications.

Sleep Bruxism Bruxism is an involuntary, forceful grinding of teeth during sleep that affects 10–20% of the population. The patient is usually unaware of the problem. The typical age of onset is 17–20 years, and spontaneous remission usually occurs by age 40. In many cases, the diagnosis is made during dental examination, damage is minor, and no treatment is indicated. In more severe cases, treatment with a mouth guard is necessary to prevent tooth injury. Stress management, benzodiazepines, and biofeedback can be useful when bruxism is a manifestation of psychological stress.

REM Sleep Behavior Disorder (RBD) RBD **(Video 31-2)** is distinct from other parasomnias in that it occurs during REM sleep. The patient or the bed partner usually reports agitated or violent behavior during sleep, and upon awakening, the patient can often report a dream that matches the accompanying movements. During normal REM sleep, nearly all nonrespiratory skeletal muscles are paralyzed, but in patients with RBD, dramatic limb movements such as punching or kicking lasting seconds to minutes occur during REM sleep, and it is not uncommon for the patient or the bed partner to be injured.

The prevalence of RBD increases with age, afflicting about 2% of adults aged >70, and is about twice as common in men. Within 12 years of disease onset, half of RBD patients develop a synucleinopathy such as Parkinson's disease **(Chap. 435)** or dementia with Lewy bodies **(Chap. 434)**, or occasionally multiple system atrophy **(Chap. 440)**, and over 90% develop a synucleinopathy by 25 years. RBD can occur in patients taking antidepressants, and in some, these medications may unmask this early indicator of neurodegeneration. Synucleinopathies probably cause neuronal loss in brainstem regions that regulate muscle paralysis during REM sleep, and loss of these neurons permits movements to break through during REM sleep. RBD also occurs in about 30% of patients with narcolepsy, but the underlying cause is probably different, as they seem to be at no increased risk of a neurodegenerative disorder.

Many patients with RBD have sustained improvement with clonazepam (0.5–2.0 mg qhs).[3] Melatonin at doses up to 9 mg nightly may also prevent attacks.

CIRCADIAN RHYTHM SLEEP DISORDERS

A subset of patients presenting with either insomnia or hypersomnia may have a disorder of sleep *timing* rather than sleep *generation*. Disorders of sleep timing can be either organic (i.e., due to an abnormality of circadian pacemaker[s]) or environmental/behavioral (i.e., due to a disruption of environmental synchronizers). Effective therapies aim to entrain the circadian rhythm of sleep propensity to the appropriate behavioral phase.

Delayed Sleep-Wake Phase Disorder DSWPD is characterized by: (1) sleep onset and wake times persistently later than desired; (2) actual sleep times at nearly the same clock hours daily; and (3) if conducted at the habitual delayed sleep time, essentially normal sleep on polysomnography (except for delayed sleep onset). About half of patients with DSWPD exhibit an abnormally delayed endogenous circadian phase, which can be assessed by measuring the onset of secretion of melatonin in either the blood or saliva; this is best done in a dimly lit environment as light suppresses melatonin secretion. Dim-light melatonin onset (DLMO) in DSWPD patients occurs later in the evening than normal, which is about 8:00–9:00 P.M. (i.e., about 1–2 h before habitual bedtime). Patients tend to be young adults. The delayed circadian phase could be due to: (1) an abnormally long, genetically determined intrinsic period of the endogenous circadian pacemaker; (2) reduced phase-advancing capacity of the pacemaker; (3) slower buildup of homeostatic sleep drive during wakefulness; or (4) an irregular prior sleep-wake schedule, characterized by frequent nights when the patient chooses to remain awake while exposed to artificial light well past midnight (for personal, social, school, or work reasons). In most cases, it is difficult to distinguish among these factors, as patients with either a behaviorally induced or biologically driven circadian phase delay may both exhibit a similar circadian phase delay in DLMO, and both factors make it difficult to fall asleep at the desired hour. Late onset of dim-light melatonin secretion can help distinguish DSWPD from other forms of sleep-onset insomnia. DSWPD is a chronic condition that can persist for years and may not respond to attempts to reestablish normal bedtime hours. Treatment methods involving phototherapy with blue-enriched light during the morning hours and/or melatonin administration in the evening hours show promise in these patients, although the relapse rate is high.

Advanced Sleep-Wake Phase Disorder Advanced sleep-wake phase disorder (ASWPD) is the converse of DSWPD. Most commonly, this syndrome occurs in older people, 15% of whom report that they cannot sleep past 5:00 A.M., with twice that number complaining that they wake up too early at least several times per week. Patients with ASWPD are sleepy during the evening hours, even in social settings. Sleep-wake timing in ASWPD patients can interfere with a normal social life. Patients with this circadian rhythm sleep disorder can be distinguished from those who have early wakening due to insomnia because ASWPD patients show early onset of dim-light melatonin secretion.

In addition to age-related ASWPD, an early-onset familial variant of this condition has also been reported. In two families in which ASWPD was inherited in an autosomal dominant pattern, the syndrome was due to missense mutations in a circadian clock component (in the casein kinase binding domain of *PER2* in one family, and in casein kinase I delta in the other) that shortens the circadian period. Patients with ASWPD may benefit from bright light and/or blue enriched phototherapy during the evening hours to reset the circadian pacemaker to a later hour.

Non-24-h Sleep-Wake Rhythm Disorder Non-24-h sleep-wake rhythm disorder (N24SWD) most commonly occurs when the primary synchronizing input (i.e., the light-dark cycle) from the environment to the circadian pacemaker is lost (as occurs in many blind people with no light perception), and the maximal phase-advancing capacity of the circadian pacemaker in response to nonphotic cues cannot accommodate the difference between the 24-h geophysical day and the intrinsic period of the patient's circadian pacemaker, resulting in loss of entrainment to the 24-h day. The sleep of most blind patients with N24SWD is restricted to the nighttime hours due to social or occupational demands. Despite this regular sleep-wake schedule, affected patients with N24SWD are nonetheless unable to maintain

[3]No medications have been approved by the FDA for the treatment of RBD.

a stable phase relationship between the output of the non-entrained circadian pacemaker and the 24-h day. Therefore, most blind patients present with intermittent bouts of insomnia. When the blind patient's endogenous circadian rhythms are out of phase with the local environment, nighttime insomnia coexists with excessive daytime sleepiness. Conversely, when the endogenous circadian rhythms of those same patients are in phase with the local environment, symptoms remit. The interval between symptomatic phases may last several weeks to several months in blind patients with N24SWD, depending on the period of the underlying nonentrained rhythm and the 24-h day. Nightly low-dose (0.5 mg) melatonin administration may improve sleep and, in some cases, induce synchronization of the circadian pacemaker. In sighted patients, N24SWD can be caused by self-selected exposure to artificial light that inadvertently entrains the circadian pacemaker to a >24-h schedule, and these individuals present with an incremental pattern of successive delays in sleep timing, progressing in and out of phase with local time—a clinical presentation that is seldom seen in blind patients with N24SWD.

Shift-Work Disorder More than 7 million workers in the United States regularly work at night, either on a permanent or rotating schedule. Many more begin the commute to work or school between 4:00 A.M. and 7:00 A.M., requiring them to commute and then work during a time of day that they would otherwise be asleep. In addition, each week, millions of "day" workers and students elect to remain awake at night or awaken very early in the morning to work or study to meet work or school deadlines, drive long distances, compete in sporting events, or participate in recreational activities. Such schedules can result in both sleep loss and misalignment of circadian rhythms with respect to the sleep-wake cycle.

The circadian timing system usually fails to adapt successfully to the inverted schedules required by overnight work or the phase advance required by early morning (4:00 A.M. to 7:00 A.M.) start times. This leads to a misalignment between the desired work-rest schedule and the output of the pacemaker, resulting in disturbed daytime sleep in most such individuals. Excessive work hours (per day or per week), insufficient time off between consecutive days of work or school, and frequent travel across time zones may be contributing factors. Sleep deficiency, increased length of time awake prior to work, and misalignment of circadian phase impair alertness and performance, increase reaction time, and increase risk of performance lapses, thereby resulting in greater safety hazards among night workers and other sleep-deprived individuals. Sleep disturbance nearly doubles the risk of a fatal work accident. In addition, long-term night-shift workers have higher rates of breast, colorectal, and prostate cancer and of cardiac, gastrointestinal, metabolic, and reproductive disorders. The World Health Organization has added night-shift work to its list of probable carcinogens.

Sleep onset begins in local brain regions before gradually sweeping over the entire brain as sensory thresholds rise and consciousness is lost. A sleepy individual struggling to remain awake may attempt to continue performing routine and familiar motor tasks during the transition state between wakefulness and stage N1 sleep, while unable to adequately process sensory input from the environment. Such sleep-related attentional failures typically last only seconds but are known on occasion to persist for longer durations. Motor vehicle operators who fail to heed the warning signs of sleepiness are especially vulnerable to sleep-related accidents, as sleep processes can slow reaction times, induce automatic behavior, and intrude involuntarily upon the waking brain, causing catastrophic consequences—including 6400 fatalities and 50,000 debilitating injuries in the United States annually. For this reason, an expert consensus panel has concluded that individuals who have slept <2 h in the prior 24 h are unfit to drive a motor vehicle. There is a significant increase in the risk of sleep-related, fatal-to-the-driver highway crashes in the early morning and late afternoon hours, coincident with bimodal peaks in the daily rhythm of sleep tendency.

Physicians who work prolonged shifts, especially intermittent overnight shifts, constitute another group of workers at greater risk for accidents and other adverse consequences of lack of sleep and misalignment of the circadian rhythm. Recurrent scheduling of resident physicians to work shifts of ≥24 consecutive hours impairs psychomotor performance to a degree that is comparable to alcohol intoxication, doubles the risk of attentional failures among intensive care unit resident physicians working at night, and significantly increases the risk of serious medical errors in intensive care units, including a fivefold increase in the risk of serious diagnostic mistakes. Some 20% of hospital resident physicians report making a fatigue-related mistake that injured a patient, and 5% admit making a fatigue-related mistake that resulted in the death of a patient. Moreover, working for >24 consecutive hours increases the risk of percutaneous injuries and more than doubles the risk of motor vehicle crashes during the commute home. For these reasons, in 2008, the National Academy of Medicine concluded that the practice of scheduling resident physicians to work for >16 consecutive hours without sleep is hazardous for both resident physicians and their patients.

Of individuals scheduled to work at night or in the early morning hours, 5–15% have much greater-than-average difficulties remaining awake during night work and sleeping during the day; these individuals are diagnosed with chronic and severe shift-work disorder (SWD). Patients with this disorder have a level of excessive sleepiness during work at night or in the early morning and insomnia during day sleep that the physician judges to be clinically significant; the condition is associated with an increased risk of sleep-related accidents and with some of the illnesses associated with night-shift work. Patients with chronic and severe SWD are profoundly sleepy at work. In fact, their sleep latencies during night work average just 2 min, comparable to mean daytime sleep latency durations of patients with narcolepsy or severe sleep apnea.

TREATMENT

Shift-Work Disorder

Caffeine is frequently used by night workers to promote wakefulness. However, it cannot forestall sleep indefinitely, and it does not shield users from sleep-related performance lapses. Postural changes, exercise, and strategic placement of nap opportunities can sometimes temporarily reduce the risk of fatigue-related performance lapses. Properly timed exposure to blue-enriched light or bright white light can directly enhance alertness and facilitate more rapid adaptation to night-shift work.

Modafinil (200 mg) or armodafinil (150 mg) 30–60 min before the start of an 8-h overnight shift is an effective treatment for the excessive sleepiness during night work in patients with SWD. Although treatment with modafinil or armodafinil significantly improves performance and reduces sleep propensity and the risk of lapses of attention during night work, affected patients remain excessively sleepy.

Fatigue risk management programs for night-shift workers should promote education about sleep, increase awareness of the hazards associated with sleep deficiency and night work, and screen for common sleep disorders. Work schedules should be designed to minimize: (1) exposure to night work; (2) the frequency of shift rotations; (3) the number of consecutive night shifts; and (4) the duration of night shifts.

Jet Lag Disorder Each year, >60 million people fly from one time zone to another, often resulting in excessive daytime sleepiness, sleep-onset insomnia, and frequent arousals from sleep, particularly in the latter half of the night. The syndrome is transient, typically lasting 2–14 d depending on the number of time zones crossed, the direction of travel, and the traveler's age and phase-shifting capacity. Travelers who spend more time outdoors at their destination reportedly adapt more quickly than those who remain in hotel or seminar rooms, presumably due to brighter (outdoor) light exposure. Avoidance of antecedent sleep loss or napping on the afternoon prior to overnight travel can reduce the difficulties associated with extended wakefulness. Laboratory studies suggest that low doses of melatonin can enhance

sleep efficiency, but only if taken when endogenous melatonin concentrations are low (i.e., during the biologic daytime).

In addition to jet lag associated with travel across time zones, many patients report a behavioral pattern that has been termed *social jet lag*, in which bedtimes and wake times on weekends or days off occur 4–8 h later than during the week. Such recurrent displacement of the timing of the sleep-wake cycle is common in adolescents and young adults and is associated with delayed circadian phase, sleep-onset insomnia, excessive daytime sleepiness, poorer academic performance, and increased risk of both obesity and depressive symptoms.

MEDICAL IMPLICATIONS OF CIRCADIAN RHYTHMICITY

Prominent circadian variations have been reported in the incidence of acute myocardial infarction, sudden cardiac death, and stroke, the leading causes of death in the United States. Platelet aggregability is increased in the early morning hours, coincident with the peak incidence of these cardiovascular events. Recurrent circadian disruption combined with chronic sleep deficiency, such as occurs during night-shift work, is associated with increased plasma glucose concentrations after a meal due to inadequate pancreatic insulin secretion. Night-shift workers with elevated fasting glucose have an increased risk of progressing to diabetes. Blood pressure of night workers with sleep apnea is higher than that of day workers. A better understanding of the possible role of circadian rhythmicity in the acute destabilization of a chronic condition such as atherosclerotic disease could improve the understanding of its pathophysiology.

Diagnostic and therapeutic procedures may also be affected by the time of day at which data are collected. Examples include blood pressure, body temperature, the dexamethasone suppression test, and plasma cortisol levels. The timing of chemotherapy administration has been reported to have an effect on the outcome of treatment. In addition, both the toxicity and effectiveness of drugs can vary with time of day. For example, more than a fivefold difference has been observed in mortality rates after administration of toxic agents to experimental animals at different times of day. Anesthetic agents are particularly sensitive to time-of-day effects. Finally, the physician must be aware of the public health risks associated with the ever-increasing demands made by the 24/7 schedules in our round-the-clock society.

32 Disorders of the Eye

Jonathan C. Horton

THE HUMAN VISUAL SYSTEM

The visual system provides a supremely efficient means for the rapid assimilation of information from the environment to aid in the guidance of behavior. The act of seeing begins with the capture of images focused by the cornea and lens on a light-sensitive membrane in the back of the eye called the *retina*. The retina is actually part of the brain, banished to the periphery to serve as a transducer for the conversion of patterns of light energy into neuronal signals. Light is absorbed by pigment in two types of photoreceptors: rods and cones. In the human retina, there are 100 million rods and 5 million cones. The rods operate in dim (scotopic) illumination. The cones function under daylight (photopic) conditions. The cone system is specialized for color perception and high spatial resolution. The majority of cones are within the macula, the portion of the retina that serves the central 10° of vision. In the middle of the macula, a small pit termed the *fovea*, packed exclusively with cones, provides the best visual acuity.

Photoreceptors hyperpolarize in response to light, activating bipolar, amacrine, and horizontal cells in the inner nuclear layer. After processing of photoreceptor responses by this complex retinal circuit, the flow of sensory information ultimately converges on a final common pathway: the ganglion cells. These cells translate the visual image impinging on the retina into a continuously varying barrage of action potentials that propagates along the primary optic pathway to visual centers within the brain. There are a million ganglion cells in each retina and hence a million fibers in each optic nerve.

Ganglion cell axons sweep along the inner surface of the retina in the nerve fiber layer, exit the eye at the optic disc, and travel through the optic nerve, optic chiasm, and optic tract to reach targets in the brain. The majority of fibers synapse on cells in the lateral geniculate body, a thalamic relay station. Cells in the lateral geniculate body project in turn to the primary visual cortex. This afferent retinogeniculocortical sensory pathway provides the neural substrate for visual perception. Although the lateral geniculate body is the main target of the retina, separate classes of ganglion cells project to other subcortical visual nuclei involved in different functions. Ganglion cells that mediate pupillary constriction and circadian rhythms are light sensitive owing to a novel visual pigment, melanopsin. Pupil responses are mediated by input to the pretectal olivary nuclei in the midbrain. The pretectal nuclei send their output to the Edinger-Westphal nuclei, which in turn provide parasympathetic innervation to the iris sphincter via an interneuron in the ciliary ganglion. Circadian rhythms are

timed by a retinal projection to the suprachiasmatic nucleus. Visual orientation and eye movements are served by retinal input to the superior colliculus. Gaze stabilization and optokinetic reflexes are governed by a group of small retinal targets known collectively as the *brainstem accessory optic system*.

The eyes must be rotated constantly within their orbits to place and maintain targets of visual interest on the fovea. This activity, called *foveation*, or looking, is governed by an elaborate efferent motor system. Each eye is moved by six extraocular muscles that are supplied by cranial nerves from the oculomotor (III), trochlear (IV), and abducens (VI) nuclei. Activity in these ocular motor nuclei is coordinated by pontine and midbrain mechanisms for smooth pursuit, saccades, and gaze stabilization during head and body movements. Large regions of the frontal and parietooccipital cortex control these brainstem eye movement centers by providing descending supranuclear input.

CLINICAL ASSESSMENT OF VISUAL FUNCTION

REFRACTIVE STATE

In approaching a patient with reduced vision, the first step is to decide whether refractive error is responsible. In *emmetropia*, parallel rays from infinity are focused perfectly on the retina. Sadly, this condition is enjoyed by only a minority of the population. In *myopia*, the globe is too long, and light rays come to a focal point in front of the retina. Near objects can be seen clearly, but distant objects require a diverging lens in front of the eye. In *hyperopia*, the globe is too short, and hence, a converging lens is used to supplement the refractive power of the eye. In *astigmatism*, the corneal surface is not perfectly spherical, necessitating a cylindrical corrective lens. Most patients elect to wear eyeglasses or contact lenses to neutralize refractive error. An alternative is to permanently alter the refractive properties of the cornea by performing laser in situ keratomileusis (LASIK) or photorefractive keratectomy (PRK).

With the onset of middle age, *presbyopia* develops as the lens within the eye becomes unable to increase its refractive power to accommodate on near objects. To compensate for presbyopia, an emmetropic patient must use reading glasses. A patient already wearing glasses for distance correction usually switches to bifocals. The only exception is a myopic patient, who may achieve clear vision at near simply by removing glasses containing the distance prescription.

Refractive errors usually develop slowly and remain stable after adolescence, except in unusual circumstances. For example, the acute onset of diabetes mellitus can produce sudden myopia because of lens edema induced by hyperglycemia. Testing vision through a pinhole aperture is a useful way to screen quickly for refractive error. If visual acuity is better through a pinhole than it is with the unaided eye, the patient needs refraction to obtain best corrected visual acuity.

VISUAL ACUITY

The Snellen chart is used to test acuity at a distance of 6 m (20 ft). For convenience, a scale version of the Snellen chart called the Rosenbaum card is held at 36 cm (14 in.) from the patient **(Fig. 32-1)**. All subjects should be able to read the 6/6 m (20/20 ft) line with each eye using their refractive correction, if any. Patients who need reading glasses because of presbyopia must wear them for accurate testing with the Rosenbaum card. If 6/6 (20/20) acuity is not present in each eye, the deficiency in vision must be explained. If it is worse than 6/240 (20/800), acuity should be recorded in terms of counting fingers, hand motions, light perception, or no light perception. Legal blindness is defined by the Internal Revenue Service as a best corrected acuity of 6/60 (20/200) or less in the better eye or a binocular visual field subtending 20° or less. Loss of vision in one eye only does not constitute legal blindness. For driving, the laws vary by state, but most require a corrected acuity of 6/12 (20/40) in at least one eye for unrestricted privileges. Patients who develop a homonymous hemianopia should not drive.

PUPILS

The pupils should be tested individually in dim light with the patient fixating on a distant target. There is no need to check the near response

FIGURE 32-1 The Rosenbaum card is a miniature, scale version of the Snellen chart for testing visual acuity at near. When the visual acuity is recorded, the Snellen distance equivalent should bear a notation indicating that vision was tested at near, not at 6 m (20 ft), or else the Jaeger number system should be used to report the acuity. *(Design Courtesy J.G. Rosenbaum MD.)*

if the pupils respond briskly to light, because isolated loss of constriction (miosis) to accommodation does not occur. For this reason, the ubiquitous abbreviation PERRLA (pupils equal, round, and reactive to light and accommodation) implies a wasted effort with the last step. However, it is important to test the near response if the light response is poor or absent. Light-near dissociation occurs with neurosyphilis (Argyll Robertson pupil), with lesions of the dorsal midbrain (*Parinaud's syndrome*), and after aberrant regeneration (oculomotor nerve palsy, Adie's tonic pupil).

An eye with no light perception has no pupillary response to direct light stimulation. If the retina or optic nerve is only partially injured, the direct pupillary response will be weaker than the consensual pupillary response evoked by shining a light into the healthy fellow eye. A *relative afferent pupillary defect* (Marcus Gunn pupil) is elicited with the swinging flashlight test **(Fig. 32-2)**. It is an extremely useful sign in retrobulbar optic neuritis and other optic nerve diseases, in which it may be the sole objective evidence for disease. In bilateral optic neuropathy, no afferent pupil defect is present if the optic nerves are affected equally.

Subtle inequality in pupil size, up to 0.5 mm, is a fairly common finding in normal persons. The diagnosis of essential or physiologic anisocoria is secure as long as the relative pupil asymmetry remains constant as ambient lighting varies. Anisocoria that increases in dim light indicates a sympathetic paresis of the iris dilator muscle. The triad of miosis with ipsilateral ptosis and anhidrosis constitutes *Horner's*

A

B

C

FIGURE 32-2 Demonstration of a relative afferent pupil defect (Marcus Gunn pupil) in the left eye, done with the patient fixating on a distant target. *A.* With dim background lighting, the pupils are equal and relatively large. ***B.*** Shining a flashlight into the right eye evokes equal, strong constriction of both pupils. ***C.*** Swinging the flashlight over to the damaged left eye causes dilation of both pupils, although they remain smaller than in ***A.*** Swinging the flashlight back over to the healthy right eye would result in symmetric constriction back to the appearance shown in ***B.*** Note that the pupils always remain equal; the damage to the left retina/optic nerve is revealed by weaker bilateral pupil constriction to a flashlight in the left eye compared with the right eye. *(From P Levatin: Arch Ophthalmol 62:768, 1959. Copyright © 1959 American Medical Association. All rights reserved.)*

syndrome, although anhidrosis is an inconstant feature. A drop of 1% apraclonidine produces no effect on the normal pupil, but the miotic pupil dilates because of denervation hypersensitivity. Brainstem stroke, carotid dissection, and neoplasm impinging on the sympathetic chain occasionally are identified as the cause of Horner's syndrome, but most cases are idiopathic.

Anisocoria that increases in bright light suggests a parasympathetic palsy. The first concern is an oculomotor nerve paresis. This possibility is excluded if the eye movements are full and the patient has no ptosis or diplopia. Acute pupillary dilation (mydriasis) can result from damage to the ciliary ganglion in the orbit. Common mechanisms are infection (herpes zoster, influenza), trauma (blunt, penetrating, surgical), and ischemia (diabetes, temporal arteritis). After denervation of the iris sphincter, the pupil does not respond well to light, but the response to near is often relatively intact. When the near stimulus is removed, the pupil redilates very slowly compared with the normal pupil, hence the term *tonic pupil*. In *Adie's syndrome*, a tonic pupil is present, sometimes in conjunction with weak or absent tendon reflexes in the lower extremities. This benign disorder, which occurs predominantly in healthy young women, is assumed to represent a mild dysautonomia. Tonic pupils are also associated with multiple system atrophy, segmental hypohidrosis, diabetes, and amyloidosis. Occasionally, a tonic pupil is discovered incidentally in an otherwise completely normal, asymptomatic individual. The diagnosis is confirmed by placing a drop of dilute (0.125%) pilocarpine into each eye. Denervation hypersensitivity produces pupillary constriction in a tonic pupil, whereas the normal pupil shows no response. Pharmacologic dilatation from accidental or deliberate instillation of anticholinergic (atropine, scopolamine) drops can produce pupillary mydriasis. Gardener's pupil refers to mydriasis induced by exposure to tropane alkaloids, contained in plants such as deadly nightshade, jimsonweed, or angel's trumpet. When an anticholinergic agent is responsible for pupil dilation, 1% pilocarpine causes no constriction.

Both pupils are affected equally by systemic medications. They are small with narcotic use (morphine, oxycodone) and large with anticholinergics (scopolamine). Parasympathetic agents (pilocarpine) used to treat glaucoma produce miosis. In any patient with an unexplained pupillary abnormality, a slit-lamp examination is helpful to exclude surgical trauma to the iris, an occult foreign body, perforating injury, intraocular inflammation, adhesions (synechia), angle-closure glaucoma, and iris sphincter rupture from blunt trauma.

EYE MOVEMENTS AND ALIGNMENT

Eye movements are tested by asking the patient, with both eyes open, to pursue a small target such as a pen tip into the cardinal fields of gaze. Normal ocular versions are smooth, symmetric, full, and maintained in all directions without nystagmus. Saccades, or quick refixation eye movements, are assessed by having the patient look back and forth between two stationary targets. The eyes should move rapidly and accurately in a single jump to their target. Ocular alignment can be judged by holding a penlight directly in front of the patient at about 1 m. If the eyes are straight, the corneal light reflex will be centered in the middle of each pupil. To test eye alignment more precisely, the cover test is useful. The patient is instructed to look at a small fixation target in the distance. One eye is occluded with a paddle or hand, while the other eye is observed. If the viewing eye shifts position to take up fixation on the target, it was misaligned. If it remains motionless, the first eye is uncovered and the test is repeated on the second eye. If neither eye moves, the eyes are aligned orthotropically. If the eyes are orthotropic in primary gaze but the patient complains of diplopia, the cover test should be performed with the head tilted or turned in whatever direction elicits diplopia. With practice, the examiner can detect an ocular deviation (heterotropia) as small as 1–2° with the cover test. In a patient with vertical diplopia, a small deviation can be difficult to detect and easy to dismiss. The magnitude of the deviation can be measured by placing a prism in front of the misaligned eye to determine the power required to neutralize the fixation shift evoked by covering the other eye. Temporary press-on plastic Fresnel prisms, prism eyeglasses, or eye muscle surgery can be used to restore binocular alignment.

STEREOPSIS

Stereoacuity is determined by presenting targets with retinal disparity separately to each eye by using polarized images. The most popular office tests measure a range of thresholds from 800 to 40 s of arc. Normal stereoacuity is 40 s of arc. If a patient achieves this level of stereoacuity, one is assured that the eyes are aligned orthotropically and that vision is intact in each eye. Random dot stereograms have no monocular depth cues and provide an excellent screening test for strabismus.

COLOR VISION

The retina contains three classes of cones, with visual pigments of differing peak spectral sensitivity: red (560 nm), green (530 nm), and blue (430 nm). The red and green cone pigments are encoded on the X chromosome, and the blue cone pigment on chromosome 7. Mutations of the blue cone pigment are exceedingly rare. Mutations of the red and green pigments cause congenital X-linked color blindness in 8% of males. Affected individuals are not truly color blind; rather, they differ

from normal subjects in the way they perceive color and how they combine primary monochromatic lights to match a particular color. Anomalous trichromats have three cone types, but a mutation in one cone pigment (usually red or green) causes a shift in peak spectral sensitivity, altering the proportion of primary colors required to achieve a color match. Dichromats have only two cone types and therefore will accept a color match based on only two primary colors. Anomalous trichromats and dichromats have 6/6 (20/20) visual acuity, but their hue discrimination is impaired. Ishihara color plates can be used to detect red-green color blindness. The test plates contain a hidden number that is visible only to subjects with color confusion from red-green color blindness. Because color blindness is almost exclusively X-linked, it is worthwhile screening only male children.

The Ishihara plates often are used to detect acquired defects in color vision, although they are intended as a screening test for congenital color blindness. Acquired defects in color vision frequently result from disease of the macula or optic nerve. For example, patients with a history of optic neuritis often complain of color desaturation long after their visual acuity has returned to normal. Color blindness also can result from bilateral strokes involving the ventral portion of the occipital lobe (cerebral achromatopsia). Such patients can perceive only shades of gray and also may have difficulty recognizing faces (prosopagnosia) **(Chap. 30)**. Infarcts of the dominant occipital lobe sometimes give rise to color anomia. Affected patients can discriminate colors but cannot name them.

VISUAL FIELDS

Vision can be impaired by damage to the visual system anywhere from the eyes to the occipital lobes. One can localize the site of the lesion with considerable accuracy by mapping the visual field deficit by finger confrontation and then correlating it with the topographic anatomy of the visual pathway **(Fig. 32-3)**. Quantitative visual field mapping is performed by computer-driven perimeters that present a target of variable intensity at fixed positions in the visual field **(Fig. 32-3*A*)**. By generating an automated printout of light thresholds, these static perimeters provide a sensitive means of detecting scotomas in the visual field. They are exceedingly useful for serial assessment of visual function in chronic diseases such as glaucoma and pseudotumor cerebri.

The crux of visual field analysis is to decide whether a lesion is before, at, or behind the optic chiasm. If a scotoma is confined to one eye, it must be due to a lesion anterior to the chiasm, involving either the optic nerve or the retina. Retinal lesions produce scotomas that correspond optically to their location in the fundus. For example, a superior-nasal retinal detachment results in an inferior-temporal field cut. Damage to the macula causes a central scotoma **(Fig. 32-3*B*)**.

Optic nerve disease produces characteristic patterns of visual field loss. Glaucoma selectively destroys axons that enter the superotemporal or inferotemporal poles of the optic disc, resulting in arcuate scotomas shaped like a Turkish scimitar, which emanate from the blind spot and curve around fixation to end flat against the horizontal meridian **(Fig. 32-3*C*)**. This type of field defect mirrors the arrangement of the nerve fiber layer in the temporal retina. Arcuate or nerve fiber layer scotomas also result from optic neuritis, ischemic optic neuropathy, optic disc drusen, and branch retinal artery or vein occlusion.

Damage to the entire upper or lower pole of the optic disc causes an altitudinal field cut that follows the horizontal meridian **(Fig. 32-3*D*)**. This pattern of visual field loss is typical of ischemic optic neuropathy but also results from retinal vascular occlusion, advanced glaucoma, and optic neuritis.

About half the fibers in the optic nerve originate from ganglion cells serving the macula. Damage to papillomacular fibers causes a cecocentral scotoma that encompasses the blind spot and macula **(Fig. 32-3*E*)**. If the damage is irreversible, pallor eventually appears in the temporal portion of the optic disc. Temporal pallor from a cecocentral scotoma may develop in optic neuritis, nutritional optic neuropathy, toxic optic neuropathy, Leber's hereditary optic neuropathy, Kjer's dominant optic atrophy, and compressive optic neuropathy. It is worth mentioning that the temporal side of the optic disc is slightly paler than the nasal side in most normal individuals. Therefore, it sometimes can be difficult to decide whether the temporal pallor visible on fundus examination represents a pathologic change. Pallor of the nasal rim of the optic disc is a less equivocal sign of optic atrophy.

At the optic chiasm, fibers from nasal ganglion cells decussate into the contralateral optic tract. Crossed fibers are damaged more by compression than are uncrossed fibers. As a result, mass lesions of the sellar region cause a temporal hemianopia in each eye. Tumors anterior to the optic chiasm, such as meningiomas of the tuberculum sella, produce a junctional scotoma characterized by an optic neuropathy in one eye and a superior-temporal field cut in the other eye **(Fig. 32-3*G*)**. More symmetric compression of the optic chiasm by a pituitary adenoma **(see Fig. 380-1)**, meningioma, craniopharyngioma, glioma, or aneurysm results in a bitemporal hemianopia **(Fig. 32-3*H*)**. The insidious development of a bitemporal hemianopia often goes unnoticed by the patient and will escape detection by the physician unless each eye is tested separately.

It is difficult to localize a postchiasmal lesion accurately, because injury anywhere in the optic tract, lateral geniculate body, optic radiations, or visual cortex can produce a homonymous hemianopia (i.e., a temporal hemifield defect in the contralateral eye and a matching nasal hemifield defect in the ipsilateral eye) **(Fig. 32-3*I*)**. A unilateral postchiasmal lesion leaves the visual acuity in each eye unaffected, although the patient may read the letters on only the left or right half of the eye chart. Lesions of the optic radiations tend to cause poorly matched or incongruous field defects in each eye. Damage to the optic radiations in the temporal lobe (Meyer's loop) produces a superior quadrantic homonymous hemianopia **(Fig. 32-3*J*)**, whereas injury to the optic radiations in the parietal lobe results in an inferior quadrantic homonymous hemianopia **(Fig. 32-3*K*)**. Lesions of the primary visual cortex give rise to dense, congruous hemianopic field defects. Occlusion of the posterior cerebral artery supplying the occipital lobe is a common cause of total homonymous hemianopia. Some patients have macular sparing, because the central field representation at the tip of the occipital lobe is supplied by collaterals from the middle cerebral artery **(Fig. 32-3*L*)**. Destruction of both occipital lobes produces cortical blindness. This condition can be distinguished from bilateral prechiasmal visual loss by noting that the pupil responses and optic fundi remain normal.

Partial recovery of homonymous hemianopia has been reported through computer-based rehabilitation therapy. During daily training sessions, patients fixate a central target while visual stimuli are presented within the blind region. The premise of vision restoration programs is that extra stimulation can promote recovery of partially damaged tissue located at the fringe of a cortical lesion. When fixation is controlled rigorously, however, no improvement of the visual fields can be demonstrated. No effective treatment exists for homonymous hemianopia caused by permanent brain damage.

DISORDERS

RED OR PAINFUL EYE

Corneal Abrasions Corneal abrasions are seen best by placing a drop of fluorescein in the eye and looking with the slit lamp, using a cobalt-blue light. A penlight with a blue filter will suffice if a slit lamp is not available. Damage to the corneal epithelium is revealed by yellow fluorescence of the basement membrane exposed by loss of the overlying epithelium. It is important to check for foreign bodies. To search the conjunctival fornices, the lower lid should be pulled down and the upper lid everted. A foreign body can be removed with a moistened cotton-tipped applicator after a drop of a topical anesthetic such as proparacaine has been placed in the eye. Alternatively, it may be possible to flush the foreign body from the eye by irrigating copiously with saline or artificial tears. If the corneal epithelium has been abraded, antibiotic ointment and a patch may be applied to the eye. A drop of an intermediate-acting cycloplegic such as cyclopentolate hydrochloride 1% helps reduce pain by relaxing the ciliary body. The eye should be reexamined the next day. Minor abrasions may not require patching, antibiotics, or cycloplegia.

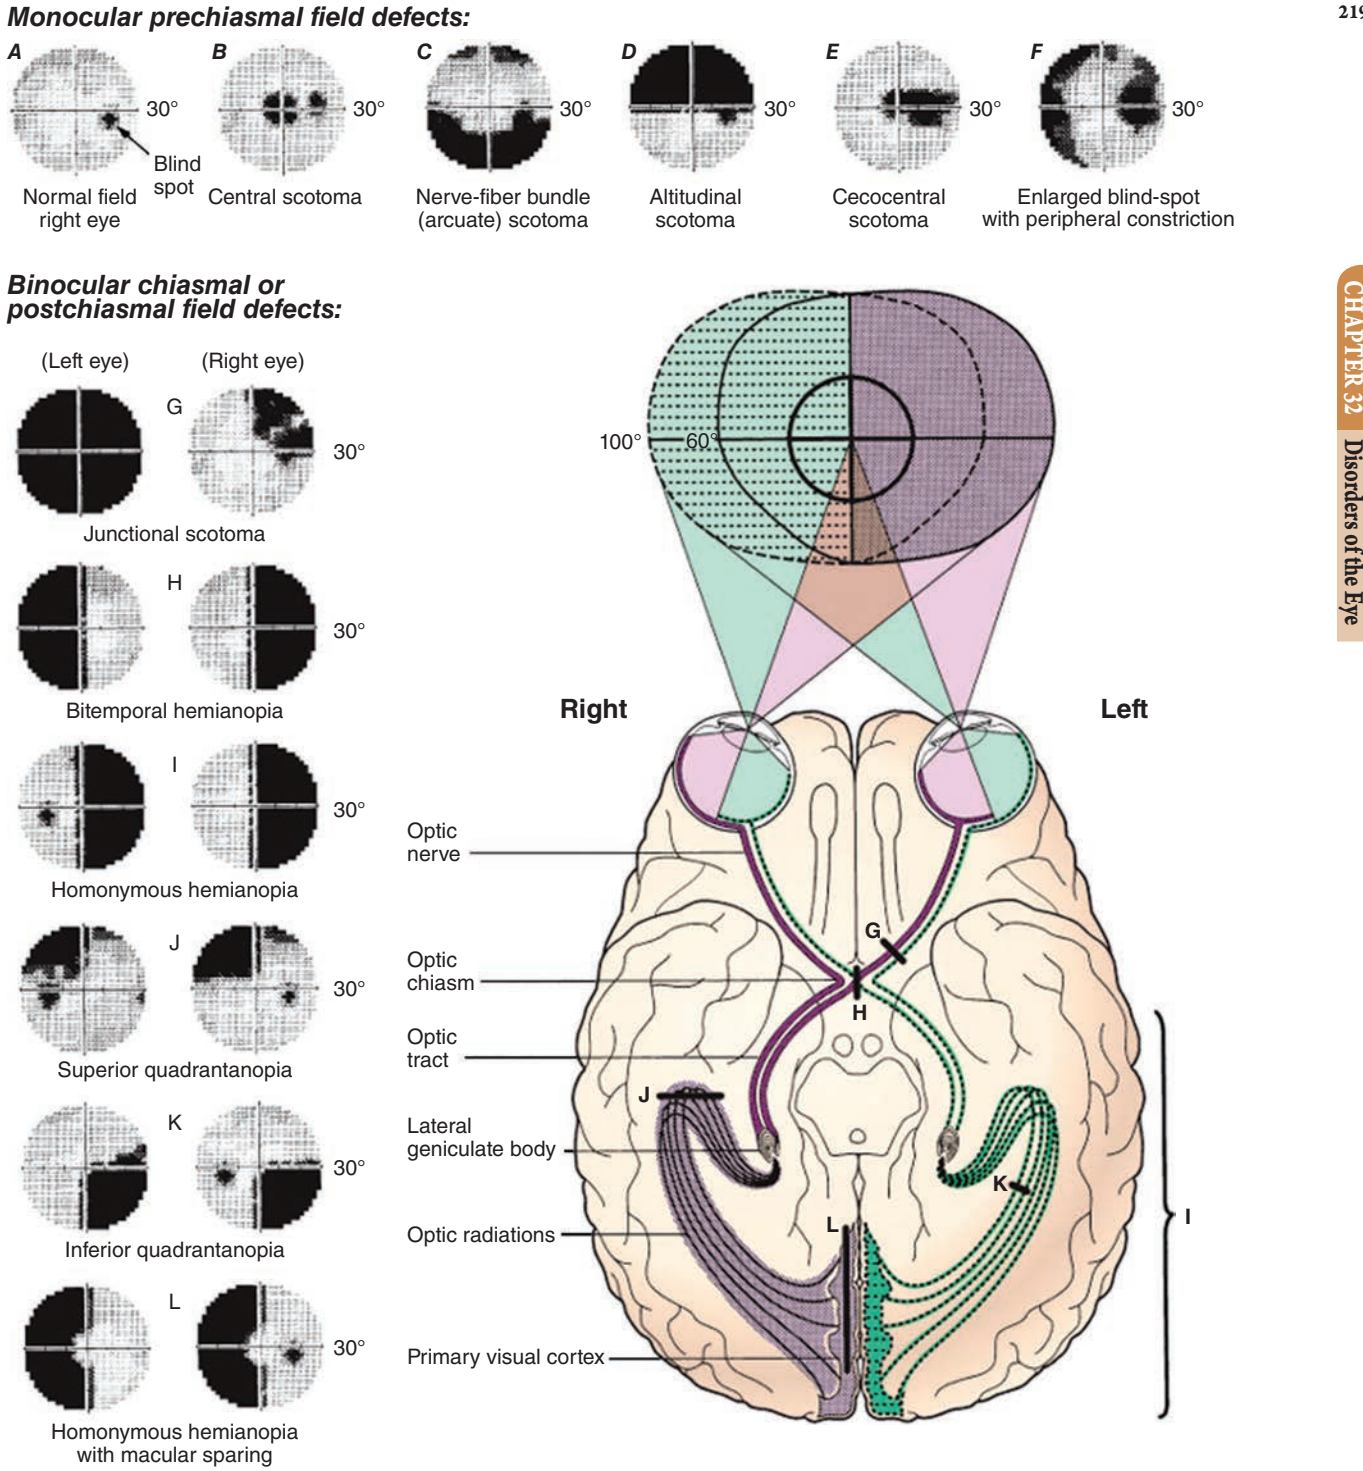

FIGURE 32-3 Ventral view of the brain, correlating patterns of visual field loss with the sites of lesions in the visual pathway. The visual fields overlap partially, creating 120° of central binocular field flanked by a 40° monocular crescent on either side. The visual field maps in this figure were done with a computer-driven perimeter (Humphrey Instruments, Carl Zeiss, Inc.). It plots the retinal sensitivity to light in the central 30° by using a gray scale format. Areas of visual field loss are shown in black. The examples of common monocular, prechiasmal field defects are all shown for the right eye. By convention, the visual fields are always recorded with the left eye's field on the left and the right eye's field on the right, just as the patient sees the world.

Subconjunctival Hemorrhage This results from rupture of small vessels bridging the potential space between the episclera and the conjunctiva. Blood dissecting into this space can produce a spectacular red eye, but vision is not affected and the hemorrhage resolves without treatment. Subconjunctival hemorrhage is usually spontaneous but can result from blunt trauma, eye rubbing, or vigorous coughing. Occasionally, it is a clue to an underlying bleeding disorder.

Pinguecula Pinguecula is a small, raised conjunctival nodule, usually at the nasal limbus. In adults, such lesions are extremely common and have little significance unless they become inflamed (pinguecu-litis). They are more apt to occur in workers with outdoor exposure. A *pterygium* resembles a pinguecula but has crossed the limbus to encroach on the corneal surface. Removal is justified when symptoms of irritation or blurring develop, but recurrence is common.

Blepharitis This refers to inflammation of the eyelids. The most common form occurs in association with acne rosacea or seborrheic dermatitis. The eyelid margins usually are colonized heavily by staphylococci. Upon close inspection, they appear greasy, ulcerated, and

crusted with scaling debris that clings to the lashes. Treatment consists of strict eyelid hygiene, applying warm compresses, and eyelash scrubs with baby shampoo. An external *hordeolum* (sty) is caused by staphylococcal infection of the superficial accessory glands of Zeis or Moll located in the eyelid margins. An internal hordeolum occurs after suppurative infection of the oil-secreting meibomian glands within the tarsal plate of the eyelid. Topical antibiotics such as bacitracin/polymyxin B ophthalmic ointment can be applied. Systemic antibiotics, usually tetracyclines or azithromycin, sometimes are necessary for treatment of meibomian gland inflammation (meibomitis) or chronic, severe blepharitis. A *chalazion* is a painless, chronic granulomatous inflammation of a meibomian gland that produces a pealike nodule within the eyelid. It can be incised and drained, but injection with glucocorticoids is equally effective. Basal cell, squamous cell, or meibomian gland carcinoma should be suspected with any nonhealing ulcerative lesion of the eyelids.

Dacryocystitis An inflammation of the lacrimal drainage system, dacryocystitis can produce epiphora (tearing) and ocular injection. Gentle pressure over the lacrimal sac evokes pain and reflux of mucus or pus from the tear puncta. Dacryocystitis usually occurs after obstruction of the lacrimal system. It is treated with topical and systemic antibiotics, followed by probing, silicone stent intubation, or surgery to reestablish patency. *Entropion* (inversion of the eyelid) or *ectropion* (sagging or eversion of the eyelid) can also lead to epiphora and ocular irritation.

Conjunctivitis Conjunctivitis is the most common cause of a red, irritated eye. Pain is minimal, and visual acuity is reduced only slightly. The most common viral etiology is adenovirus infection. It causes a watery discharge, a mild foreign-body sensation, and photophobia. Bacterial infection tends to produce a more mucopurulent exudate. Mild cases of infectious conjunctivitis usually are treated empirically with broad-spectrum topical ocular antibiotics such as sulfacetamide 10%, polymyxin-bacitracin, or a trimethoprim-polymyxin combination. Smears and cultures usually are reserved for severe, resistant, or recurrent cases of conjunctivitis. To prevent contagion, patients should be admonished to wash their hands frequently, not to touch their eyes, and to avoid direct contact with others.

Allergic Conjunctivitis This condition is extremely common and often is mistaken for infectious conjunctivitis. Itching, redness, and epiphora are typical. The palpebral conjunctiva may become hypertropic with giant excrescences called cobblestone papillae. Irritation from contact lenses or any chronic foreign body also can induce formation of cobblestone papillae. *Atopic conjunctivitis* occurs in subjects with atopic dermatitis or asthma. Symptoms caused by allergic conjunctivitis can be alleviated with cold compresses, topical vasoconstrictors, antihistamines (olopatadine), and mast cell stabilizers (cromolyn). Topical glucocorticoid solutions provide dramatic relief of immune-mediated forms of conjunctivitis, but their long-term use is ill advised because of the complications of glaucoma, cataract, and secondary infection. Topical nonsteroidal anti-inflammatory drugs (NSAIDs; ketorolac) are better alternatives.

Keratoconjunctivitis Sicca Also known as dry eye, this produces a burning foreign-body sensation, injection, and photophobia. In mild cases, the eye appears surprisingly normal, but tear production measured by wetting of a filter paper (Schirmer strip) is deficient. A variety of systemic drugs, including antihistaminic, anticholinergic, and psychotropic medications, result in dry eye by reducing lacrimal secretion. Disorders that involve the lacrimal gland directly, such as sarcoidosis and Sjögren's syndrome, also cause dry eye. Patients may develop dry eye after radiation therapy if the treatment field includes the orbits. Problems with ocular drying are also common after lesions affecting cranial nerve V or VII. Corneal anesthesia is particularly dangerous, because the absence of a normal blink reflex exposes the cornea to injury without pain to warn the patient. Dry eye is managed by frequent and liberal application of artificial tears and ocular lubricants. In severe cases, the tear puncta can be plugged or cauterized to reduce lacrimal outflow.

Keratitis Keratitis is a threat to vision because of the risk of corneal clouding, scarring, and perforation. Worldwide, the two leading causes of blindness from keratitis are trachoma from chlamydial infection and vitamin A deficiency related to malnutrition. In the United States, contact lenses play a major role in corneal infection and ulceration. They should not be worn by anyone with an active eye infection. In evaluating the cornea, it is important to differentiate between a superficial infection (*keratoconjunctivitis*) and a deeper, more serious ulcerative process. The latter is accompanied by greater visual loss, pain, photophobia, redness, and discharge. Slit-lamp examination shows disruption of the corneal epithelium, a cloudy infiltrate or abscess in the stroma, and an inflammatory cellular reaction in the anterior chamber. In severe cases, pus settles at the bottom of the anterior chamber, giving rise to a hypopyon. Immediate empirical antibiotic therapy should be initiated after corneal scrapings are obtained for Gram's stain, Giemsa stain, potassium hydroxide (KOH) prep, and cultures. Fortified topical antibiotics are most effective, supplemented with subconjunctival antibiotics as required. A fungal etiology should always be considered in a patient with keratitis. Fungal infection is common in warm humid climates, especially after penetration of the cornea by plant or vegetable material. Acanthamoeba keratitis is associated with improper disinfection of contact lenses.

Herpes Simplex The *herpesviruses* are a major cause of blindness from keratitis. Most adults in the United States have serum antibodies to herpes simplex, indicating prior viral infection **(Chap. 192)**. Primary ocular infection generally is caused by herpes simplex type 1 rather than type 2. It manifests as a unilateral follicular blepharoconjunctivitis that is easily confused with adenoviral conjunctivitis, unless telltale vesicles are present on the eyelids or conjunctiva. Recurrent ocular infection arises from reactivation of latent herpesvirus. A dendritic pattern of corneal epithelial ulceration revealed by fluorescein staining is pathognomonic for herpes infection but often not present. Involvement of both eyes is extremely rare. Corneal stromal inflammation produces edema, vascularization, and iridocyclitis. Herpes keratitis is treated with cycloplegia and either a topical antiviral (trifluridine, ganciclovir) or an oral antiviral (acyclovir, valacyclovir) agent. Topical glucocorticoids are effective in mitigating corneal scarring but generally are reserved for cases involving stromal damage. Risks include corneal melting, perforation, prolonged infection, and glaucoma.

Herpes Zoster Herpes zoster from reactivation of latent varicella (chickenpox) virus causes a dermatomal pattern of painful vesicular dermatitis **(Chap. 193)**. Ocular symptoms can occur after zoster eruption in any branch of the trigeminal nerve but are particularly common when vesicles form on the nose, reflecting nasociliary (V1) nerve involvement (Hutchinson's sign). Herpes zoster ophthalmicus produces corneal dendrites, which can be difficult to distinguish from those seen in herpes simplex. Stromal keratitis, anterior uveitis, raised intraocular pressure, ocular motor nerve palsies, acute retinal necrosis, and postherpetic scarring and neuralgia are other common sequelae. Herpes zoster ophthalmicus is treated with antiviral agents and cycloplegics. In severe cases, glucocorticoids may be added to prevent permanent visual loss from corneal scarring. Shingles should be prevented by vaccination of all healthy adults aged 50 years and older.

Episcleritis This is an inflammation of the episclera, a thin layer of connective tissue between the conjunctiva and the sclera. Episcleritis resembles conjunctivitis, but it is a more localized process and discharge is absent. Most cases of episcleritis are idiopathic, but some occur in the setting of an autoimmune disease. *Scleritis* refers to a deeper, more severe inflammatory process that frequently is associated with a connective tissue disease such as rheumatoid arthritis, lupus erythematosus, polyarteritis nodosa, granulomatosis with polyangiitis, or relapsing polychondritis. The inflammation and thickening of the sclera can be diffuse or nodular. In anterior forms of scleritis, the globe assumes a violet hue and the patient complains of severe ocular tenderness and pain. With posterior scleritis, the pain and redness may be less marked, but there is often proptosis, choroidal effusion, reduced motility, and visual loss. Episcleritis and scleritis should be treated with NSAIDs. If these agents fail, topical or even systemic glucocorticoid therapy may be necessary, especially if an underlying autoimmune process is active.

Anterior Uveitis Involving the anterior structures of the eye, uveitis was previously called *iritis* or *iridocyclitis*. The diagnosis requires slit-lamp examination to identify inflammatory cells floating in the aqueous humor or deposited on the corneal endothelium (keratic precipitates). Anterior uveitis develops in sarcoidosis, ankylosing spondylitis, juvenile idiopathic arthritis, inflammatory bowel disease, psoriasis, reactive arthritis, and Behçet's disease. It also is associated with herpes infections, syphilis, Lyme disease, onchocerciasis, tuberculosis, and leprosy. Although anterior uveitis can occur in conjunction with many diseases, no cause is found to explain the majority of cases. For this reason, laboratory evaluation usually is reserved for patients with recurrent or severe anterior uveitis. Treatment is aimed at reducing inflammation and scarring by judicious use of topical glucocorticoids. Dilatation of the pupil reduces pain and prevents the formation of synechiae.

Posterior Uveitis This diagnosis is made by observing inflammation of the vitreous, retina, or choroid on fundus examination. It is more likely than anterior uveitis to be associated with an identifiable systemic disease. Some patients have panuveitis, or inflammation of both the anterior and posterior segments of the eye. Posterior uveitis is a manifestation of autoimmune diseases such as sarcoidosis, Behçet's disease, Vogt-Koyanagi-Harada syndrome, and inflammatory bowel disease. It also accompanies diseases such as toxoplasmosis, onchocerciasis, cysticercosis, coccidioidomycosis, toxocariasis, and histoplasmosis; infections caused by organisms such as *Candida*, *Pneumocystis carinii*, *Cryptococcus*, *Aspergillus*, herpes, and cytomegalovirus (see Fig. 195-1); and other diseases, such as syphilis, Lyme disease, tuberculosis, cat-scratch disease, Whipple's disease, and brucellosis. In multiple sclerosis, chronic inflammatory changes can develop in the extreme periphery of the retina (pars planitis or intermediate uveitis). Glucocorticoids have been the mainstay of treatment for noninfectious uveitis. Biologic agents that target proinflammatory cytokines, such as the tumor necrosis factor alpha (TNF-α) inhibitor adalimumab, are effective at preventing vision loss in chronic uveitis.

Acute Angle-Closure Glaucoma This is an unusual but frequently misdiagnosed cause of a red, painful eye. Asian populations have a particularly high risk of angle-closure glaucoma. Susceptible eyes have a shallow anterior chamber because the eye has either a short axial length (hyperopia) or a lens enlarged by the gradual development of cataract. When the pupil becomes mid-dilated, the peripheral iris blocks aqueous outflow via the anterior chamber angle and the intraocular pressure rises abruptly, producing pain, injection, corneal edema, obscurations, and blurred vision. In some patients, ocular symptoms are overshadowed by nausea, vomiting, or headache, prompting a fruitless workup for abdominal or neurologic disease. The diagnosis is made by measuring the intraocular pressure during an acute attack or by performing gonioscopy, a procedure that allows one to observe a narrow chamber angle with a mirrored contact lens. Acute angle closure is treated with acetazolamide (PO or IV), topical beta blockers, prostaglandin analogues, α_2-adrenergic agonists, and pilocarpine to induce miosis. If these measures fail, a laser can be used to create a hole in the peripheral iris to relieve pupillary block. Many physicians are reluctant to dilate patients routinely for fundus examination because they fear precipitating an angle-closure glaucoma. The risk is actually remote and more than outweighed by the potential benefit to patients of discovering a hidden fundus lesion visible only through a fully dilated pupil. Moreover, a single attack of angle closure after pharmacologic dilatation rarely causes any permanent damage to the eye and serves as an inadvertent provocative test to identify patients with narrow angles who would benefit from prophylactic laser iridectomy.

Endophthalmitis This results from bacterial, viral, fungal, or parasitic infection of the internal structures of the eye. It usually is acquired by hematogenous seeding from a remote site. Chronically ill, diabetic, or immunosuppressed patients, especially those with a history of indwelling IV catheters or positive blood cultures, are at greatest risk for endogenous endophthalmitis. Although most patients have ocular pain and injection, visual loss is sometimes the only symptom. Septic emboli from a diseased heart valve or a dental abscess that lodge in the retinal circulation can give rise to endophthalmitis. White-centered retinal hemorrhages known as Roth's spots (Fig. 32-4) are considered pathognomonic for subacute bacterial endocarditis, but they also appear in leukemia, diabetes, and many other conditions. Endophthalmitis occurs as a complication of ocular surgery, especially glaucoma filtering, occasionally months or even years after the operation. An occult penetrating foreign body or unrecognized trauma to the globe should be considered in any patient with unexplained intraocular infection or inflammation.

FIGURE 32-4 Roth's spot, cotton-wool spot, and retinal hemorrhages in a 48-year-old liver transplant patient with candidemia from immunosuppression.

TRANSIENT OR SUDDEN VISUAL LOSS

Amaurosis Fugax This term refers to a transient ischemic attack of the retina (Chap. 427). Because neural tissue has a high rate of metabolism, interruption of blood flow to the retina for more than a few seconds results in *transient monocular blindness*, a term used interchangeably with amaurosis fugax. Patients describe a rapid fading of vision like a curtain descending, sometimes affecting only a portion of the visual field. Amaurosis fugax usually results from an embolus that becomes stuck within a retinal arteriole (Fig. 32-5). If the embolus breaks up or passes, flow is restored and vision returns quickly to normal without permanent damage. With prolonged interruption of blood flow, the inner retina suffers infarction. Ophthalmoscopy reveals zones of whitened, edematous retina following the distribution of branch retinal arterioles. Complete occlusion of the central retinal artery

FIGURE 32-5 Hollenhorst plaque lodged at the bifurcation of a retinal arteriole proves that a patient is shedding emboli from the carotid artery, great vessels, or heart.

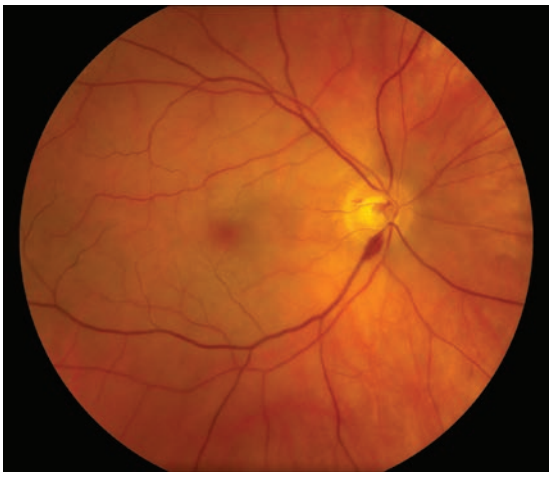

FIGURE 32-6 Central retinal artery occlusion in a 78-year-old man reducing acuity to counting fingers in the right eye. Note the splinter hemorrhage on the optic disc and the slightly milky appearance to the macula with a cherry-red fovea.

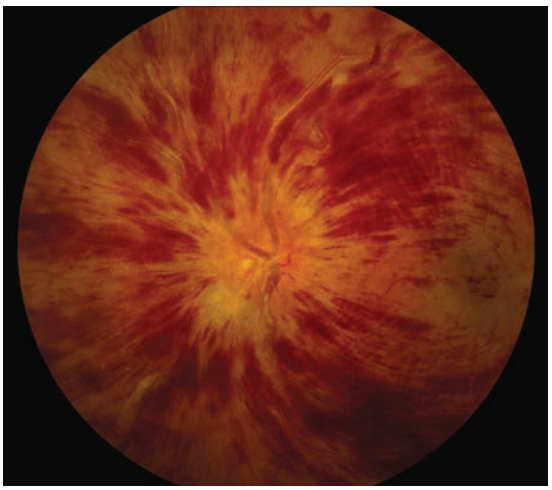

FIGURE 32-8 Central retinal vein occlusion can produce massive retinal hemorrhage ("blood and thunder"), ischemia, and vision loss.

produces arrest of blood flow and a milky retina with a cherry-red fovea **(Fig. 32-6)**. Emboli are composed of cholesterol (Hollenhorst plaque), calcium, or platelet-fibrin debris. The most common source is an atherosclerotic plaque in the carotid artery or aorta, although emboli also can arise from the heart, especially in patients with diseased valves, atrial fibrillation, or wall motion abnormalities.

In rare instances, amaurosis fugax results from low central retinal artery perfusion pressure in a patient with a critical stenosis of the ipsilateral carotid artery and poor collateral flow via the circle of Willis. In this situation, amaurosis fugax develops when there is a dip in systemic blood pressure or a slight worsening of the carotid stenosis. Sometimes there is contralateral motor or sensory loss, indicating concomitant hemispheric cerebral ischemia.

Retinal arterial occlusion also occurs rarely in association with retinal migraine, lupus erythematosus, anticardiolipin antibodies, anticoagulant deficiency states (protein S, protein C, and antithrombin deficiency), Susac's syndrome, pregnancy, IV drug abuse, blood dyscrasias, dysproteinemias, and temporal arteritis.

Marked *systemic hypertension* causes sclerosis of retinal arterioles, splinter hemorrhages, focal infarcts of the nerve fiber layer (cotton-wool spots), and leakage of lipid and fluid (hard exudate) into the macula **(Fig. 32-7)**. In hypertensive crisis, sudden visual loss can result from ischemia induced by vasospasm of retinal arterioles. In addition, visual loss can occur from ischemic optic disc swelling. Patients with acute hypertensive retinopathy should be treated by lowering the blood pressure. However, the blood pressure should not be reduced precipitously, because there is a danger of optic disc infarction from sudden hypoperfusion.

Impending *branch* or *central retinal vein occlusion* can produce prolonged visual obscurations that resemble those described by patients with amaurosis fugax. The veins appear engorged and phlebitic, with numerous retinal hemorrhages **(Fig. 32-8)**. In some patients, venous blood flow recovers spontaneously, whereas others evolve a frank obstruction with extensive retinal bleeding ("blood and thunder" appearance), infarction, and visual loss. Venous occlusion of the retina is often idiopathic, but hypertension, diabetes, and glaucoma are prominent risk factors. Polycythemia, thrombocythemia, or other factors leading to an underlying hypercoagulable state should be corrected; aspirin treatment may be beneficial.

Anterior Ischemic Optic Neuropathy (AION) This is caused by insufficient blood flow through the posterior ciliary arteries that supply the optic disc. It produces painless monocular visual loss that is sudden in onset, followed sometimes by stuttering progression. The optic disc is edematous and usually bordered by nerve fiber layer splinter hemorrhages **(Fig. 32-9)**. AION is divided into two forms: arteritic and nonarteritic. The nonarteritic form is most common. No specific cause is known, although diabetes, renal failure, and hypertension are common risk factors. Case reports have linked erectile dysfunction

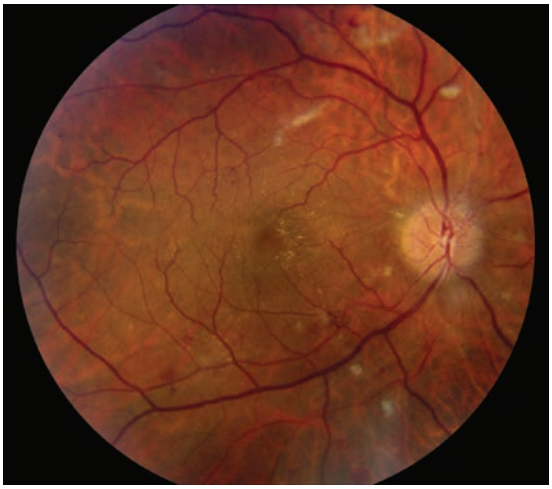

FIGURE 32-7 Hypertensive retinopathy with blurred optic disc, scattered hemorrhages, cotton-wool spots (nerve fiber layer infarcts), and foveal exudate in a 62-year-old man with chronic renal failure and a systolic blood pressure of 220.

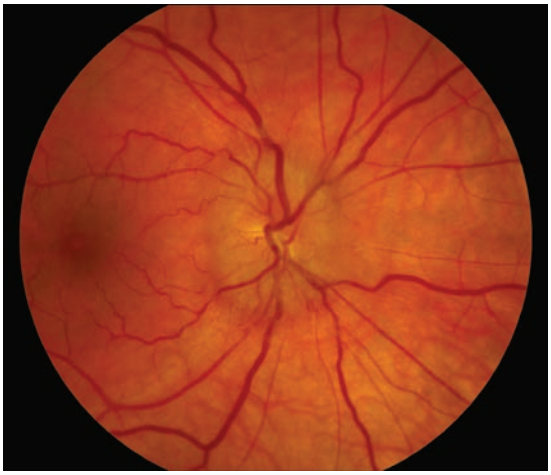

FIGURE 32-9 Anterior ischemic optic neuropathy from temporal arteritis in a 64-year-old woman with acute disc swelling, splinter hemorrhages, visual loss, and an erythrocyte sedimentation rate of 60 mm/h.

drugs to AION, but a causal association is doubtful. Evidence is strong that a crowded disc architecture and small optic cup predispose to the development of nonarteritic AION. In patients with such a "disc-at-risk," the advent of AION in one eye increases the likelihood of the same event occurring in the other eye. No treatment is available for nonarteritic AION; glucocorticoids should not be prescribed.

About 5% of patients, especially Caucasian females aged >60, have the arteritic form of AION in conjunction with giant cell (temporal) arteritis **(Chap. 363)**. It is urgent to recognize arteritic AION so that high doses of glucocorticoids can be instituted immediately to prevent blindness in the second eye. Tocilizumab, a monoclonal antibody against interleukin 6 receptor, is an effective alternative to glucocorticoids for sustained suppression of symptoms of giant cell arteritis. Symptoms of polymyalgia rheumatica may be present; the sedimentation rate and C-reactive protein level are usually elevated. In a patient with visual loss from suspected arteritic AION, temporal artery biopsy is mandatory to confirm the diagnosis. Administer glucocorticoids immediately, without waiting for the biopsy to be completed. The biopsy should be obtained as soon as practical, because prolonged glucocorticoid treatment can hide inflammatory changes. It is important to harvest an arterial segment at least 3 cm long and to examine a sufficient number of tissue sections. The histologic features of granulomatous inflammation are often quite subtle in temporal artery specimens. If the biopsy is declared negative by an experienced pathologist, the diagnosis of arteritic AION is highly unlikely and glucocorticoids should usually be discontinued.

Posterior Ischemic Optic Neuropathy This is an uncommon cause of acute visual loss, induced by the combination of severe anemia and hypotension. Cases have been reported after major blood loss during surgery (especially in patients undergoing cardiac or lumbar spine operations), shock, gastrointestinal bleeding, and renal dialysis. The fundus usually appears normal, although optic disc swelling develops if the process extends anteriorly far enough to reach the globe. Vision can be salvaged in some patients by immediate blood transfusion and reversal of hypotension.

Optic Neuritis This is a common inflammatory disease of the optic nerve. In the Optic Neuritis Treatment Trial (ONTT), the mean age of patients was 32 years, 77% were female, 92% had ocular pain (especially with eye movements), and 35% had optic disc swelling. In most patients, the demyelinating event was retrobulbar and the ocular fundus appeared normal on initial examination **(Fig. 32-10)**, although optic disc pallor slowly developed over subsequent months.

Virtually all patients experience a gradual recovery of vision after a single episode of optic neuritis, even without treatment. This rule is so reliable that failure of vision to improve after a first attack of optic neuritis casts doubt on the original diagnosis. Treatment with high-dose IV methylprednisolone (250 mg every 6 h for 3 days) followed by oral prednisone (1 mg/kg per day for 11 days) makes no difference in ultimate acuity 6 months after the attack, but the recovery of visual function occurs more rapidly. Therefore, when visual loss is severe (worse than 20/100), IV followed by PO glucocorticoids are often recommended.

For some patients, optic neuritis remains an isolated event. However, the ONTT showed that the 15-year cumulative probability of developing clinically definite multiple sclerosis after optic neuritis is 50%. A brain magnetic resonance (MR) scan is advisable in every patient with a first attack of optic neuritis. If two or more plaques are present on initial imaging, treatment should be considered to prevent the development of additional demyelinating lesions **(Chap. 444)**.

A particularly severe optic neuritis, often involving a long segment of nerve, occurs in neuromyelitis optica (NMO); it may be bilateral and associated with myelitis. NMO can occur as a primary disorder, in the setting of systemic autoimmune disease, or rarely, as a paraneoplastic condition. Detection of circulating antibodies directed against aquaporin-4 or myelin oligodendrocyte glycoprotein (MOG) is diagnostic. Treatment for acute episodes consists of glucocorticoids followed by satralizumab, eculizumab, or inebilizumab to prevent relapse. **Neuromyelitis optica is discussed in detail in Chap. 445.**

LEBER'S HEREDITARY OPTIC NEUROPATHY

This disease usually affects young men, causing progressive, painless, severe central visual loss in one eye, followed weeks to years later by the same process in the other eye. Acutely, the optic disc appears mildly plethoric with surface capillary telangiectasias but no vascular leakage on fluorescein angiography. Eventually, optic atrophy ensues. Leber's optic neuropathy is caused by a point mutation at codon 11778 in the mitochondrial gene encoding nicotinamide adenine dinucleotide dehydrogenase (NADH) subunit 4. Additional mutations responsible for the disease have been identified, most in mitochondrial genes that encode proteins involved in electron transport. Mitochondrial mutations that cause Leber's neuropathy are maternally inherited by all children, but for unknown reasons, only 10% of cases occur in females. Clinical trials of gene therapy for this condition have been unsuccessful.

Toxic Optic Neuropathy This can result in acute visual loss with bilateral optic disc swelling and cecocentral scotomas. Cases have been reported from exposure to ethambutol, methyl alcohol (moonshine), ethylene glycol (antifreeze), or carbon monoxide. In toxic optic neuropathy, visual loss also can develop gradually and produce optic atrophy **(Fig. 32-11)** without a phase of acute optic disc edema. Many agents have been implicated in toxic optic neuropathy, but evidence supporting the association is often weak. The following is a partial list of potential offending drugs or toxins: disulfiram, ethchlorvynol, chloramphenicol,

FIGURE 32-10 Retrobulbar optic neuritis is characterized by a normal fundus examination initially, hence the rubric "the doctor sees nothing, and the patient sees nothing." Optic atrophy develops after severe or repeated attacks.

FIGURE 32-11 Optic atrophy is not a specific diagnosis but refers to the combination of optic disc pallor, arteriolar narrowing, and nerve fiber layer destruction produced by a host of eye diseases, especially optic neuropathies.

FIGURE 32-12 Papilledema means optic disc edema from raised intracranial pressure. This young woman developed acute papilledema, with hemorrhages and cotton-wool spots, as a rare side effect of treatment with tetracycline for acne.

FIGURE 32-13 Optic disc drusen are calcified, mulberry-like deposits of unknown etiology within the optic disc, giving rise to "pseudopapilledema."

amiodarone, monoclonal anti-CD3 antibody, ciprofloxacin, digitalis, streptomycin, lead, arsenic, thallium, D-penicillamine, isoniazid, emetine, and sulfonamides. Metallosis (chromium, cobalt, nickel) from hip implant failure is a rare cause of toxic optic neuropathy. Deficiency states induced by starvation, malabsorption, alcoholism, or gastric bypass can lead to insidious visual loss. Thiamine, vitamin B_{12}, and folate levels should be checked in any patient with unexplained bilateral central scotomas and optic pallor.

Papilledema This connotes bilateral optic disc swelling from raised intracranial pressure **(Fig. 32-12)**. Headache is a common but not invariable accompaniment. All other forms of optic disc swelling (e.g., from optic neuritis or ischemic optic neuropathy) should be called "optic disc edema." This convention is arbitrary but serves to avoid confusion. Often it is difficult to differentiate papilledema from other forms of optic disc edema by fundus examination alone. Transient visual obscurations are a classic symptom of papilledema. They occur in only one eye or simultaneously in both eyes. They usually last seconds but can persist longer. Obscurations follow abrupt shifts in posture or happen spontaneously. When obscurations are prolonged or spontaneous, the papilledema is more threatening. Visual acuity is not affected by papilledema unless the papilledema is severe, long-standing, or accompanied by macular edema and hemorrhage. Visual field testing shows enlarged blind spots and peripheral constriction (Fig. 32-3*F*). With unremitting papilledema, peripheral visual field loss progresses in an insidious fashion while the optic nerve develops atrophy. In this setting, reduction of optic disc swelling is an ominous sign of a dying nerve rather than an encouraging indication of resolving papilledema.

Evaluation of papilledema requires neuroimaging to exclude an intracranial lesion. Noninvasive MR vascular imaging may be useful in selected cases to search for a dural venous sinus thrombosis or an arteriovenous shunt. If neuroradiologic studies are negative, the subarachnoid opening pressure should be measured in the lateral decubitus position by lumbar puncture. Inaccurate pressure readings are a common pitfall. An elevated pressure, with normal cerebrospinal fluid, points by exclusion to the diagnosis of *pseudotumor cerebri* (idiopathic intracranial hypertension). Almost all patients are female, and most are obese. Treatment with a carbonic anhydrase inhibitor such as acetazolamide lowers intracranial pressure by reducing the production of cerebrospinal fluid and improves the visual fields. Weight reduction is vital: bariatric surgery should be considered in patients who cannot lose weight by diet control. If vision loss is severe or progressive, a shunt should be performed without delay to prevent blindness. Placement of a stent across the junction of the transverse and sigmoid dural sinuses, where stenosis is usually present, has emerged as a new treatment option. Optic nerve sheath fenestration is a less effective approach and does not address other neurologic symptoms. Occasionally, fulminant papilledema produces rapid onset of blindness. In such patients, emergency surgery should be performed to install a shunt.

Optic Disc Drusen These are refractile, glittering particles within the substance of the optic nerve head **(Fig. 32-13)**. They are unrelated to drusen of the retina, which occur in age-related macular degeneration. Optic disc drusen are most common in people of northern European descent. Their diagnosis is obvious when they are visible on the surface of the optic disc. However, in many patients, they are hidden beneath the surface, producing pseudopapilledema. It is important to recognize optic disc drusen to avoid an unnecessary evaluation for papilledema. When optic disc drusen are buried, B-ultrasound is the most sensitive way to detect them. They appear hyperechoic because they contain calcium. They are also visible on computed tomography (CT) or optical coherence tomography (OCT), a technique for acquiring cross-section images of the retina. In most patients, optic disc drusen are an incidental, innocuous finding, but they can produce visual obscurations. On perimetry, they give rise to enlarged blind spots and arcuate scotomas from damage to the optic disc. With increasing age, drusen tend to become more exposed on the disc surface as optic atrophy develops. Hemorrhage, choroidal neovascular membrane, and AION are more likely to occur in patients with optic disc drusen. No treatment is available.

Vitreous Degeneration This occurs in all individuals with advancing age, leading to visual symptoms. Opacities develop in the vitreous, casting annoying shadows on the retina. As the eye moves, these distracting "floaters" move synchronously, with a slight lag caused by inertia of the vitreous gel. Vitreous traction on the retina causes mechanical stimulation, resulting in perception of flashing lights. This photopsia is brief and is confined to one eye, in contrast to the bilateral, prolonged scintillations of cortical migraine. Contraction of the vitreous can result in sudden separation from the retina, heralded by an alarming shower of floaters and photopsia. This process, known as *vitreous detachment*, is a common involutional event in the elderly. It is not harmful unless it damages the retina. A careful examination of the dilated fundus is important in any patient complaining of floaters or photopsia to search for peripheral tears or holes. If such a lesion is found, laser application can forestall a retinal detachment. Occasionally a tear ruptures a retinal blood vessel, causing vitreous hemorrhage and sudden loss of vision. On attempted ophthalmoscopy the fundus is hidden by a dark haze of blood. Ultrasound is required to examine the interior of the eye for a retinal tear or detachment. If the hemorrhage does not resolve spontaneously, the vitreous can be removed surgically. Vitreous hemorrhage also results from the fragile neovascular vessels that proliferate on the surface of the retina in diabetes, sickle cell anemia, and other ischemic ocular diseases.

FIGURE 32-14 Retinal detachment appears as an elevated sheet of retinal tissue with folds. In this patient, the fovea was spared, so acuity was normal, but an inferior detachment produced a superior scotoma.

Retinal Detachment This produces symptoms of floaters, flashing lights, and a scotoma in the peripheral visual field corresponding to the detachment (Fig. 32-14). If the detachment includes the fovea, there is an afferent pupil defect and the visual acuity is reduced. In most eyes, retinal detachment starts with a hole, flap, or tear in the peripheral retina (rhegmatogenous retinal detachment). Patients with peripheral retinal thinning (lattice degeneration) are particularly vulnerable to this process. Once a break has developed in the retina, liquefied vitreous is free to enter the subretinal space, separating the retina from the pigment epithelium. The combination of vitreous traction on the retinal surface and passage of fluid behind the retina leads inexorably to detachment. Patients with a history of myopia, trauma, or prior cataract extraction are at greatest risk for retinal detachment. The diagnosis is confirmed by ophthalmoscopic examination of the dilated eye.

Classic Migraine (See also Chap. 430) This usually occurs with a visual aura lasting about 20 min. In a typical attack, a small central disturbance in the field of vision marches toward the periphery, leaving a transient scotoma in its wake. The expanding border of migraine scotoma has a scintillating, dancing, or zigzag edge, resembling the bastions of a fortified city, hence the term *fortification spectra*. Patients' descriptions of fortification spectra vary widely and can be confused with amaurosis fugax. Migraine patterns usually last longer and are perceived in both eyes, whereas amaurosis fugax is briefer and occurs in only one eye. Migraine phenomena also remain visible in the dark or with the eyes closed. Generally, they are confined to either the right or the left visual hemifield, but sometimes, both fields are involved simultaneously. Patients often have a long history of stereotypic attacks. After the visual symptoms recede, headache develops in most patients.

Transient Ischemic Attacks Vertebrobasilar insufficiency may result in acute homonymous visual symptoms. Many patients mistakenly describe symptoms in the left or right eye when in fact the symptoms are occurring in the left or right hemifield of both eyes. Interruption of blood supply to the visual cortex causes a sudden fogging or graying of vision, occasionally with flashing lights or other positive phenomena that mimic migraine. Cortical ischemic attacks are briefer in duration than migraine, occur in older patients, and are not followed by headache. There may be associated signs of brainstem ischemia, such as diplopia, vertigo, numbness, weakness, and dysarthria.

Stroke Stroke occurs when interruption of blood supply from the posterior cerebral artery to the visual cortex is prolonged. The only finding on examination is a homonymous visual field defect that stops abruptly at the vertical meridian. Occipital lobe stroke usually is due to thrombotic occlusion of the vertebrobasilar system, embolus, or dissection. Lobar hemorrhage, tumor, abscess, and arteriovenous malformation are other common causes of hemianopic cortical visual loss.

Factitious (Functional, Nonorganic) Visual Loss This is claimed by hysterics or malingerers. The latter account for the vast majority, seeking sympathy, special treatment, or financial gain by feigning loss of sight. The diagnosis is suspected when the history is atypical, physical findings are lacking or contradictory, inconsistencies emerge on testing, and a secondary motive can be identified. In our litigious society, the fraudulent pursuit of recompense has spawned an epidemic of factitious visual loss.

CHRONIC VISUAL LOSS

Cataract Cataract is a clouding of the lens sufficient to reduce vision. Most cataracts develop slowly as a result of aging, leading to gradual impairment of vision. The formation of cataract occurs more rapidly in patients with a history of uveitis, diabetes mellitus, ocular trauma, or vitrectomy. Cataracts are acquired in a variety of genetic diseases, such as myotonic dystrophy, neurofibromatosis type 2, and galactosemia. Radiation therapy and glucocorticoid treatment can induce cataract as a side effect. The cataracts associated with radiation or glucocorticoids have a typical posterior subcapsular location. Cataract can be detected by noting an impaired red reflex when viewing light reflected from the fundus with an ophthalmoscope or by examining the dilated eye with the slit lamp.

The only treatment for cataract is surgical extraction of the opacified lens. Millions of cataract operations are performed each year around the globe. The operation generally is done under local anesthesia on an outpatient basis. A plastic or silicone intraocular lens is placed within the empty lens capsule in the posterior chamber, substituting for the natural lens and leading to rapid recovery of sight. More than 95% of patients who undergo cataract extraction can expect an improvement in vision. In some patients, the lens capsule remaining in the eye after cataract extraction eventually turns cloudy, causing secondary loss of vision. A small opening, called a posterior capsulotomy, is made in the lens capsule with a laser to restore clarity.

Glaucoma Glaucoma is a slowly progressive, insidious optic neuropathy that usually is associated with chronic elevation of intraocular pressure. After cataract, it is the most common cause of blindness in the world. It is especially prevalent in people of African descent. The mechanism by which raised intraocular pressure injures the optic nerve is not understood. Axons entering the inferotemporal and superotemporal aspects of the optic disc are damaged first, producing typical nerve fiber bundle defects called arcuate scotomas. As fibers are destroyed, the neural rim of the optic disc shrinks and the physiologic cup within the optic disc enlarges (Fig. 32-15). This process is referred to as pathologic "cupping." The cup-to-disc diameter is expressed as a fraction (e.g., 0.2). The cup-to-disc ratio ranges widely in normal individuals, making it difficult to diagnose glaucoma reliably simply by

FIGURE 32-15 Glaucoma results in "cupping" as the neural rim is destroyed and the central cup becomes enlarged and excavated. The cup-to-disc ratio is about 0.8 in this patient.

observing an unusually large or deep optic cup. Careful documentation of serial examinations is helpful. In a patient with physiologic cupping, the large cup remains stable, whereas in a patient with glaucoma, it expands relentlessly over the years. Observation of progressive cupping and detection of an arcuate scotoma or a nasal step on computerized visual field testing is sufficient to establish the diagnosis of glaucoma. OCT reveals corresponding loss of fibers along the arcuate pathways in the nerve fiber layer.

The preponderance of patients with glaucoma have open anterior chamber angles. In most affected individuals, the intraocular pressure is elevated. The cause of elevated intraocular pressure is unknown, but it is associated with gene mutations in the heritable forms. Surprisingly, a third of patients with open-angle glaucoma have an intraocular pressure within the normal range of 10–20 mmHg. For this so-called normal or low-tension form of glaucoma, high myopia is a risk factor.

Chronic angle-closure glaucoma and chronic open-angle glaucoma are usually asymptomatic. Only acute angle-closure glaucoma causes a red or painful eye, from abrupt elevation of intraocular pressure. In all forms of glaucoma, foveal acuity is spared until end-stage disease is reached. For these reasons, severe and irreversible damage can occur before either the patient or the physician recognizes the diagnosis. Screening of patients for glaucoma by noting the cup-to-disc ratio on ophthalmoscopy and by measuring intraocular pressure is vital. Glaucoma is treated with topical adrenergic agonists, cholinergic agonists, beta blockers, prostaglandin analogues, and carbonic anhydrase inhibitors. Occasionally, systemic absorption of beta blocker from eyedrops can be sufficient to cause side effects of bradycardia, hypotension, heart block, bronchospasm, or depression. Laser treatment of the trabecular meshwork in the anterior chamber angle improves aqueous outflow from the eye. If medical or laser treatments fail to halt optic nerve damage from glaucoma, a filter must be constructed surgically (trabeculectomy) or a drainage device placed to release aqueous from the eye in a controlled fashion.

Macular Degeneration This is a major cause of gradual, painless, bilateral central visual loss in the elderly. It occurs in a nonexudative (dry) form and an exudative (wet) form. Inflammation may be important in both forms of macular degeneration; susceptibility is associated with variants in the gene for complement factor H, an inhibitor of the alternative complement pathway. The nonexudative process begins with the accumulation of extracellular deposits called drusen underneath the retinal pigment epithelium. On ophthalmoscopy, they are pleomorphic but generally appear as small discrete yellow lesions clustered in the macula **(Fig. 32-16)**. With time, they become larger, more numerous, and confluent. The retinal pigment epithelium becomes focally detached and atrophic, causing visual loss by interfering with photoreceptor function. Treatment with vitamins C and E, beta-carotene, and zinc may retard dry macular degeneration.

Exudative macular degeneration, which develops in only a minority of patients, occurs when neovascular vessels from the choroid grow through defects in Bruch's membrane and proliferate underneath the retinal pigment epithelium or the retina. Leakage from these vessels produces elevation of the retina, with distortion (metamorphopsia) and blurring of vision. Although the onset of these symptoms is usually gradual, bleeding from a subretinal choroidal neovascular membrane sometimes causes acute visual loss. Neovascular membranes can be difficult to see on fundus examination because they are located beneath the retina. Fluorescein angiography and OCT are extremely useful for their detection. Major or repeated hemorrhage under the retina from neovascular membranes results in fibrosis, development of a round (disciform) macular scar, and permanent loss of central vision.

A major therapeutic advance has occurred with the discovery that exudative macular degeneration can be treated with intraocular injection of antagonists to vascular endothelial growth factor. Bevacizumab, ranibizumab, aflibercept, or brolucizumab is administered by direct injection into the vitreous cavity, beginning on a monthly basis. These antibodies cause the regression of neovascular membranes by blocking the action of vascular endothelial growth factor, thereby improving visual acuity.

Central Serous Chorioretinopathy This primarily affects males between the ages of 20 and 50 years. Leakage of serous fluid from the choroid causes small, localized detachment of the retinal pigment epithelium and the neurosensory retina. These detachments produce acute or chronic symptoms of metamorphopsia and blurred vision when the macula is involved. They are difficult to visualize with a direct ophthalmoscope because the detached retina is transparent and only slightly elevated. OCT shows fluid beneath the retina, and fluorescein angiography shows dye streaming into the subretinal space. The cause of central serous chorioretinopathy is unknown. Symptoms may resolve spontaneously if the retina reattaches, but recurrent detachment is common. Laser photocoagulation has benefited some patients with this condition.

Diabetic Retinopathy A rare disease until 1921, when the discovery of insulin resulted in a dramatic improvement in life expectancy for patients with diabetes mellitus, diabetic retinopathy is now a leading cause of blindness in the United States. The retinopathy takes years to develop but eventually appears in nearly all cases. Regular surveillance of the dilated fundus is crucial for any patient with diabetes. In advanced diabetic retinopathy, the proliferation of neovascular vessels leads to blindness from vitreous hemorrhage, retinal detachment, and glaucoma **(Fig. 32-17)**. These complications can be avoided in most patients by administration of panretinal laser photocoagulation at the appropriate point in the evolution of the disease. Anti-vascular

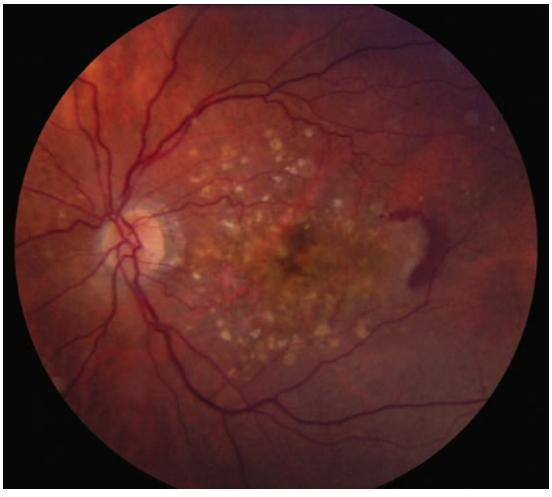

FIGURE 32-16 Age-related macular degeneration consisting of scattered yellow drusen in the macula (dry form) and a crescent of fresh hemorrhage temporal to the fovea from a subretinal neovascular membrane (wet form).

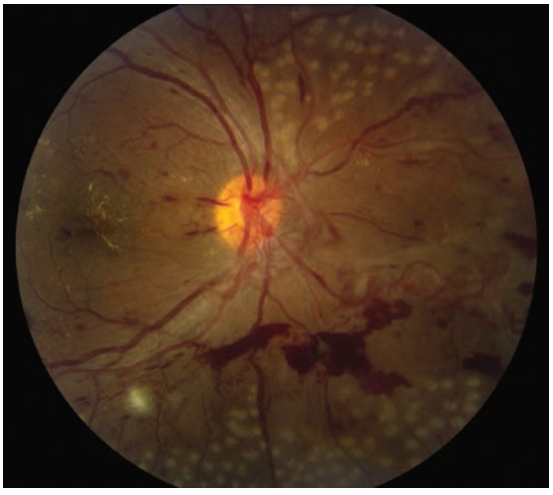

FIGURE 32-17 Proliferative diabetic retinopathy in a 25-year-old man with an 18-year history of diabetes, showing neovascular vessels emanating from the optic disc, retinal and vitreous hemorrhage, cotton-wool spots, and macular exudate. Round spots in the periphery represent recently applied panretinal photocoagulation.

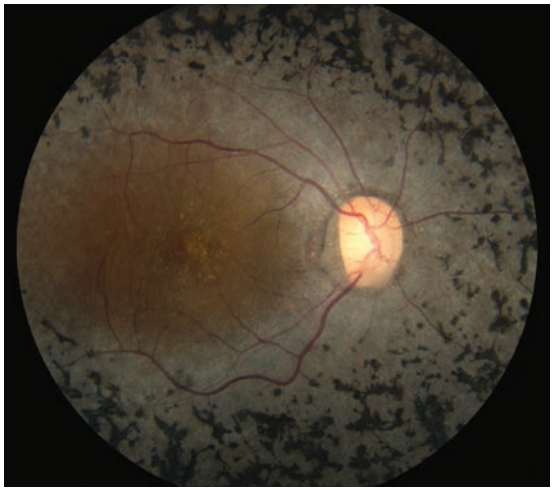

FIGURE 32-18 Retinitis pigmentosa with black clumps of pigment known as "bone spicules." The patient had peripheral visual field loss with sparing of central (macular) vision.

FIGURE 32-19 Melanoma of the choroid, appearing as an elevated dark mass in the inferior fundus, with overlying hemorrhage. The black line denotes the plane of the optical coherence tomography scan (*below*) showing the subretinal tumor.

endothelial growth factor antibody treatment is equally effective, but intraocular injections must be given repeatedly. **For further discussion of the manifestations and management of diabetic retinopathy, see Chaps. 403–405.**

Retinitis Pigmentosa This is a general term for a disparate group of rod-cone dystrophies characterized by progressive night blindness, visual field constriction with a ring scotoma, loss of acuity, and an abnormal electroretinogram (ERG). It occurs sporadically or in an autosomal recessive, dominant, or X-linked pattern. Irregular black deposits of clumped pigment in the peripheral retina, called *bone spicules* because of their vague resemblance to the spicules of cancellous bone, give the disease its name **(Fig. 32-18)**. The name is actually a misnomer because retinitis pigmentosa is not an inflammatory process. Genetic testing usually identifies a mutation in the gene for rhodopsin, the rod photopigment, or in the gene for peripherin, a glycoprotein located in photoreceptor outer segments. Vitamin A (15,000 IU/d) slightly retards the deterioration of the ERG in patients with retinitis pigmentosa but has no beneficial effect on visual acuity or fields.

Leber's congenital amaurosis, a rare cone dystrophy, has been treated by replacement of the missing RPE65 protein through gene therapy, resulting in slight improvement in visual function. Some forms of retinitis pigmentosa occur in association with rare, hereditary systemic diseases (olivopontocerebellar degeneration, Bassen-Kornzweig disease, Kearns-Sayre syndrome, Refsum's disease). Chronic treatment with chloroquine, hydroxychloroquine, and phenothiazines (especially thioridazine) can produce visual loss from a toxic retinopathy that resembles retinitis pigmentosa. Patients receiving long-term treatment with hydroxychloroquine require regular eye examinations to monitor for potential development of a bull's eye maculopathy.

Epiretinal Membrane This is a fibrocellular tissue that grows across the inner surface of the retina, causing metamorphopsia and reduced visual acuity from distortion of the macula. A crinkled, cellophane-like membrane is visible on the retinal examination. Epiretinal membrane is most common in patients aged >50 years and is usually unilateral. Most cases are idiopathic, but some occur as a result of hypertensive retinopathy, diabetes, retinal detachment, or trauma. When visual acuity is reduced to the level of about 6/24 (20/80), vitrectomy and surgical peeling of the membrane to relieve macular puckering are recommended. Contraction of an epiretinal membrane sometimes gives rise to a *macular hole*. Most macular holes, however, are caused by local vitreous traction within the fovea. Vitrectomy can improve acuity in selected cases.

Melanoma and Other Tumors Melanoma is the most common primary tumor of the eye **(Fig. 32-19)**. Approximately 2000 cases occur annually in the United States. It causes photopsia, an enlarging scotoma, and loss of vision. A small melanoma is often difficult to differentiate from a benign choroidal nevus. Serial examinations are required to document a malignant pattern of growth. Risk factors include light skin, hair, and eyes. Uveal origin accounts for 85% of cases. *GNAQ* and *GNA11* mutations are common. About half metastasize, mainly to the liver. Small and medium-sized tumors may be treated with radiation therapy; enucleation is the best treatment for large tumors. *Metastatic tumors* to the eye outnumber primary tumors. Breast and lung carcinomas have a special propensity to spread to the choroid or iris. Leukemia and lymphoma also commonly invade ocular tissues. Sometimes their only sign on eye examination is cellular debris in the vitreous, which can masquerade as a chronic posterior uveitis.

In a patient with vision loss, CT or MR scanning should be considered if the cause remains unknown after careful review of the history, visual fields, and thorough examination of the eye. Optic nerve sheath meningioma is a common retrobulbar tumor. It produces the classic triad of optociliary shunt vessels, optic atrophy, and progressive visual loss. Optic disc swelling and proptosis are also frequent signs. Optic nerve glioma in young patients is usually a pilocytic astrocytoma and has a good prognosis for preservation of vision, especially in neurofibromatosis type 1 **(Chap. 90)**. In adults, optic nerve glioma is rare and highly malignant. Chiasmal tumors (pituitary adenoma, meningioma, craniopharyngioma) produce visual loss with few objective findings except for optic disc pallor. Loss of the temporal visual field in each eye is typically described, but in fact, patients complain of vision loss in just one eye. A high degree of vigilance is necessary to avoid missing chiasmal tumors. Although symptoms progress gradually, in rare instances, the sudden expansion of a pituitary adenoma from infarction and bleeding (*pituitary apoplexy*) causes acute retrobulbar visual loss, with headache, nausea, and ocular motor nerve palsies.

PROPTOSIS

When the globes appear asymmetric, the clinician must first decide which eye is abnormal. Is one eye recessed within the orbit (*enophthalmos*), or is the other eye protuberant (*exophthalmos*, or *proptosis*)? A small globe or Horner's syndrome can give the appearance of enophthalmos. True enophthalmos occurs commonly after trauma, from atrophy of retrobulbar fat, or from fracture of the orbital floor. The position of the eyes within the orbits is measured by using a Hertel exophthalmometer, a handheld instrument that records the position of the anterior corneal surface relative to the lateral orbital rim. If this instrument is not available, relative eye position can be judged by bending the patient's head forward and looking down upon the orbits.

A proptosis of only 2 mm in one eye is detectable from this perspective. The development of proptosis implies a space-occupying lesion in the orbit and usually warrants CT or MR imaging.

Graves' Ophthalmopathy This is the leading cause of proptosis in adults (Chap. 382). The proptosis is often asymmetric and can even appear to be unilateral. Orbital inflammation and engorgement of the extraocular muscles, particularly the medial rectus and the inferior rectus, account for the protrusion of the globe. Corneal exposure, lid retraction, lid lag on downgaze, conjunctival injection, restriction of gaze, diplopia, and visual loss from optic nerve compression are cardinal symptoms. Graves' eye disease is a clinical diagnosis, but laboratory testing can be useful. The serum level of thyroid-stimulating immunoglobulins is often elevated. Orbital imaging usually reveals enlarged extraocular eye muscles, but not always. Topical lubricants, taping the eyelids closed at night, and moisture chambers are helpful to limit exposure of ocular tissues. Graves' ophthalmopathy can be treated with oral prednisone (60 mg/d) for 1 month, followed by a taper over several months, but worsening of symptoms upon glucocorticoid withdrawal is common. Infusions of teprotumumab, an inhibitor of the insulin-like growth factor I receptor, reduce proptosis and diplopia. Radiation therapy is not effective. Orbital decompression should be performed for severe, symptomatic exophthalmos or if visual function is reduced by optic nerve compression. In patients with diplopia, prisms or eye muscle surgery can be used to restore ocular alignment in primary gaze.

Orbital Pseudotumor This is an idiopathic, inflammatory orbital syndrome that is distinguished from Graves' ophthalmopathy by the prominent complaint of pain. Other symptoms include diplopia, ptosis, proptosis, and orbital congestion. Evaluation for sarcoidosis, granulomatosis with polyangiitis, and other types of orbital vasculitis or collagen-vascular disease is negative. Imaging often shows swollen eye muscles (orbital myositis) with enlarged tendons. By contrast, in Graves' ophthalmopathy, the tendons of the eye muscles usually are spared. The Tolosa-Hunt syndrome (Chap. 441) may be regarded as an extension of orbital pseudotumor through the superior orbital fissure into the cavernous sinus. The diagnosis of orbital pseudotumor is difficult. Biopsy of the orbit frequently yields nonspecific evidence of fat infiltration by lymphocytes, plasma cells, and eosinophils. A dramatic response to a therapeutic trial of systemic glucocorticoids indirectly provides the best confirmation of the diagnosis.

Orbital Cellulitis This causes pain, lid erythema, proptosis, conjunctival chemosis, restricted motility, decreased acuity, afferent pupillary defect, fever, and leukocytosis. It often arises from the paranasal sinuses, especially by contiguous spread of infection from the ethmoid sinus through the lamina papyracea of the medial orbit. A history of recent upper respiratory tract infection, chronic sinusitis, thick mucus secretions, or dental disease is significant in any patient with suspected orbital cellulitis. Blood cultures should be obtained, but they are usually negative. Most patients respond to empirical therapy with broad-spectrum IV antibiotics. Occasionally, orbital cellulitis follows an overwhelming course, with massive proptosis, blindness, septic cavernous sinus thrombosis, and meningitis. To avert this disaster, orbital cellulitis should be managed aggressively in the early stages, with immediate imaging of the orbits and antibiotic therapy that includes coverage of methicillin-resistant *Staphylococcus aureus* (MRSA). Prompt surgical drainage of an orbital abscess or paranasal sinusitis is indicated if optic nerve function deteriorates despite antibiotics.

Tumors Tumors of the orbit cause painless, progressive proptosis. The most common primary tumors are cavernous hemangioma, lymphangioma, neurofibroma, schwannoma, dermoid cyst, adenoid cystic carcinoma, optic nerve glioma, optic nerve meningioma, and benign mixed tumor of the lacrimal gland. Metastatic tumor to the orbit occurs frequently in breast carcinoma, lung carcinoma, and lymphoma. Diagnosis by fine-needle aspiration followed by urgent radiation therapy sometimes can preserve vision.

Carotid Cavernous Fistulas With anterior drainage through the orbit, these fistulas produce proptosis, diplopia, glaucoma, and corkscrew, arterialized conjunctival vessels. Direct fistulas usually result from trauma. They are easily diagnosed because of the prominent signs produced by high-flow, high-pressure shunting. Indirect fistulas, or dural arteriovenous malformations, are more likely to occur spontaneously, especially in older women. The signs are more subtle, and the diagnosis frequently is missed. The combination of slight proptosis, diplopia, enlarged muscles, and an injected eye often is mistaken for thyroid ophthalmopathy. A bruit heard upon auscultation of the head or reported by the patient is a valuable diagnostic clue. Imaging shows an enlarged superior ophthalmic vein in the orbits. Carotid cavernous shunts can be eliminated by intravascular embolization.

PTOSIS

Blepharoptosis This is an abnormal drooping of the eyelid. Unilateral or bilateral ptosis can be congenital, from dysgenesis of the levator palpebrae superioris, or from abnormal insertion of its aponeurosis into the eyelid. Acquired ptosis can develop so gradually that the patient is unaware of the problem. Inspection of old photographs is helpful in dating the onset. A history of prior trauma, eye surgery, contact lens use, diplopia, systemic symptoms (e.g., dysphagia or peripheral muscle weakness), or a family history of ptosis should be sought. Fluctuating ptosis that worsens late in the day is typical of myasthenia gravis. Ptosis evaluation should focus on evidence for proptosis, eyelid masses or deformities, inflammation, pupil inequality, or limitation of motility. The width of the palpebral fissures is measured in primary gaze to determine the degree of ptosis. The ptosis will be underestimated if the patient compensates by lifting the brow with the frontalis muscle.

Mechanical Ptosis This occurs in many elderly patients from stretching and redundancy of eyelid skin and subcutaneous fat (dermatochalasis). The extra weight of these sagging tissues causes the lid to droop. Enlargement or deformation of the eyelid from infection, tumor, trauma, or inflammation also results in ptosis on a purely mechanical basis.

Aponeurotic Ptosis This is an acquired dehiscence or stretching of the aponeurotic tendon, which connects the levator muscle to the tarsal plate of the eyelid. It occurs commonly in older patients, presumably from loss of connective tissue elasticity. Aponeurotic ptosis is also a common sequela of eyelid swelling from infection or blunt trauma to the orbit, cataract surgery, or contact lens use.

Myogenic Ptosis The causes of *myogenic ptosis* include myasthenia gravis (Chap. 448) and a number of rare myopathies that manifest with ptosis. The term *chronic progressive external ophthalmoplegia* refers to a spectrum of systemic diseases caused by mutations of mitochondrial DNA. As the name implies, the most prominent findings are symmetric, slowly progressive ptosis and limitation of eye movements. In general, diplopia is a late symptom because all eye movements are reduced equally. In the *Kearns-Sayre* variant, retinal pigmentary changes and abnormalities of cardiac conduction develop. Peripheral muscle biopsy shows characteristic "ragged-red fibers." *Oculopharyngeal dystrophy* is a distinct autosomal dominant disease with onset in middle age, characterized by ptosis, limited eye movements, and trouble swallowing. *Myotonic dystrophy*, another autosomal dominant disorder, causes ptosis, ophthalmoparesis, cataract, and pigmentary retinopathy. Patients have muscle wasting, myotonia, frontal balding, and cardiac abnormalities.

Neurogenic Ptosis This results from a lesion affecting the innervation to either of the two muscles that open the eyelid: Müller's muscle or the levator palpebrae superioris. Examination of the pupil helps distinguish between these two possibilities. In Horner's syndrome, the eye with ptosis has a smaller pupil and the eye movements are full. In an oculomotor nerve palsy, the eye with the ptosis has a larger or a normal pupil. If the pupil is normal but there is limitation of adduction, elevation, and depression, a pupil-sparing oculomotor nerve palsy is likely (see next section). Rarely, a lesion affecting the small, central subnucleus of the oculomotor complex will cause bilateral ptosis with normal eye movements and pupils.

DOUBLE VISION (DIPLOPIA)

The first point to clarify is whether diplopia persists in either eye after the opposite eye is covered. If it does, the diagnosis is monocular diplopia. The cause is usually intrinsic to the eye and therefore has no dire implications for the patient. Corneal aberrations (e.g., keratoconus, pterygium), uncorrected refractive error, cataract, or foveal traction may give rise to monocular diplopia. Occasionally, it is a symptom of malingering or psychiatric disease. Diplopia alleviated by covering one eye is binocular diplopia and is caused by disruption of ocular alignment. Inquiry should be made into the nature of the double vision (purely side-by-side versus partial vertical displacement of images), mode of onset, duration, intermittency, diurnal variation, and associated neurologic or systemic symptoms. If the patient has diplopia while being examined, motility testing should reveal a deficiency corresponding to the patient's symptoms. However, subtle limitation of ocular excursions is often difficult to detect. For example, a patient with a slight left abducens nerve paresis may appear to have full eye movements despite a complaint of horizontal diplopia upon looking to the left. In this situation, the cover test provides a more sensitive method for demonstrating the ocular misalignment. It should be conducted in primary gaze and then with the head turned and tilted in each direction while the patient fixates a central, distant target. In the above example, a cover test with the head turned to the right bringing the eyes into left gaze will maximize the fixation shift evoked by the cover test.

Occasionally, a cover test performed in an asymptomatic patient during a routine examination will reveal an ocular deviation. If the eye movements are full and the ocular misalignment is equal in all directions of gaze (comitant deviation), the diagnosis is strabismus. In this condition, which affects about 1% of the population, fusion is disrupted in infancy or early childhood. To avoid diplopia, retinal input from the nonfixating eye may be partially suppressed. In some children, this leads to impaired vision (amblyopia, or "lazy" eye) in the deviated eye.

Binocular diplopia results from a wide range of processes: infectious, neoplastic, metabolic, degenerative, inflammatory, and vascular. One must decide whether the diplopia is neurogenic in origin or is due to restriction of globe rotation by local disease in the orbit. Orbital pseudotumor, myositis, infection, tumor, thyroid disease, and muscle entrapment (e.g., from a blowout fracture) cause restrictive diplopia. The diagnosis of restriction is usually made by recognizing other associated signs and symptoms of local orbital disease. Dedicated, high-resolution orbital imaging is helpful when the cause of diplopia is not evident.

Myasthenia Gravis (See also Chap. 448) This is a major cause of painless diplopia. The diplopia is often intermittent, variable, and not confined to any single ocular motor nerve distribution. The pupils are always normal. Serial observation of a fatigable ptosis, often accompanied by diplopia from fluctuating ocular misalignment, establishes the diagnosis. Many patients have a purely ocular form of the disease, with no evidence of systemic muscular weakness. Classically, the diagnosis was confirmed by an IV edrophonium injection, which produces a transient reversal of eyelid or eye muscle weakness, but this drug is discontinued in the United States. Blood tests for antibodies against the acetylcholine receptor or the MuSK protein are frequently negative in the purely ocular form of myasthenia gravis. *Botulism* from food or wound poisoning can mimic ocular myasthenia.

If restrictive orbital disease and myasthenia gravis are excluded, a lesion of a cranial nerve supplying innervation to the extraocular muscles is the most likely cause of binocular diplopia.

Oculomotor Nerve The third cranial nerve innervates the medial, inferior, and superior recti; inferior oblique; levator palpebrae superioris; and the iris sphincter. Total palsy of the oculomotor nerve causes ptosis, a dilated pupil, and leaves the eye "down and out" because of the unopposed action of the lateral rectus and superior oblique. This combination of findings is obvious. More challenging is the diagnosis of early or partial oculomotor nerve palsy. In this setting, any combination of ptosis, pupil dilation, and weakness of the eye muscles supplied by the oculomotor nerve may be encountered. Frequent serial examinations during the rapidly evolving phase of the palsy help ensure that the diagnosis is not missed. The advent of an oculomotor nerve palsy with a pupil involvement, especially when accompanied by pain, suggests a compressive lesion, such as a tumor or circle of Willis aneurysm. Urgent neuroimaging should be obtained, along with a CT or MR angiogram. The resolution of these noninvasive techniques has advanced to the point that catheter angiography is rarely necessary to exclude an aneurysm.

A lesion of the oculomotor nucleus in the rostral midbrain produces signs that differ from those caused by a lesion of the nerve itself. There is bilateral ptosis because the levator muscle is innervated by a single central subnucleus. There is also weakness of the contralateral superior rectus, because it is supplied by the oculomotor nucleus on the other side. Occasionally both superior recti are weak. Isolated nuclear oculomotor palsy is rare. Usually, neurologic examination reveals additional signs that suggest brainstem damage from infarction, hemorrhage, tumor, or infection.

Injury to structures surrounding fascicles of the oculomotor nerve descending through the midbrain has given rise to a number of classic eponymic designations. In *Nothnagel's syndrome*, injury to the superior cerebellar peduncle causes ipsilateral oculomotor palsy and contralateral cerebellar ataxia. In *Benedikt's syndrome*, injury to the red nucleus results in ipsilateral oculomotor palsy and contralateral tremor, chorea, and athetosis. *Claude's syndrome* incorporates features of both of these syndromes, by injury to both the red nucleus and the superior cerebellar peduncle. Finally, in *Weber's syndrome*, injury to the cerebral peduncle causes ipsilateral oculomotor palsy with contralateral hemiparesis.

In the subarachnoid space, the oculomotor nerve is vulnerable to aneurysm, meningitis, tumor, infarction, and compression. In cerebral herniation, the nerve becomes trapped between the edge of the tentorium and the uncus of the temporal lobe. Oculomotor palsy also can result from midbrain torsion and hemorrhage during herniation. In the cavernous sinus, oculomotor palsy arises from carotid aneurysm, carotid cavernous fistula, cavernous sinus thrombosis, tumor (pituitary adenoma, meningioma, metastasis), herpes zoster infection, and the Tolosa-Hunt syndrome.

The etiology of an isolated, pupil-sparing oculomotor palsy often remains an enigma even after neuroimaging and extensive laboratory testing. Most cases are thought to result from microvascular infarction of the nerve somewhere along its course from the brainstem to the orbit. Usually, the patient complains of pain. Diabetes, hypertension, and vascular disease are major risk factors. Spontaneous recovery over a period of months is the rule. If this fails to occur or if new findings develop, the diagnosis of microvascular oculomotor nerve palsy should be reconsidered. Aberrant regeneration is common when the oculomotor nerve is injured by trauma or compression (tumor, aneurysm). Miswiring of sprouting fibers to the levator muscle and the rectus muscles results in elevation of the eyelid upon downgaze or adduction. The pupil also constricts upon attempted adduction, elevation, or depression of the globe. Aberrant regeneration is not seen after oculomotor palsy from microvascular infarct and hence vitiates that diagnosis.

Trochlear Nerve The fourth cranial nerve originates in the midbrain, just caudal to the oculomotor nerve complex. Fibers exit the brainstem dorsally and cross to innervate the contralateral superior oblique. The principal actions of this muscle are to depress and intort the globe. A palsy therefore results in hypertropia and excyclotorsion. The cyclotorsion seldom is noticed by patients. Instead, they complain of vertical diplopia, especially upon reading or looking down. Vertical diplopia is exacerbated by tilting the head toward the side with the muscle palsy and alleviated by tilting it away. This "head tilt test" is a cardinal diagnostic feature. Review of old photographs will sometimes reveal a habitual head tilt, signifying a patient with a decompensated, congenital trochlear nerve palsy.

New, isolated trochlear nerve palsy results from all the causes listed above for the oculomotor nerve except aneurysm. The trochlear nerve is particularly apt to suffer injury after closed head trauma. The free edge of the tentorium impinges on the nerve during a concussive blow.

Most isolated trochlear nerve palsies are idiopathic and hence are diagnosed by exclusion as "microvascular." Spontaneous improvement occurs over a period of months in most patients. A base-down prism (conveniently applied to the patient's glasses as a stick-on Fresnel lens) may serve as a temporary measure to alleviate diplopia. If the palsy does not resolve, the eyes can be realigned by weakening the inferior oblique muscle.

Abducens Nerve The sixth cranial nerve innervates the lateral rectus muscle. A palsy produces horizontal diplopia, worse on gaze to the side of the lesion. A nuclear lesion has different consequences, because the abducens nucleus contains interneurons that project via the medial longitudinal fasciculus to the medial rectus subnucleus of the contralateral oculomotor complex. Therefore, an abducens nuclear lesion produces a complete lateral gaze palsy from weakness of both the ipsilateral lateral rectus and the contralateral medial rectus. *Foville's syndrome* after dorsal pontine injury includes lateral gaze palsy, ipsilateral facial palsy, and contralateral hemiparesis incurred by damage to descending corticospinal fibers. *Millard-Gubler syndrome* from ventral pontine injury is similar except for the eye findings. There is lateral rectus weakness only, instead of gaze palsy, because the abducens fascicle is injured rather than the nucleus. Infarct, tumor, hemorrhage, vascular malformation, and multiple sclerosis are the most common etiologies of brainstem abducens palsy.

After leaving the ventral pons, the abducens nerve runs forward along the clivus to pierce the dura at the petrous apex, where it enters the cavernous sinus. Along its subarachnoid course, it is susceptible to meningitis, tumor (meningioma, chordoma, carcinomatous meningitis), subarachnoid hemorrhage, trauma, and compression by aneurysm or dolichoectatic vessels. At the petrous apex, mastoiditis can produce deafness, pain, and ipsilateral abducens palsy (*Gradenigo's syndrome*). In the cavernous sinus, the nerve can be affected by carotid aneurysm, carotid cavernous fistula, tumor (pituitary adenoma, meningioma, nasopharyngeal carcinoma), herpes infection, and Tolosa-Hunt syndrome.

Unilateral or bilateral abducens palsy is a classic sign of raised intracranial pressure. The diagnosis can be confirmed if papilledema is observed on fundus examination. The mechanism is still debated but probably is related to rostral-caudal displacement of the brainstem. The same phenomenon accounts for abducens palsy from Chiari malformation or low intracranial pressure (e.g., after lumbar puncture, spinal anesthesia, or spontaneous dural cerebrospinal fluid leak).

Treatment of abducens palsy is aimed at prompt correction of the underlying cause. However, the cause remains obscure in many instances despite diligent evaluation. As was mentioned above for isolated trochlear or oculomotor palsy, most cases are assumed to represent microvascular infarcts because they often occur in the setting of diabetes or other vascular risk factors. Some cases may develop as a postinfectious mononeuritis (e.g., after a viral flu). Patching one eye, occluding one eyeglass lens with tape, or applying a temporary prism will provide relief of diplopia until the palsy resolves. If recovery is incomplete, eye muscle surgery nearly always can realign the eyes, at least in primary position. A patient with an abducens palsy that fails to improve should be reevaluated for an occult etiology (e.g., chordoma, carcinomatous meningitis, carotid cavernous fistula, myasthenia gravis). Skull base tumors are easily missed even on contrast-enhanced neuroimaging studies.

Multiple Ocular Motor Nerve Palsies These should not be attributed to spontaneous microvascular events affecting more than one cranial nerve at a time. This remarkable coincidence does occur, especially in diabetic patients, but the diagnosis is made only in retrospect after all other diagnostic alternatives have been exhausted. Neuroimaging should focus on the cavernous sinus, superior orbital fissure, and orbital apex, where all three ocular motor nerves are in close proximity. In a diabetic or immunocompromised host, fungal infection (*Aspergillus*, Mucorales, *Cryptococcus*) is a common cause of multiple nerve palsies. In a patient with systemic malignancy, carcinomatous meningitis is a likely diagnosis. Cytologic examination may be negative despite repeated sampling of the cerebrospinal fluid. The cancer-associated Lambert-Eaton myasthenic syndrome also can produce ophthalmoplegia. Giant cell (temporal) arteritis occasionally manifests as diplopia from ischemic palsies of extraocular muscles. Fisher's syndrome, an ocular variant of Guillain-Barré, produces ophthalmoplegia with areflexia and ataxia. Often the ataxia is mild, and the reflexes are normal. Antiganglioside antibodies (GQ1b) can be detected in about 50% of cases.

Supranuclear Disorders of Gaze These are often mistaken for multiple ocular motor nerve palsies. For example, Wernicke's encephalopathy can produce nystagmus and a partial deficit of horizontal and vertical gaze that mimics a combined abducens and oculomotor nerve palsy. The disorder occurs in patients who are malnourished, alcoholic, or following bariatric surgery, and can be reversed by thiamine. Infarct, hemorrhage, tumor, multiple sclerosis, encephalitis, vasculitis, and Whipple's disease are other important causes of supranuclear gaze palsy. Disorders of vertical gaze, especially downward saccades, are an early feature of progressive supranuclear palsy. Smooth pursuit is affected later in the course of the disease. Parkinson's disease, Huntington's disease, and olivopontocerebellar degeneration also can affect vertical gaze.

The *frontal eye field* of the cerebral cortex is involved in generation of saccades to the contralateral side. After hemispheric stroke, the eyes usually deviate toward the lesioned side because of the unopposed action of the frontal eye field in the normal hemisphere. With time, this deficit resolves. Seizures generally have the opposite effect: the eyes deviate conjugately away from the irritative focus. *Parietal lesions* disrupt smooth pursuit of targets moving toward the side of the lesion. Bilateral parietal lesions produce *Bálint's syndrome*, which is characterized by impaired eye-hand coordination (optic ataxia), difficulty initiating voluntary eye movements (ocular apraxia), and visuospatial disorientation (simultanagnosia).

Horizontal Gaze Descending cortical inputs mediating horizontal gaze ultimately converge at the level of the pons. Neurons in the paramedian pontine reticular formation are responsible for controlling conjugate gaze toward the same side. They project directly to the ipsilateral abducens nucleus. A lesion of either the paramedian pontine reticular formation or the abducens nucleus causes an ipsilateral conjugate gaze palsy. Lesions at either locus produce nearly identical clinical syndromes, with the following exception: vestibular stimulation (oculocephalic maneuver or caloric irrigation) will succeed in driving the eyes conjugately to the side in a patient with a lesion of the paramedian pontine reticular formation but not in a patient with a lesion of the abducens nucleus.

INTERNUCLEAR OPHTHALMOPLEGIA This results from damage to the medial longitudinal fasciculus ascending from the abducens nucleus in the pons to the oculomotor nucleus in the midbrain (hence, "internuclear"). Damage to fibers carrying the conjugate signal from abducens interneurons to the contralateral medial rectus motoneurons results in a failure of adduction on attempted lateral gaze. For example, a patient with a left internuclear ophthalmoplegia (INO) will have slowed or absent adducting movements of the left eye **(Fig. 32-20)**. A patient with bilateral injury to the medial longitudinal fasciculus will have bilateral INO. Multiple sclerosis is the most common cause, although tumor, stroke, trauma, or any brainstem process may be responsible. *One-and-a-half syndrome* is due to a lesion of the medial longitudinal fasciculus combined with a lesion of either the abducens nucleus or the paramedian pontine reticular formation on the same side. The patient's only horizontal eye movement is abduction of the eye on the other side.

Vertical Gaze This is controlled at the level of the midbrain. The neuronal circuits affected in disorders of vertical gaze are not fully elucidated, but lesions of the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal cause supranuclear paresis of upgaze, downgaze, or all vertical eye movements. Distal basilar artery ischemia is the most common etiology.

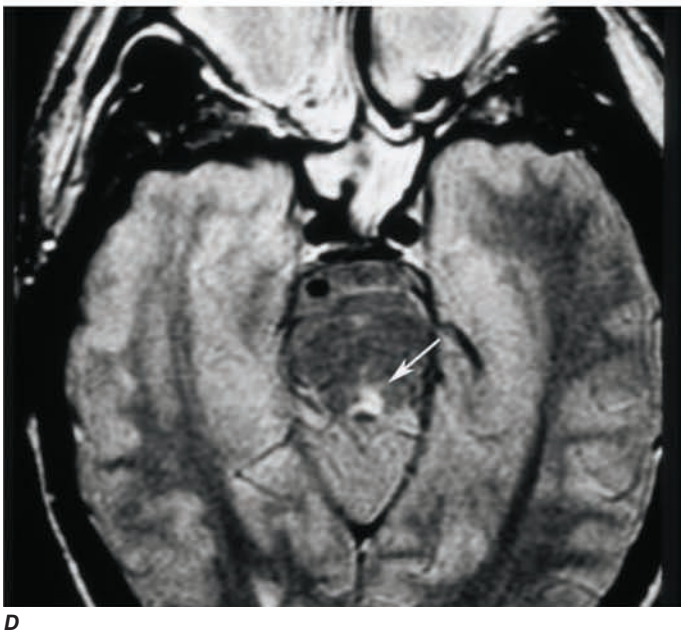
C



D

FIGURE 32-20 Left internuclear ophthalmoplegia (INO). ***A.*** In primary position of gaze, the eyes appear normal. ***B.*** Horizontal gaze to the left is intact. ***C.*** On attempted horizontal gaze to the right, the left eye fails to adduct. In mildly affected patients, the eye may adduct partially or more slowly than normal. Nystagmus is usually present in the abducted eye. ***D.*** T2-weighted axial magnetic resonance image through the pons showing a demyelinating plaque in the left medial longitudinal fasciculus (*arrow*).

Skew deviation refers to a vertical misalignment of the eyes, usually constant in all positions of gaze. The finding has poor localizing value because skew deviation has been reported after lesions in widespread regions of the brainstem and cerebellum.

PARINAUD'S SYNDROME Also known as dorsal midbrain syndrome, this is a distinct supranuclear vertical gaze disorder caused by damage to the posterior commissure. It is a classic sign of hydrocephalus from aqueductal stenosis. Pineal region or midbrain tumors, cysticercosis, and stroke also cause Parinaud's syndrome. Features include loss of upgaze (and sometimes downgaze), convergence-retraction nystagmus on attempted upgaze, downward ocular deviation ("setting sun" sign), lid retraction (Collier's sign), skew deviation, pseudoabducens palsy, and light-near dissociation of the pupils.

Nystagmus This is a rhythmic oscillation of the eyes, occurring physiologically from vestibular and optokinetic stimulation or pathologically in a wide variety of diseases (Chap. 22). Abnormalities of the eyes or optic nerves, present at birth or acquired in childhood, can produce a complex, searching nystagmus with irregular pendular (sinusoidal) and jerk features. Examples are albinism, Leber's congenital amaurosis, and bilateral cataract. This nystagmus is commonly referred to as *congenital sensory nystagmus*. This is a poor term because even in children with congenital lesions, the nystagmus does not appear until weeks after birth. *Congenital motor nystagmus*, which looks similar to congenital sensory nystagmus, develops in the absence of any abnormality of the sensory visual system. Visual acuity also is reduced in congenital motor nystagmus, probably by the nystagmus itself, but seldom below a level of 20/200.

JERK NYSTAGMUS This is characterized by a slow drift off the target, followed by a fast corrective saccade. By convention, the nystagmus is named after the quick phase. Jerk nystagmus can be downbeat, upbeat, horizontal (left or right), and torsional. The pattern of nystagmus may vary with gaze position. Some patients will be oblivious to their nystagmus. Others will complain of blurred vision or a subjective to-and-fro movement of the environment (oscillopsia) corresponding to the nystagmus. Fine nystagmus may be difficult to see on gross examination of the eyes. Observation of nystagmoid movements of the optic disc on ophthalmoscopy is a sensitive way to detect subtle nystagmus.

GAZE-EVOKED NYSTAGMUS This is the most common form of jerk nystagmus. When the eyes are held eccentrically in the orbits, they have a natural tendency to drift back to primary position. The subject compensates by making a corrective saccade to maintain the deviated eye position. Many normal patients have mild gaze-evoked nystagmus. Exaggerated gaze-evoked nystagmus can be induced by drugs (sedatives, anticonvulsants, alcohol); muscle paresis; myasthenia gravis; demyelinating disease; and cerebellopontine angle, brainstem, and cerebellar lesions.

VESTIBULAR NYSTAGMUS *Vestibular nystagmus* results from dysfunction of the labyrinth (Ménière's disease), vestibular nerve, or vestibular nucleus in the brainstem. Peripheral vestibular nystagmus often occurs in discrete attacks, with symptoms of nausea and vertigo. There may be associated tinnitus and hearing loss. Sudden shifts in head position may provoke or exacerbate symptoms.

DOWNBEAT NYSTAGMUS *Downbeat nystagmus* results from lesions near the craniocervical junction (Chiari malformation, basilar invagination). It also has been reported in brainstem or cerebellar stroke, lithium or anticonvulsant intoxication, alcoholism, and multiple sclerosis. *Upbeat nystagmus* is associated with damage to the pontine tegmentum from stroke, demyelination, or tumor.

Opsoclonus This rare, dramatic disorder of eye movements consists of bursts of consecutive saccades (saccadomania). When the saccades are confined to the horizontal plane, the term *ocular flutter* is preferred. It can result from viral encephalitis, trauma, or a paraneoplastic effect of neuroblastoma, breast carcinoma, and other malignancies. It has also been reported as a benign, transient phenomenon in otherwise healthy patients.

33 Disorders of Smell and Taste

Richard L. Doty, Steven M. Bromley

All environmental chemicals necessary for life enter the body by the nose and mouth. The senses of smell (olfaction) and taste (gustation) monitor such chemicals, determine the flavor and palatability of foods and beverages, and warn of dangerous environmental conditions, including fire, air pollution, leaking natural gas, and bacteria-laden foodstuffs. These senses contribute significantly to quality of life and, when dysfunctional, can have untoward physical and psychological consequences. A longitudinal study of 1162 nondemented elderly persons found, even after controlling for confounders, that those with the lowest baseline olfactory test scores had a 45% mortality rate over a 4-year period, compared to an 18% mortality rate for those with the highest olfactory test scores. A basic understanding of these senses in health and disease is critical for the physician, because thousands of patients present to doctors' offices each year with complaints of chemosensory dysfunction. Among the more important recent developments in neurology is the discovery that decreased smell function is among the first signs of such neurodegenerative diseases as Parkinson's disease (PD) and Alzheimer's disease (AD), signifying their "presymptomatic" phase.

ANATOMY AND PHYSIOLOGY

Olfactory System Odorous chemicals enter the front of nose during inhalation and active sniffing, as well as the back of the nose (nasopharynx) during deglutition. After reaching the highest recesses of the nasal cavity, they dissolve in the olfactory mucus and diffuse or are actively transported by specialized proteins to receptors located on the cilia of olfactory receptor cells. The cilia, dendrites, cell bodies, and proximal axonal segments of these bipolar cells are located within a unique neuroepithelium covering the cribriform plate, the superior nasal septum, superior turbinate, and sectors of the middle turbinate **(Fig. 33-1)**. Nearly 400 types of G-protein-coupled odor receptors (GPCRs) are expressed on the cilia of the receptor cells, with only one type of GPCR being expressed on a given cell. Other receptors, including trace amine-associated receptors and members of the non-GPCR membrane-spanning 4-domain family, subfamily A (MS4A) protein family, are also present on some receptor cells. Such a plethora of receptor cell types does not exist in any other sensory system. Importantly, when damaged, the receptor cells can be replaced by stem cells near the basement membrane, although such replacement is often incomplete.

After coalescing into bundles surrounded by glia-like ensheathing cells (termed fila), the receptor cell axons pass through the cribriform plate to the olfactory bulbs, where they synapse with dendrites of other cell types within the glomeruli **(Fig. 33-2)**. These spherical structures, which make up a distinct layer of the olfactory bulb, are a site of convergence of information, because many more fibers enter than leave them. Receptor cells that express the same type of receptor project to the same glomeruli, effectively making each glomerulus a functional unit. The major projection neurons of the olfactory system—the mitral and tufted cells—send primary dendrites into the glomeruli, connecting not only with the incoming receptor cell axons, but with dendrites of periglomerular cells. The activity of the mitral/tufted cells is modulated by the periglomerular cells, secondary dendrites from other mitral/tufted cells, and granule cells, the most numerous cells of the bulb. The latter cells, which are largely GABAergic, receive inputs from central brain structures and modulate the output of the mitral/tufted cells. Interestingly, like the olfactory receptor cells, some cells within the bulb undergo replacement. Thus, neuroblasts formed within the anterior subventricular zone of the brain migrate along the rostral migratory stream, ultimately becoming granule and periglomerular cells.

The axons of the mitral and tufted cells synapse within secondary olfactory structures, which largely compose the primary olfactory cortex (POC) **(Fig. 33-3)**. The POC is defined as those cortical structures that receive direct projections from the olfactory bulb, most notably the piriform and entorhinal cortices. Although olfaction is unique

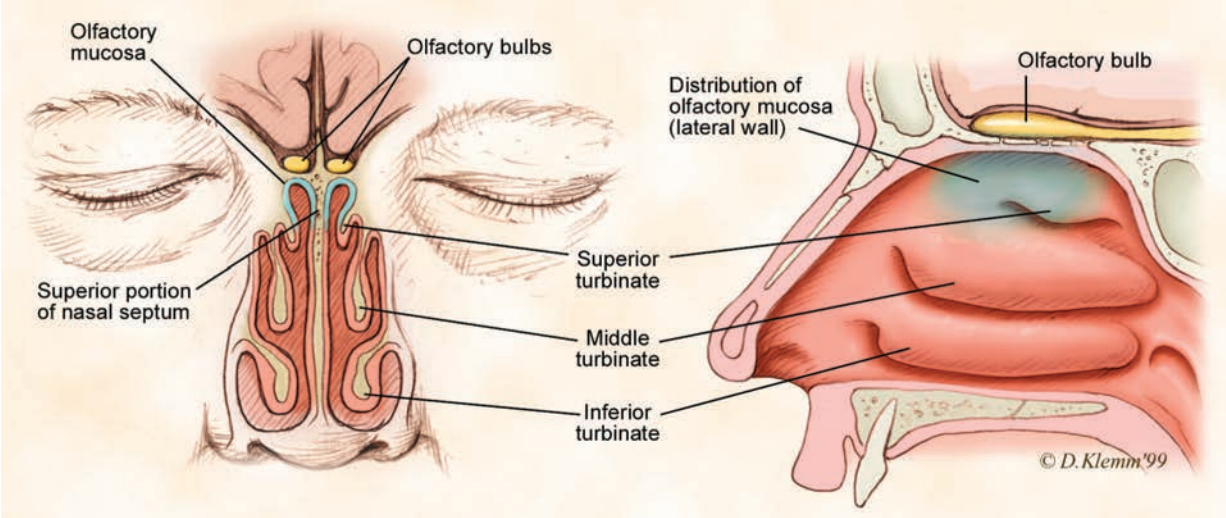

FIGURE 33-1 Anatomy of the nose, showing the distribution of olfactory receptors in the roof of the nasal cavity. *(Copyright David Klemm, Faculty and Curriculum Support [FACS], Georgetown University Medical Center.)*

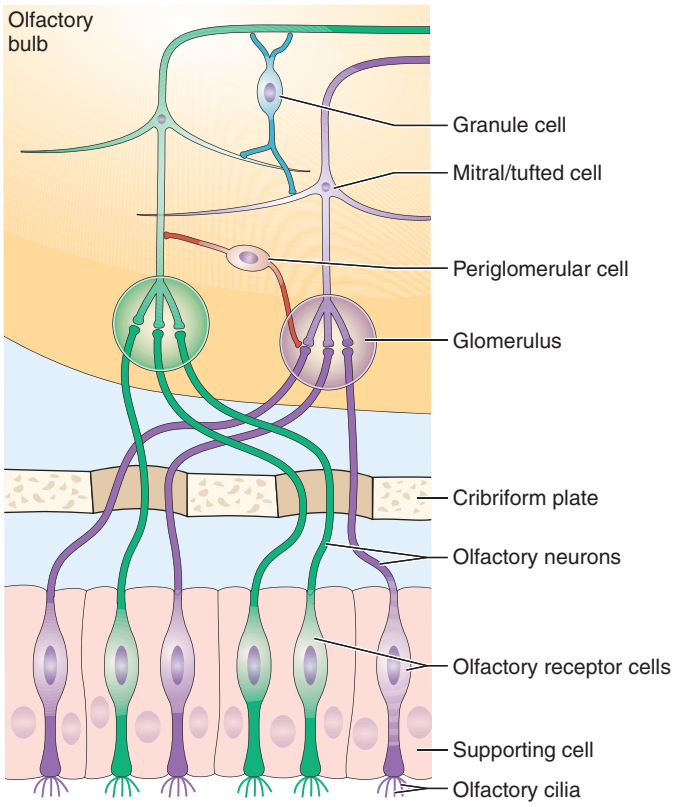

FIGURE 33-2 Schematic of the layers and wiring of the olfactory bulb. Each receptor type (red, green, blue) projects to a common glomerulus. The neural activity within each glomerulus is modulated by periglomerular cells. The activity of the primary projection cells, the mitral and tufted cells, is modulated by granule cells, periglomerular cells, and secondary dendrites from adjacent mitral and tufted cells. *(Adapted from www.med.yale.edu/neurosurg/treloar/index.html)*

in that its initial afferent projections bypass the thalamus, persons with damage to the thalamus can exhibit olfactory deficits, particularly ones of odor identification. Such deficits likely reflect the involvement of thalamic connections between the POC and the orbitofrontal cortex (OFC), where odor identification largely occurs. The close anatomic ties between the olfactory system and the amygdala, hippocampus, and hypothalamus help to explain the intimate associations between odor perception and cognitive functions such as memory, motivation, arousal, autonomic activity, digestion, and sex.

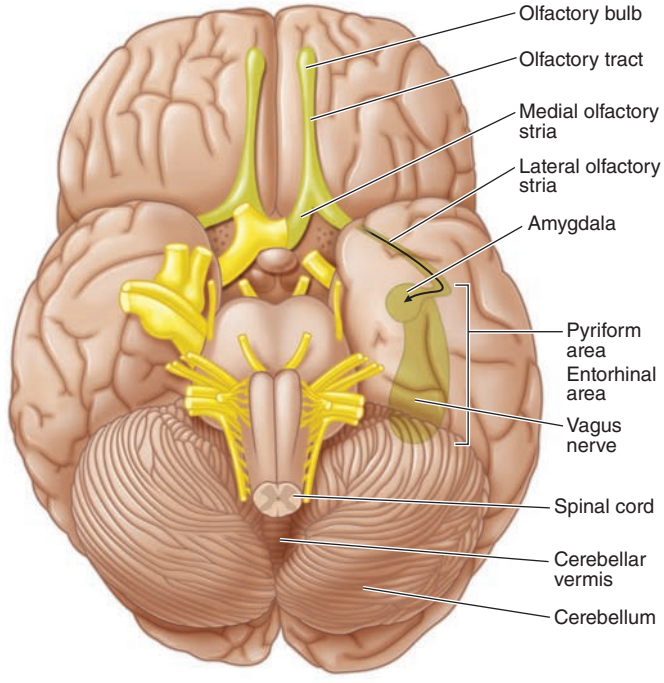

FIGURE 33-3 Anatomy of the base of the brain showing the primary olfactory cortex.

Taste System Tastants are sensed by specialized receptor cells present within taste buds—small grapefruit-like segmented structures located on the lateral margins and dorsum of the tongue, roof of the mouth, pharynx, larynx, and superior esophagus **(Fig. 33-4)**. Lingual taste buds are embedded in well-defined protuberances, termed fungiform, foliate, and circumvallate papillae. After dissolving in a liquid, tastants enter the opening of the taste bud—the taste pore—and bind to receptors on microvilli, small extensions of receptor cells within each taste bud. Such binding changes the electrical potential across the taste cell, resulting in neurotransmitter release onto the first-order taste neurons. Although humans have ~7500 taste buds, not all harbor taste-sensitive cells; some contain only one class of receptor (e.g., cells responsive only to sugars), whereas others contain cells sensitive to more than one class. The number of taste receptor cells per taste bud ranges from zero to well over 100. A small family of three GPCRs, namely T1R1, T1R2, and T1R3, mediate sweet and umami taste sensations. Bitter sensations, on the other hand, depend on T2R receptors, a family of ~30 GPCRs expressed on cells different from those that express the sweet and umami receptors. T2Rs sense a wide range of bitter substances but do not distinguish among them. Sour tastants are sensed by the PKD2L1 receptor, a member of the transient receptor potential protein (TRP) family. Perception of salty sensations, such as induced by sodium chloride, arises from the entry of Na^+ ions into the cells via specialized membrane channels, such as the amiloride-sensitive Na^+ channel.

It is now well established that both bitter and sweet taste-related receptors are also present elsewhere in the body, most notably in the alimentary and respiratory tracts. This important discovery generalizes the concept of taste-related chemoreception to areas of the body beyond the mouth and throat, with α-gustducin, the taste-specific G-protein α-subunit, expressed in so-called brush cells found specifically within the human trachea, lung, pancreas, and gallbladder. These brush cells are rich in nitric oxide (NO) synthase, known to defend against xenobiotic organisms, protect the mucosa from acid-induced lesions, and, in the case of the gastrointestinal tract, stimulate vagal and splanchnic afferent neurons. NO further acts on nearby cells, including enteroendocrine cells, absorptive or secretory epithelial cells, mucosal blood vessels, and cells of the immune system. Members of the T2R family of bitter receptors and the sweet receptors of the T1R family have been identified within the gastrointestinal tract and in enteroendocrine cell lines. In some cases, these receptors are important for metabolism, with the T1R3 receptors and gustducin playing decisive roles in the sensing and transport of dietary sugars from the intestinal lumen into absorptive enterocytes via a sodium-dependent glucose transporter and in regulation of hormone release from gut enteroendocrine cells. In other cases, these receptors may be important for airway protection, with a number of T2R bitter receptors in the motile cilia of the human airway that respond to bitter compounds by increasing their beat frequency. One specific T2R38 taste receptor is expressed in human upper respiratory epithelia and responds to acyl-monoserine lactone quorum-sensing molecules secreted by *Pseudomonas aeruginosa* and other gram-negative bacteria. Differences in T2R38 functionality, as related to TAS2R38 genotype, correlate with susceptibility to upper respiratory infections in humans.

Taste information is sent to the brain via three cranial nerves (CNs): CN VII (the *facial nerve*, which involves the intermediate nerve with its branches, the greater petrosal and chorda tympani nerves), CN IX (the *glossopharyngeal nerve*), and CN X (the *vagus nerve*) **(Fig. 33-5)**. CN VII innervates the anterior tongue and all of the soft palate, CN IX innervates the posterior tongue, and CN X innervates the laryngeal surface of the epiglottis, larynx, and proximal portion of the esophagus. The mandibular branch of CN V (V_3) conveys somatosensory information (e.g., touch, burning, cooling, irritation) to the brain. Although not technically a gustatory nerve, CN V shares primary nerve routes with many of the gustatory nerve fibers and adds temperature, texture, pungency, and spiciness to the taste experience. The chorda tympani

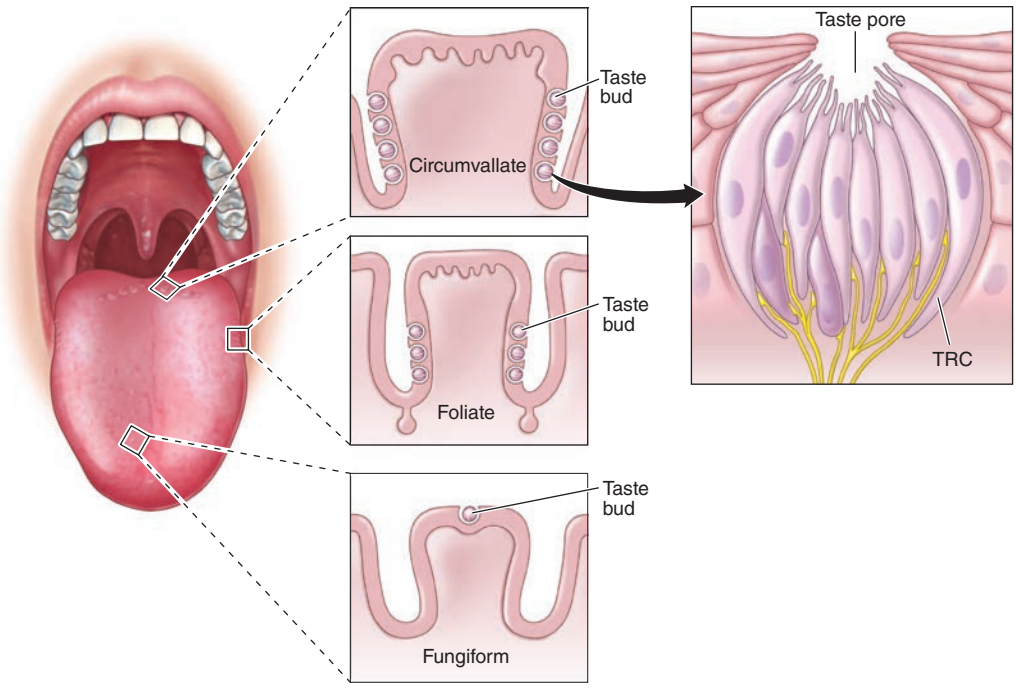

FIGURE 33-4 Schematic of the taste bud and its opening (pore), as well as the location of buds on the three major types of papillae: fungiform (anterior), foliate (lateral), and circumvallate (posterior). TRC, taste receptor cell.

nerve is famous for taking a recurrent course through the facial canal in the petrosal portion of the temporal bone, passing through the middle ear, and then exiting the skull via the petrotympanic fissure, where it joins the lingual nerve (a division of CN V) near the tongue. This nerve also carries parasympathetic fibers to the submandibular and sublingual glands, whereas the greater petrosal nerve supplies the palatine glands, thereby influencing saliva production.

The axons of the projection cells, which synapse with taste buds, enter the rostral portion of the nucleus of the solitary tract (NTS) within the medulla of the brainstem (Fig. 33-5). From the NTS, neurons then project to a division of the ventroposteromedial thalamic nucleus (VPM) via the medial lemniscus. From here, projections are made to the rostral part of the frontal operculum and adjoining insula, a brain region considered the *primary taste cortex* (PTC). Projections from the PTC then go to the *secondary taste cortex*, namely the caudolateral OFC. This brain region is involved in the conscious recognition of taste qualities. Moreover, because it contains cells that are activated by several sensory modalities, it is likely a center for establishing "flavor."

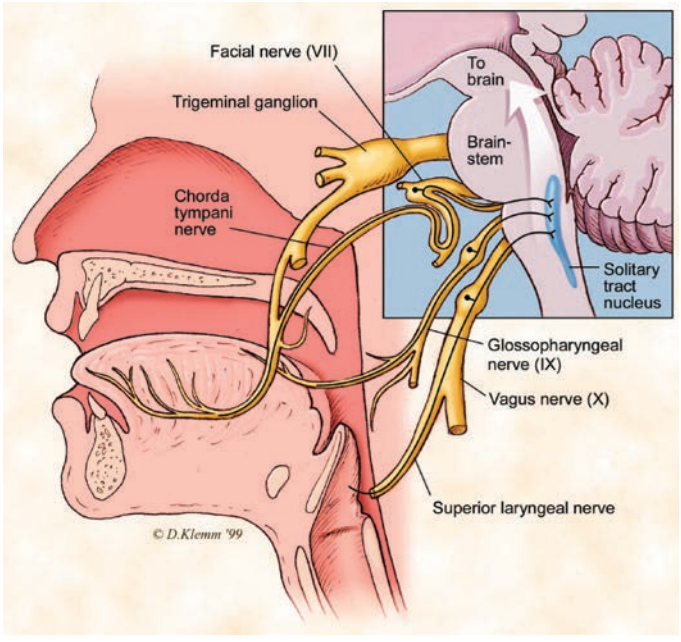

FIGURE 33-5 Schematic of the cranial nerves (CNs) that mediate taste function, including the chorda tympani nerve (CN VII), the glossopharyngeal nerve (CN IX), and the vagus nerve (CN X). *(Copyright David Klemm, Faculty and Curriculum Support [FACS], Georgetown University Medical Center.)*

DISORDERS OF OLFACTION

The ability to smell is influenced, in everyday life, by such factors as age, gender, general health, nutrition, smoking, and reproductive state. Women typically outperform men on tests of olfactory function and retain normal smell function to a later age than do men.

Estimates of the prevalence of olfactory dysfunction in the general population vary; a cross-sectional analysis from the National Health and Nutrition Examination Survey (NHANES 2013–2014) found an overall prevalence of 13.5%. However, it is apparent that significant decrements in the ability to smell are present in >50% of the population between 65 and 80 years of age and in 75% of those aged ≥80 years (Fig. 33-6). Such presbyosmia helps to explain why many elderly report

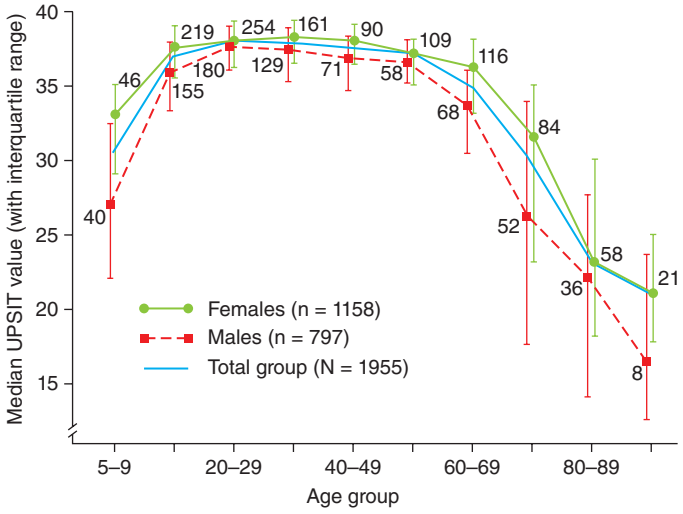

FIGURE 33-6 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of subject age and sex. Numbers by each data point indicate sample sizes. Note that women identify odorants better than men at all ages. *(RL Doty et al: Smell identification ability: Changes with age. Science 226:4681, 1984. TABLE 33-1 Disorders and Conditions Associated with Compromised Olfactory Function, as Measured by Olfactory Testing

Endocrine and Metabolic Conditions
Adrenal cortical insufficiency (Addison's disease)
Chromatin-negative gonadal dysgenesis (Turner's syndrome)
Cushing's syndrome
Diabetes
Hypertension
Hypothyroidism
Idiopathic hypogonadotropic hypogonadism
Kallmann's syndrome
Liver disease
Renal disease/kidney failure
Pregnancy
Pseudohypoparathyroidism
Wilson's disease

Immune-Related Diseases
Acute disseminated encephalomyelitis
Allergic rhinitis
Asthma
Autoimmune pancreatitis
Behçet's disease
Churg-Strauss syndrome
Cystic fibrosis
Fibromyalgia
Giant cell arteritis
Hereditary angioedema
Idiopathic inflammatory myopathies
Inflammatory bowel diseases
Lupus
Mikulicz's disease
Multiple sclerosis
Myasthenia gravis
Neuromyelitis optica
Pemphigus vulgaris
Psoriasis vulgaris
Rheumatoid arthritis
Sjögren's syndrome
Systemic sclerosis (scleroderma)
Wegener's granulomatosis

Nasosinus Disorders
Adenoid hypertrophy
Bacterial and viral upper respiratory infections
Laryngopharyngeal reflux disease
Rhinosinusitis/polyposis

Neurologic Diseases/Disorders
Alzheimer's disease
Amyotrophic lateral sclerosis (ALS)
Bell's palsy
Degenerative ataxias
Down's syndrome
Epilepsy
Facial paralysis
Fibromyalgia
Frontotemporal lobe degeneration
Guamanian ALS/Parkinson's disease/dementia syndrome
Head trauma
Huntington's disease
Idiopathic inflammatory myopathies
Korsakoff psychosis
Lubag disease
Migraine
Multi-infarct dementia
Narcolepsy with cataplexy
Neoplasms, cranial/nasal
Orthostatic tremor
Parkinson's disease
Pick's disease
Rapid eye movement behavioral sleep disorder
Stroke

Psychiatric-Related Diseases/Disorders
Anorexia nervosa
Asperger's syndrome
Attention deficit/hyperactivity disorder
Depression
Obsessive compulsive disorder
Panic disorder
Posttraumatic stress disorder
Psychopathy
Schizophrenia
Seasonal affective disorder
22q11 deletion syndrome

Viral, Bacterial, and Fungal Infections
Candidiasis
COVID-19
Hepatitis C
Herpetic meningoencephalitis
Human immunodeficiency virus
Legionnaires' disease
Leprosy (Hansen's disease)
Lyme disease
Poliomyelitis
Rhinosinusitis
Upper respiratory infections

Other Disorders or Factors
Alcoholism
Bardet-Biedl syndrome
Chemical exposure
Congenital
Iatrogenesis, including chemotherapy and radiation
Nutritional deficiencies
Obesity
Tobacco smoking
Toxic chemical exposures
Vitamin B_{12} deficiency

Note: These disease/disorder classifications are not necessarily mutually exclusive.

that food has little flavor, a problem that can result in nutritional disturbances. This also helps to explain why a disproportionate number of elderly die in accidental gas poisonings. A relatively complete listing of conditions and disorders that have been associated with olfactory dysfunction is presented in Table 33-1.

Aside from aging, the three most common identifiable causes of long-lasting or permanent smell loss seen in the clinic are, in order of frequency, severe upper respiratory infections, head trauma, and chronic rhinosinusitis. The physiologic basis for most head trauma–related losses is the shearing and subsequent scarring of the olfactory fila as they pass from the nasal cavity into the brain cavity. The cribriform plate does not have to be fractured or show pathology for smell loss to be present. Severity of trauma, as indexed by a poor Glasgow Coma Scale score on presentation and the length of posttraumatic amnesia, is associated with higher risk of olfactory impairment. Less than 10% of posttraumatic anosmic patients will recover age-related normal function over time. This increases to nearly 25% of those with less-than-total loss. Respiratory infections, such as those associated with the common cold, influenza, pneumonia, HIV, and COVID-19 can directly and permanently damage the olfactory epithelium, decreasing receptor cell number, damaging cilia on remaining receptor cells, and inducing the replacement of sensory epithelium with respiratory epithelium. The smell loss associated with chronic rhinosinusitis is related to disease severity, with most loss occurring in cases where rhinosinusitis and polyposis are both present. Smell loss is among the first signs of the SARS-CoV-2 infection responsible for COVID-19, a loss that is seemingly independent of nasal inflammation. Although in rhinosinusitis cases systemic glucocorticoid therapy can usually induce short-term functional improvement, it does not, on average, return smell test scores to normal, implying that chronic permanent neural loss is present and/or that short-term administration of systemic glucocorticoids does not completely mitigate the inflammation. It is well established that microinflammation in an otherwise seemingly normal epithelium can influence smell function.

A number of neurodegenerative diseases are accompanied by olfactory impairment, including PD, AD, Huntington's disease, parkinsonism-dementia complex of Guam, dementia with Lewy bodies (DLB), multiple system atrophy, corticobasal degeneration, frontotemporal dementia, and Down's syndrome; smell loss can also occur in idiopathic rapid eye movement (REM) behavioral sleep disorder (iRBD), as well as in multiple sclerosis (MS) related to lesions within olfaction-related structures. Olfactory impairment in PD often predates the clinical diagnosis by a number of years. In staged cases, studies of the sequence of formation of abnormal α-synuclein aggregates and Lewy bodies suggest that the olfactory bulbs may be, along with the dorsomotor nucleus of the vagus, the first site of neural damage in PD. In postmortem studies of patients with very mild "presymptomatic" signs of AD, poorer smell function has been associated with higher levels of AD-related pathology. Smell loss is more marked in patients with early clinical manifestations of DLB than in those with mild AD. Interestingly, smell loss is minimal or nonexistent in progressive supranuclear palsy and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced parkinsonism. The relative contributions of disease-specific pathology or differential damage to forebrain neuromodulator/neurotransmitter systems in explaining different degrees of olfactory dysfunction among the various neurodegenerative diseases are presently unknown.

The smell loss seen in iRBD is of the same magnitude as that found in PD. This is of particular interest because patients with iRBD frequently develop PD and hyposmia. REM behavior disorder is not only seen in its idiopathic form, but can also be associated with narcolepsy **(Chap. 31)**. A study of narcoleptic patients with and without REM behavior disorder demonstrated that narcolepsy, independent of REM behavior disorder, was associated with impairments in olfactory function. Loss of hypothalamic neurons expressing orexin (also known as hypocretin) neuropeptides is believed to be responsible for narcolepsy and cataplexy. Orexin-containing neurons project throughout the entire olfactory system (from the olfactory epithelium to the olfactory cortex), and damage to these projections may be one underlying mechanism for impaired olfactory performance in narcoleptic patients. Administration of intranasal orexin A (hypocretin-1) improved olfactory function, supporting the notion that mild olfactory impairment is not only a primary feature of narcolepsy with cataplexy, but that orexin deficiency may be directly responsible for the loss of smell in this condition.

DISORDERS OF TASTE

The majority of patients who present with taste dysfunction exhibit olfactory, not taste, loss. This is because most flavors attributed to taste actually depend on retronasal stimulation of the olfactory receptors during deglutition. As noted earlier, taste buds only mediate basic tastes such as sweet, sour, bitter, salty, and umami. Significant impairment of whole-mouth gustatory function is rare outside of generalized metabolic disturbances or systemic use of some medications, because taste bud regeneration occurs and peripheral damage alone would require the involvement of multiple CN pathways. Taste function can be influenced by age, diet, smoking behavior, use of medications, and other subject-related factors including (1) the release of foul-tasting materials from the oral cavity from oral medical conditions (e.g., gingivitis, purulent sialadenitis) or appliances; (2) transport problems of tastants to the taste buds (e.g., drying, infections, or inflammatory conditions of the orolingual mucosa), (3) damage to the taste buds themselves (e.g., local trauma, invasive carcinomas), (4) damage to the neural pathways innervating the taste buds (e.g., middle ear infections), (5) damage to central structures (e.g., multiple sclerosis, tumor, epilepsy, stroke), and (6) systemic disturbances of metabolism (e.g., diabetes, thyroid disease, medications).

Unlike CN VII, CN IX is relatively protected along its path, although iatrogenic interventions such as tonsillectomy, bronchoscopy, laryngoscopy, endotracheal intubation, and radiation therapy can result in selective injury. CN VII damage commonly results from mastoidectomy, tympanoplasty, and stapedectomy, in some cases inducing persistent metallic sensations. Bell's palsy **(Chap. 441)** is one of the most common causes of CN VII injury that results in taste disturbance. On rare occasions, migraine **(Chap. 430)** is associated with a gustatory prodrome or aura, and in some cases, tastants can trigger a migraine attack. Interestingly, dysgeusia occurs in some cases of *burning mouth syndrome* (also termed *glossodynia* or *glossalgia*), as does dry mouth and thirst. Burning mouth syndrome is likely associated with dysfunction of the trigeminal nerve (CN V). Some of the etiologies suggested for this poorly understood syndrome are amenable to treatment, including (1) nutritional deficiencies (e.g., iron, folic acid, B vitamins, zinc), (2) diabetes mellitus (possibly predisposing to oral candidiasis), (3) denture allergy, (4) mechanical irritation from dentures or oral devices, (5) repetitive movements of the mouth (e.g., tongue thrusting, teeth grinding, jaw clenching), (6) tongue ischemia as a result of temporal arteritis, (7) periodontal disease, (8) reflux esophagitis, and (9) geographic tongue.

Although both taste and smell can be adversely influenced by drugs, taste alterations are more common. Indeed, >250 medications have been reported to alter the ability to taste. Major offenders include antineoplastic agents, antirheumatic drugs, antibiotics, and blood pressure medications. Terbinafine, a commonly used antifungal, has been linked to taste disturbance lasting up to 3 years. In a recent controlled trial, nearly two-thirds of individuals taking eszopiclone (Lunesta) for insomnia experienced a bitter dysgeusia that was stronger in women, systematically related to the time since drug administration, and positively correlated with both blood and saliva levels of the drug. Intranasal use of nasal gels and sprays containing zinc, which are common over-the-counter prophylactics for upper respiratory viral infections, has been implicated in loss of smell function. Whether their efficacy in preventing such infections, which are the most common cause of anosmia and hyposmia, outweighs their potential detriment to smell function requires study. Dysgeusia occurs commonly in the context of drugs used to treat or minimize symptoms of cancer, with a weighted prevalence from 56% to 76% depending on the type of cancer treatment. Attempts to prevent taste problems from such drugs using prophylactic zinc sulfate or amifostine have proven to be minimally beneficial. Although antiepileptic medications are occasionally used to treat smell or taste disturbances, the use of topiramate has been reported to result in a reversible loss of an ability to detect and recognize tastes and odors during treatment.

As with olfaction, a number of systemic disorders can affect taste. These include, but are not limited to, chronic renal failure, end-stage liver disease, vitamin and mineral deficiencies, diabetes mellitus, and hypothyroidism. In diabetes, there appears to be a progressive loss of taste beginning with glucose and then extending to other sweeteners, salty stimuli, and then all stimuli. Psychiatric conditions can be associated with chemosensory alterations (e.g., depression, schizophrenia, bulimia). A recent review of tactile, gustatory, and olfactory hallucinations demonstrated that no one type of hallucinatory experience is pathognomonic to any given diagnosis.

Pregnancy is a unique condition with regard to taste function. There appears to be an increase in dislike and intensity of bitter tastes during the first trimester that may help to ensure that pregnant women avoid poisons during a critical phase of fetal development. Similarly, a relative increase in the preference for salt and bitter in the second and third trimesters may support the ingestion of much needed electrolytes to expand fluid volume and support a varied diet.

CLINICAL EVALUATION

In most cases, a careful clinical history will establish the probable etiology of a chemosensory problem, including questions about its nature, onset, duration, and pattern of fluctuations. *Sudden loss* suggests the possibility of head trauma, ischemia, infection, or a psychiatric condition. *Gradual loss* can reflect the development of a progressive obstructive lesion, although gradual loss can also follow head trauma. *Intermittent loss* suggests the likelihood of an inflammatory process. The patient should be asked about potential precipitating events, such as cold or flu infections, prior to symptom onset, because these often go underappreciated. Information regarding head trauma, smoking habits, drug and alcohol abuse (e.g., intranasal cocaine, chronic alcoholism), exposures to pesticides and other toxic agents, and medical

interventions is also informative. A determination of all the medications that the patient was taking before and at the time of symptom onset is important, because many can cause chemosensory disturbances. Comorbid medical conditions associated with smell impairment, such as renal failure, liver disease, hypothyroidism, diabetes, or dementia, should be assessed. Delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann's syndrome. Recollection of epistaxis, discharge (clear, purulent, or bloody), nasal obstruction, allergies, and somatic symptoms, including headache or irritation, may have localizing value. Questions related to memory, parkinsonian symptoms, and seizure activity (e.g., automatisms, blackouts, auras, déjà vu) should be posed. Pending litigation and the possibility of malingering should be considered. Modern forced-choice olfactory tests can detect malingering from improbable responses.

Neurologic and otorhinolaryngologic (ORL) examinations, along with appropriate brain and nasosinus imaging, aid in the evaluation of patients with olfactory or gustatory complaints. The neural evaluation should focus on CN function, with particular attention to possible skull base and intracranial lesions. Visual acuity, field, and optic disc examinations aid in detection of intracranial mass lesions that produce raised intracranial pressure (papilledema) and optic atrophy. Foster Kennedy syndrome refers to raised intracranial pressure plus a compressive optic neuropathy; typical causes are olfactory groove meningiomas or other frontal lobe tumors. The ORL examination should thoroughly assess the intranasal architecture and mucosal surfaces. Polyps, masses, and adhesions of the turbinates to the septum may compromise the flow of air to the olfactory receptors, because less than a fifth of the inspired air traverses the olfactory cleft in the unobstructed state. Blood tests may be helpful to identify such conditions as diabetes, infection, heavy metal exposure, nutritional deficiency (e.g., vitamin B_6 or B_{12}), allergy, and thyroid, liver, and kidney disease.

As with other sensory disorders, quantitative sensory testing is advised. Self-reports of patients can be misleading, and a number of patients who complain of chemosensory dysfunction have normal function for their age and gender. Quantitative smell and taste testing provides objective information for worker's compensation and other legal claims, as well as a way to accurately assess the effects of treatment interventions. A number of standardized olfactory and taste tests are commercially available. The most widely used olfactory test, the 40-item University of Pennsylvania Smell Identification Test (UPSIT), uses norms based on nearly 4000 normal subjects. A determination is made of both absolute dysfunction (i.e., mild loss, moderate loss, severe loss, total loss, probable malingering) and relative dysfunction (percentile rank for age and gender). Although electrophysiologic testing is available at some smell and taste centers (e.g., odor event-related potentials), they require complex stimulus presentation and recording equipment and rarely provide additional diagnostic information. With the exception of electrogustometers, commercially available taste tests have only recently become available. Most use filter paper strips or similar materials impregnated with tastants, so no stimulus preparation is required.

TREATMENT AND MANAGEMENT

Given the various mechanisms by which olfactory and gustatory disturbance can occur, management of patients tends to be condition-specific. For example, patients with hypothyroidism, diabetes, or infections often benefit from specific treatments to correct the underlying disease process that is adversely influencing chemoreception. For most patients who present primarily with obstructive/transport loss affecting the nasal and paranasal regions (e.g., allergic rhinitis, polyposis, intranasal neoplasms, nasal deviations), medical and/or surgical intervention is often beneficial. Antifungal and antibiotic treatments may reverse taste problems secondary to candidiasis or other oral infections. Chlorhexidine mouthwash mitigates some salty or bitter dysgeusias, conceivably as a result of its strong positive charge. Excessive dryness of the oral mucosa is a problem with many medications and conditions, and artificial saliva (e.g., Xerolube) or oral pilocarpine treatments may prove beneficial. Other methods to improve salivary flow include the use of mints, lozenges, or sugarless gum. Flavor enhancers may make food more palatable (e.g., monosodium glutamate), but caution is advised to avoid overusing ingredients containing sodium or sugar, particularly in circumstances when a patient also has underlying hypertension or diabetes. Medications that induce distortions of taste can often be discontinued and replaced with other types of medications or modes of therapy. As mentioned earlier, pharmacologic agents result in taste disturbances much more frequently than smell disturbances. It is important to note, however, that many drug-related effects are long lasting and not reversed by short-term drug discontinuance.

A study of endoscopic sinus surgery in patients with chronic rhinosinusitis and hyposmia revealed that patients with severe olfactory dysfunction prior to the surgery had a more dramatic and sustained improvement over time compared to patients with more mild olfactory dysfunction prior to intervention. In the case of intranasal and sinus-related inflammatory conditions, such as seen with allergy, viruses, and traumas, the use of intranasal or systemic glucocorticoids may also be helpful. One common approach is to use a tapering course of oral prednisone. Topical intranasal administration of glucocorticoids was found to be less effective in general than systemic administration; however, the effects of different nasal administration techniques were not analyzed. For example, intranasal glucocorticoids are more effective if administered in the Moffett's position (head in the inverted position such as over the edge of the bed with the bridge of the nose perpendicular to the floor). After head trauma, an initial trial of glucocorticoids may help to reduce local edema and the potential deleterious deposition of scar tissue around olfactory fila at the level of the cribriform plate.

Treatments are limited for patients with chemosensory loss or primary injury to neural pathways. Nonetheless, spontaneous recovery can occur. In a follow-up study of 542 patients presenting to our center with smell loss from a variety of causes, modest improvement occurred over an average time period of 4 years in about half of the participants. However, only 11% of the anosmic and 23% of the hyposmic patients regained normal age-related function. Interestingly, the amount of dysfunction at the time of presentation, not etiology, was the best predictor of prognosis. Other predictors were age and the duration of dysfunction prior to initial testing.

Several studies have reported that patients with hyposmia may benefit from repeated smelling of odors over the course of weeks or months, although it remains to be determined how much improvement, if any, occurs over that known to occur spontaneously. The usual paradigm is to smell odors such as eucalyptol, citronella, eugenol, and phenyl ethyl alcohol before going to bed and immediately upon awakening each day. The rationale for such an approach comes from animal studies demonstrating that prolonged exposure to odorants can induce increased neural activity within the olfactory bulb. There is also limited evidence that α-lipoic acid (400 mg/d), an essential cofactor for many enzyme complexes with possible antioxidant effects, may be beneficial in mitigating smell loss following viral infection of the upper respiratory tract. However, double-blind studies are needed to confirm this observation. α-Lipoic acid has also been suggested to be useful in some cases of hypogeusia and burning mouth syndrome.

The use of zinc and vitamin A in treating olfactory disturbances is controversial, and there does not appear to be much benefit beyond replenishing established deficiencies. However, zinc has been shown to improve taste function secondary to hepatic deficiencies, and retinoids (bioactive vitamin A derivatives) are known to play an essential role in the survival of olfactory neurons. One protocol in which zinc was infused with chemotherapy treatments suggested a possible protective effect against developing taste impairment. Diseases of the alimentary tract can not only influence chemoreceptive function but also occasionally influence vitamin B_{12} absorption. This can result in a relative deficiency of vitamin B_{12}, theoretically contributing to olfactory nerve disturbance. Vitamin B_2 (riboflavin) and magnesium supplements are reported in the alternative literature to aid in the management of migraine that, in turn, may be associated with smell dysfunction. Because vitamin D deficiency is a cofactor of chemotherapy-induced mucocutaneous toxicity and dysgeusia, adding vitamin D_3, 1000–2000

units per day, may benefit some patients with smell and taste complaints during or following chemotherapy.

A number of medications have reportedly been used with success in ameliorating olfactory symptoms, although strong scientific evidence for efficacy is generally lacking. A report that theophylline improved smell function was uncontrolled and failed to account for the fact that some meaningful improvement occurs without treatment; indeed, the percentage of responders was about the same (~50%) as that noted by others to show spontaneous improvement over a similar time period. Antiepileptics and some antidepressants (e.g., amitriptyline) have been used to treat dysosmias and smell distortions, particularly following head trauma. Ironically, amitriptyline is also frequently on the list of medications that can ultimately distort smell and taste function, possibly from its anticholinergic effects. One study suggested that the centrally acting acetylcholinesterase inhibitor donepezil in AD resulted in improvements on smell identification measures that correlated with overall clinician-based impressions of change in dementia severity scores.

Alternative therapies, such as acupuncture, meditation, cognitive-behavioral therapy, and yoga, can help patients manage uncomfortable experiences associated with chemosensory disturbance and oral pain syndromes and to cope with the psychosocial stressors surrounding the impairment. Additionally, modification of diet and eating habits is also important. By accentuating the other sensory experiences of a meal, such as food texture, aroma, temperature, and color, one can optimize the overall eating experience for a patient. In some cases, a flavor enhancer like monosodium glutamate (MSG) can be added to foods to increase palatability and encourage intake.

Proper oral and nasal hygiene and routine dental care are extremely important ways for patients to protect themselves from disorders of the mouth and nose that can ultimately result in chemosensory disturbance. Patients should be warned not to overcompensate for their taste loss by adding excessive amounts of sugar or salt. Smoking cessation and the discontinuance of oral tobacco use are essential in the management of any patient with smell and/or taste disturbance and should be repeatedly emphasized.

A major and often overlooked element of therapy comes from chemosensory testing itself. Confirmation or lack of conformation of loss is beneficial to patients who come to believe, in light of unsupportive family members and medical providers, that they may be "crazy." In cases where the loss is minor, patients can be informed of the likelihood of a more positive prognosis. Importantly, quantitative testing places the patient's problem into overall perspective. Thus, it is often therapeutic for an older person to know that, while his or her smell function is not what it used to be, it still falls above the average of his or her peer group. Without testing, many such patients are simply told that they are getting old and nothing can be done for them, leading in some cases to depression and decreased self-esteem.

34 Disorders of Hearing

Anil K. Lalwani

Hearing loss can present at any age and is one of the most common sensory disorders in humans. Nearly 10% of the adult population has some hearing loss, and one-third of individuals age >65 years have a hearing loss of sufficient magnitude to require a hearing aid.

PHYSIOLOGY OF HEARING

The function of the external and middle ear is to amplify sound to facilitate conversion of the mechanical energy of the sound wave into an electrical signal by the inner-ear hair cells, a process called mechanotransduction **(Fig. 34-1)**. Sound waves enter the external auditory canal and set the tympanic membrane (eardrum) in motion, which in turn moves the malleus, incus, and stapes of the middle ear. Movement of the footplate of the stapes causes pressure changes in the fluid-filled inner ear, eliciting a traveling wave in the basilar membrane of the cochlea. The tympanic membrane and the ossicular chain in the middle ear serve as an impedance-matching mechanism, improving the efficiency of energy transfer from air to the fluid-filled inner ear. In its absence, nearly 99.9% of the acoustical energy would be reflected and thus not heard. Instead, the eardrum and the ossicles boost the sound energy nearly 200-fold by the time it reaches the inner ear.

Within the cochlea of the inner ear, there are two types of hair cells that aid in hearing: inner and outer. The inner and outer hair cells of the organ of Corti have different innervation patterns, but both are mechanoreceptors; they detect the mechanical energy of the acoustic signal and aid its conversion to an electrical signal that travels by the auditory nerve. The afferent innervation relates principally to the inner hair cells while the efferent innervation relates principally to the outer hair cells. The outer hair cells outnumber the inner hair cells by nearly 6:1 (20,000 vs 3500). The motility of the outer hair cells alters the micromechanics of the inner hair cells, creating a cochlear amplifier, which explains the exquisite sensitivity and frequency selectivity of the cochlea.

Stereocilia of the hair cells of the organ of Corti, which rests on the basilar membrane, are in contact with the tectorial membrane and are deformed by the traveling wave. The deformation stretches tiny filamentous connections (tip links) between stereocilia, leading to opening of ion channels, influx of potassium, and hair cell depolarization and subsequent neurotransmission. A point of maximal displacement of the basilar membrane is determined by the frequency of the stimulating tone. High-frequency tones cause maximal displacement of the basilar membrane near the base of the cochlea, whereas for low-frequency sounds, the point of maximal displacement is toward the apex of the cochlea.

Beginning in the cochlea, the frequency specificity is maintained at each point of the central auditory pathway: dorsal and ventral cochlear nuclei, trapezoid body, superior olivary complex, lateral lemniscus, inferior colliculus, medial geniculate body, and auditory cortex. At low frequencies, individual auditory nerve fibers can respond more or less synchronously with the stimulating tone. At higher frequencies, phase-locking occurs so that neurons alternate in response to particular phases of the cycle of the sound wave. Intensity is encoded by the

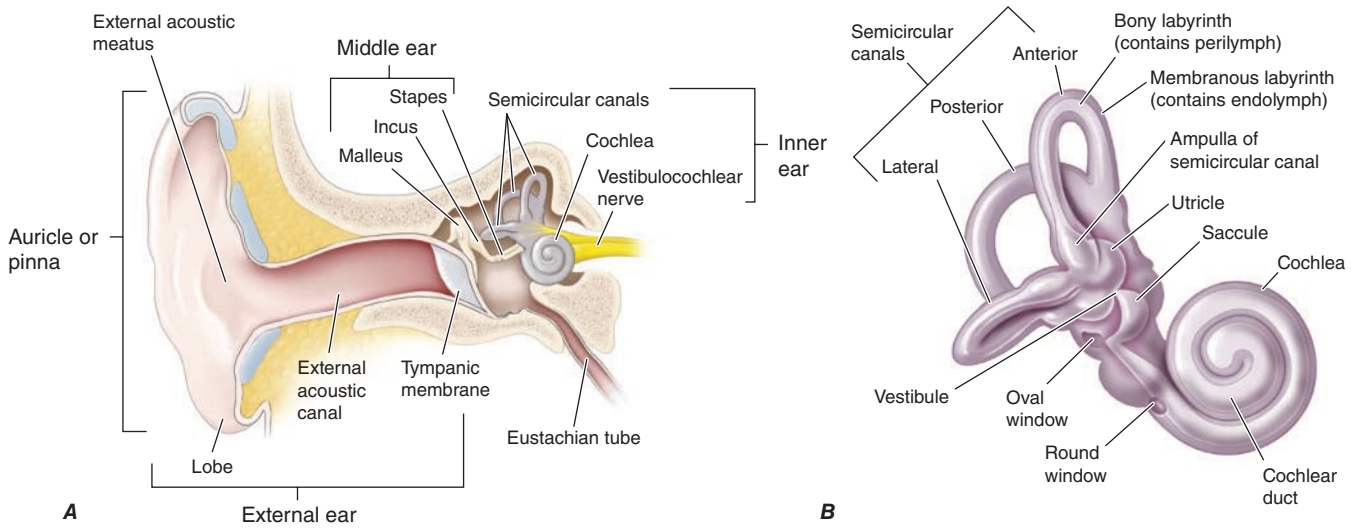

FIGURE 34-1 Ear anatomy. ***A.*** Drawing of modified coronal section through external ear and temporal bone, with structures of the middle and inner ear demonstrated. ***B.*** High-resolution view of inner ear.

amount of neural activity in individual neurons, the number of neurons that are active, and the specific neurons that are activated.

There is evidence that the right and left ears as well as the central nervous system may process speech asymmetrically. Generally, a sound is processed symmetrically from the peripheral to the central auditory system. However, a "right ear advantage" exists for dichotic listening tasks, in which subjects are asked to report on competing sounds presented to each ear. In most individuals, a perceptual right ear advantage for consonant-vowel syllables, stop consonants, and words also exists. Similarly, whereas central auditory processing for sounds is symmetric with minimal lateral specialization for the most part, speech processing is lateralized. There is specialization of the left auditory cortex for speech recognition and production, and of the right hemisphere for emotional and tonal aspects of speech. Left hemisphere dominance for speech is found in 95–98% of right-handed persons and 70–80% of left-handed persons.

DISORDERS OF THE SENSE OF HEARING

Hearing loss can result from disorders of the auricle, external auditory canal, middle ear, inner ear, or central auditory pathways **(Fig. 34-2)**. In general, lesions in the auricle, external auditory canal, or middle ear that impede the transmission of sound from the external environment to the inner ear cause conductive hearing loss, whereas lesions that impair mechanotransduction in the inner ear or transmission of the electrical signal along the eighth nerve to the brain cause sensorineural hearing loss.

Conductive Hearing Loss The external ear, the external auditory canal, and the middle-ear apparatus are designed to collect and amplify sound and efficiently transfer the mechanical energy of the sound wave to the fluid-filled cochlea. Factors that obstruct the transmission of sound or dampen the acoustic energy result in conductive hearing loss. Conductive hearing loss can occur from obstruction of the external auditory canal by cerumen, debris, and foreign bodies; swelling of the lining of the canal; atresia or neoplasms of the canal; perforations of the tympanic membrane; disruption of the ossicular chain, as occurs with necrosis of the long process of the incus in trauma or infection; otosclerosis; or fluid, scarring, or neoplasms in the middle ear. Rarely, inner-ear malformations or pathologies that create a "third window" in the inner ear such as superior semicircular canal dehiscence, lateral semicircular canal dysplasia, incomplete partition of the inner ear, and large vestibular aqueduct, are also associated with conductive hearing loss. This pathologic third window is associated with loss of mechanical energy associated with the sound wave leading to conductive hearing loss (see below).

Eustachian tube dysfunction is extremely common in adults and may predispose to acute otitis media (AOM) or serous otitis media (SOM). Recently, Eustachian tube balloon dilation has been shown to relieve acquired inflammatory obstruction of the Eustachian tube orifice and improve symptoms due to Eustachian tube dysfunction. Trauma, AOM, and chronic otitis media are the usual factors responsible for tympanic membrane perforation. While small perforations often heal spontaneously, larger defects usually require surgical intervention. Tympanoplasty is highly effective (>90%) in the repair of tympanic membrane perforations. Otoscopy is usually sufficient to diagnose AOM, SOM, chronic otitis media, cerumen impaction, tympanic membrane perforation, and Eustachian tube dysfunction; tympanometry and Eustachian tube function testing can be useful to confirm the clinical suspicion of these conditions.

Cholesteatoma, a benign tumor composed of stratified squamous epithelium in the middle ear or mastoid, occurs frequently in adults, often in the setting of severe Eustachian tube dysfunction. This is a slowly growing lesion that destroys bone and normal ear tissue. Theories of pathogenesis include traumatic immigration and invasion of squamous epithelium through a retraction pocket of the tympanic membrane, implantation of squamous epithelia in the middle ear through a perforation or surgery, and metaplasia following chronic infection and irritation. A chronically draining ear that fails to respond to appropriate antibiotic therapy should raise suspicion of a cholesteatoma. On examination, there is often a perforation of the tympanic membrane filled with cheesy white squamous debris. The presence of an aural polyp obscuring the tympanic membrane is highly suggestive of an underlying cholesteatoma. Conductive hearing loss secondary to ossicular erosion is common. Bony destruction visualized on CT of the temporal bone is also highly suggestive of cholesteatoma. Surgery is required to remove this destructive process and reconstruct the ossicles.

Conductive hearing loss with a normal ear canal and intact tympanic membrane suggests either ossicular pathology or the presence of a "third window" in the inner ear (see below). Fixation of the stapes from *otosclerosis* is a common cause of low-frequency conductive hearing loss. It occurs equally in men and women and is inherited as an autosomal dominant trait with incomplete penetrance; in some cases, it may be a manifestation of osteogenesis imperfecta. Hearing impairment usually presents between the late teens and the forties. In women, the otosclerotic process is accelerated during pregnancy, and the hearing loss is often first noticeable at this time. A hearing aid or a simple outpatient surgical procedure (stapedectomy) can provide excellent auditory rehabilitation. Extension of otosclerosis beyond the stapes footplate to involve the cochlea (cochlear otosclerosis) can lead to mixed or sensorineural hearing loss. Fluoride therapy to prevent hearing loss from cochlear otosclerosis is of uncertain value.

Disorders that lead to the formation of a pathologic "third window" in the inner ear can be associated with conductive hearing loss. There

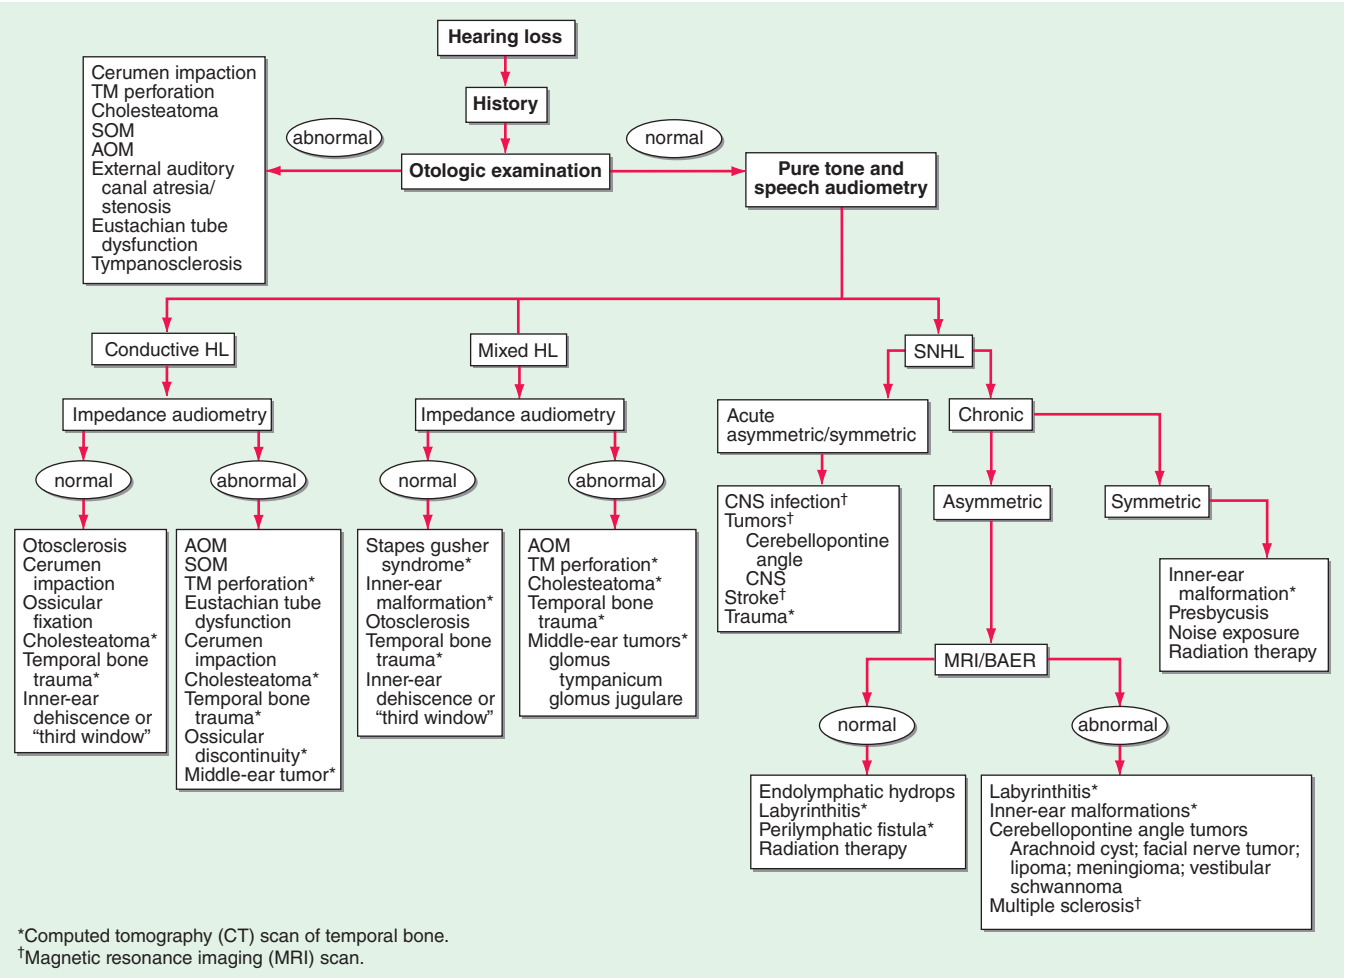

FIGURE 34-2 An algorithm for the approach to hearing loss. AOM, acute otitis media; BAER, brainstem auditory-evoked response; CNS, central nervous system; HL, hearing loss; SNHL, sensorineural hearing loss; SOM, serous otitis media; TM, tympanic membrane.

are normally two major openings, or windows, that connect the inner ear with the middle ear and serve as conduits for transmission of sound; these are, respectively, the oval and round windows. A third window is formed where the normally hard otic bone surrounding the inner ear is eroded; dissipation of the acoustic energy at the third window is responsible for the "inner-ear conductive hearing loss." The superior semicircular canal dehiscence syndrome resulting from erosion of the otic bone over the superior circular canal can present with conductive hearing loss that mimics otosclerosis. A common symptom is vertigo evoked by loud sounds (Tullio phenomenon), by Valsalva maneuvers that change middle-ear pressure, or by applying positive pressure on the tragus (the cartilage anterior to the external opening of the ear canal). Patients with this syndrome also complain of fullness of the ear, pulsatile tinnitus, and being able to hear the movement of their eyes and neck. A large jugular bulb or jugular bulb diverticulum can create a "third window" by eroding into the vestibular aqueduct or posterior semicircular canal; the symptoms are similar to those of the superior semicircular canal dehiscence syndrome. Other inner-ear malformations such as lateral semicircular canal dysplasia, large vestibular aqueduct, or incomplete partition seen in stapes gusher syndrome can also be associated with inner-ear conductive hearing loss as a result of the third window. Low activation threshold on the vestibular-evoked myogenic potential test (VEMP test, see below) and inner-ear erosion on CT are diagnostic. Recalcitrant vertigo and dizziness may respond to surgical repair of the dehiscence.

Sensorineural Hearing Loss Sensorineural hearing loss results from either damage to the mechanotransduction apparatus of the cochlea or disruption of the electrical conduction pathway from the inner ear to the brain. Thus, injury to hair cells, supporting cells, auditory neurons, or the central auditory pathway can cause sensorineural hearing loss. Damage to the hair cells of the organ of Corti may be caused by intense noise, viral infections, ototoxic drugs (e.g., salicylates, quinine and its synthetic analogues, aminoglycoside antibiotics, loop diuretics such as furosemide and ethacrynic acid, and cancer chemotherapeutic agents such as cisplatin), fractures of the temporal bone, meningitis, cochlear otosclerosis (see above), Ménière's disease, and aging. Congenital malformations of the inner ear may be the cause of hearing loss in some adults. Genetic predisposition alone or in concert with environmental exposures may also be responsible (see below).

Noise-Induced Hearing Loss Exposure to loud noise, either a short burst or over a more prolonged period of time, can lead to noise-induced hearing loss. Acute exposure to noise can lead to either temporary or permanent threshold shifts, depending on the intensity and duration of sound, due to hair cell injury and/or death. Typically, with permanent hearing loss there is a "noise notch" with elevated hearing thresholds at 3000–4000 Hz. More recently, loud noise exposure has also been associated with "hidden hearing loss"—hidden, because routine audiometry shows the pure tone hearing to be normal. Patients usually complain of not being able to hear clearly and are more bothered by the presence of background noise. In contrast to hair cell loss, hidden hearing loss is thought to be due to loss of auditory synapses on hair cells following noise exposure. In an increasingly noisy world, avoiding acoustic trauma with earplugs or earmuffs is highly recommended to prevent noise-induced or hidden hearing loss.

Presbycusis (age-associated hearing loss) is the most common cause of sensorineural hearing loss in adults. It is estimated to affect over half of adults aged >75 years in the United States, a population that is expected to double in size over the next 40 years. In the early stages, it is

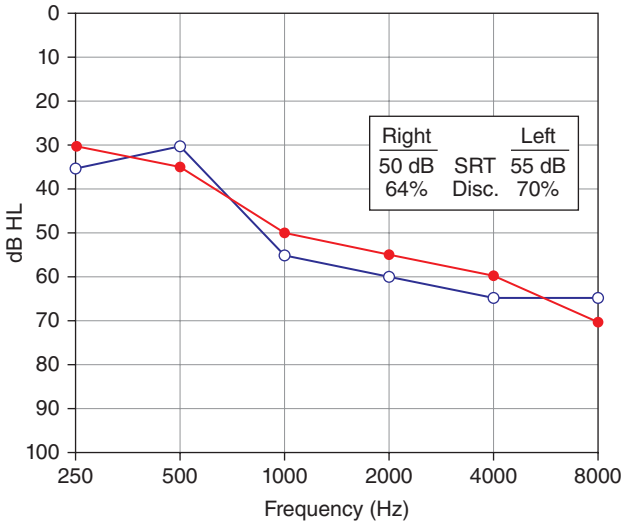

FIGURE 34-3 Presbycusis or age-related hearing loss. The audiogram shows a moderate to severe downsloping sensorineural hearing loss typical of presbycusis. The loss of high-frequency hearing is associated with a decreased speech discrimination score; consequently, patients complain of lack of clarity of hearing, especially in a noisy background. HL, hearing threshold level; SRT, speech reception threshold.

characterized by symmetric, gentle to sharply sloping, high-frequency hearing loss **(Fig. 34-3)**. With progression, the hearing loss involves all frequencies. More importantly, the hearing impairment is associated with significant loss in clarity. There is a loss of discrimination for phonemes, recruitment (abnormal growth of loudness), and particular difficulty in understanding speech in noisy environments such as at restaurants and social events. Poor hearing is also associated with an increased incidence of cognitive impairment, rate of cognitive decline, and falls. In the elderly, left untreated, hearing loss leads to diminished quality of life, and has been shown to increase overall morbidity and mortality through falls and accidents. Hearing aids are helpful in enhancing the signal-to-noise ratio by amplifying sounds that are close to the listener. Hearing aid use has been shown to reduce cognitive decline and risk of falls. Although hearing aids are able to amplify sounds, they cannot restore the clarity of hearing. Thus, amplification with hearing aids may provide only limited rehabilitation once the word recognition score deteriorates below 50%. Cochlear implants are the treatment of choice when hearing aids prove inadequate, even when hearing loss is incomplete (see below).

Ménière's disease is characterized by episodic vertigo, fluctuating sensorineural hearing loss, tinnitus, and aural fullness. An absence of vertigo is inconsistent with the diagnosis of Ménière's disease, and the presence of fluctuating sensorineural hearing loss, tinnitus, and fullness without vertigo is more suggestive of cochlear hydrops. Tinnitus and/or deafness may be absent during the initial attacks of vertigo, but invariably appear as the disease progresses and increases in severity during acute attacks. The annual incidence of Ménière's disease is 0.5–7.5 per 1000; onset is most frequently in the fifth decade of life but may also occur in young adults or the elderly. Histologically, there is distention of the endolymphatic system (endolymphatic hydrops) leading to degeneration of vestibular and cochlear hair cells. This may result from endolymphatic sac dysfunction secondary to infection, trauma, autoimmune disease, inflammatory causes, or tumor; an idiopathic etiology constitutes the largest category and is most accurately referred to as Ménière's disease. Endolymphatic sac tumors, often associated with von Hippel Lindau disease, may clinically mimic Ménière's disease. Although any pattern of hearing loss can be observed, typically, low-frequency, unilateral sensorineural hearing impairment is present. An abnormal VEMP test (see below) may be helpful in detecting Ménière's disease in a clinically unaffected contralateral ear. MRI should be obtained to exclude retrocochlear pathology such as a cerebellopontine angle tumor, endolymphatic sac tumor, or demyelinating disorder. Therapy is directed toward the control of vertigo. A 2-g/d low-salt diet is the mainstay of treatment for control of rotatory vertigo. Diuretics, a short course of oral glucocorticoids, intratympanic glucocorticoids, or intratympanic gentamicin may also be useful adjuncts in recalcitrant cases. Surgical therapy of vertigo is reserved for unresponsive cases and includes endolymphatic sac decompression, labyrinthectomy, and vestibular nerve section. Both labyrinthectomy and vestibular nerve section abolish rotatory vertigo in >90% of cases. Unfortunately, there is no effective therapy for hearing loss, tinnitus, or aural fullness from Ménière's disease.

Sensorineural hearing loss may also result from any neoplastic, vascular, demyelinating, infectious, degenerative disease, or trauma affecting the central auditory pathways. Characteristically, in hearing loss due to central nervous system pathology, a reduction in clarity of hearing and speech comprehension is much greater than the loss of the ability to hear pure tone. Auditory testing is consistent with an auditory neuropathy; normal otoacoustic emissions (OAEs) and an abnormal auditory brainstem response (ABR) are typical (see below). Hearing loss can accompany hereditary sensorimotor neuropathies and inherited disorders of myelin. Tumors of the cerebellopontine angle such as vestibular schwannoma and meningioma **(Chap. 90)** usually present with asymmetric sensorineural hearing loss with greater deterioration of speech understanding than pure tone hearing. Multiple sclerosis **(Chap. 444)** may present with acute unilateral or bilateral hearing loss; typically, pure tone testing remains relatively stable while speech understanding fluctuates. Isolated labyrinthine infarction can present with acute hearing loss and vertigo due to a cerebrovascular accident involving the posterior circulation, usually the anterior inferior cerebellar artery; it may also be the heralding sign of impending catastrophic basilar artery infarction **(Chap. 426)**. HIV **(Chap. 202)**, which can produce both peripheral and central auditory system pathology, is another consideration in the evaluation of sensorineural hearing impairment.

A finding of conductive and sensorineural hearing loss in combination is termed *mixed hearing loss*. Mixed hearing losses can result from pathology of both the middle and inner ear, as can occur in otosclerosis involving the ossicles and the cochlea, head trauma, chronic otitis media, cholesteatoma, middle-ear tumors, and some inner-ear malformations.

Trauma resulting in temporal bone fractures may be associated with conductive, sensorineural, or mixed hearing loss. If the fracture spares the inner ear, there may simply be conductive hearing loss due to rupture of the tympanic membrane or disruption of the ossicular chain. These abnormalities can be surgically corrected. Profound hearing loss and severe vertigo are associated with temporal bone fractures involving the inner ear. A perilymphatic fistula associated with leakage of inner-ear fluid into the middle ear can occur and may require surgical repair. An associated facial nerve injury is not uncommon. CT is best suited to assess fracture of the traumatized temporal bone, evaluate the ear canal, and determine the integrity of the ossicular chain and involvement of the inner ear. Cerebrospinal fluid leaks that accompany temporal bone fractures are usually self-limited; the value of prophylactic antibiotics is uncertain.

Tinnitus Tinnitus is defined as the perception of a sound when there is no sound in the environment. It can have a buzzing, roaring, or ringing quality and may be pulsatile (synchronous with the heartbeat). Tinnitus is often associated with either a conductive or sensorineural hearing loss. The pathophysiology of tinnitus is not well understood. The cause of the tinnitus can usually be determined by finding the cause of the associated hearing loss. Tinnitus may be the first symptom of a serious condition such as a vestibular schwannoma. Pulsatile tinnitus requires evaluation of the vascular system of the head to exclude vascular tumors such as glomus jugulare tumors, aneurysms, dural arteriovenous fistulas, and stenotic arterial lesions; it may also occur with SOM, superior semicircular dehiscence, and inner-ear dehiscence. It is most commonly associated with some abnormality of the jugular bulb such as a large jugular bulb or jugular bulb diverticulum. In absence of demonstrated pathology on MRA/MRV or CT angiography, pulsatile tinnitus is usually attributed to turbulent venous blood flow through the transverse sinus, sigmoid sinus, and the jugular bulb.

GENETIC CAUSES OF HEARING LOSS

More than half of childhood hearing impairment is thought to be hereditary; hereditary hearing impairment (HHI) can also manifest later in life. HHI may be classified as either nonsyndromic, when hearing loss is the only clinical abnormality, or syndromic, when hearing loss is associated with anomalies in other organ systems. Nearly two-thirds of HHIs are nonsyndromic. Between 70% and 80% of nonsyndromic HHI is inherited in an autosomal recessive manner and designated DFNB; another 15–20% is autosomal dominant (DFNA). Less than 5% is X-linked (DFNX) or maternally inherited via the mitochondria.

More than 150 loci harboring genes for nonsyndromic HHI have been mapped, with recessive loci outnumbering dominant ones; numerous genes have now been identified **(Table 34-1)**. The hearing genes fall into the categories of structural proteins (*MYH9, MYO7A, MYO15, TECTA, DIAPH1*), transcription factors (*POU3F4, POU4F3*), ion channels (*KCNQ4, SLC26A4*), and gap junction proteins (*GJB2, GJB3, GJB6*). Several of these genes, including *GJB2, TECTA*, and *TMC1*, cause both autosomal dominant and recessive forms of nonsyndromic HHI. In general, the hearing loss associated with dominant genes has its onset in adolescence or adulthood, varies in severity, and progresses with age, whereas the hearing loss associated with recessive inheritance is congenital and profound. Connexin 26, a product of the *GJB2* gene, is particularly important because it is responsible for nearly 20% of all cases of childhood deafness; half of genetic deafness in children is *GJB2* related. Two frameshift mutations, 35delG and 167delT, account for >50% of the cases; however, screening for these two mutations alone is insufficient, and sequencing of the entire gene is required to fully capture *GJB2*-related recessive deafness. The 167delT mutation is highly prevalent in Ashkenazi Jews; ~1 in 1765 individuals in this population is homozygous and affected. *GJB2* hearing loss can also vary among the members of the same family, suggesting that other genes or factors influence the auditory phenotype. A single mutation in *GJB2* in combination with a single mutation in *GJB6* (connexin 30) can also lead to hearing loss and is an example of digenic inheritance of hearing loss.

In addition to *GJB2*, several other nonsyndromic genes are associated with hearing loss that progresses with age. The contribution of genetics to presbycusis is also becoming better understood and likely reflects a combination of genetic susceptibility impacted by environmental exposure to sound. Sensitivity to aminoglycoside ototoxicity can be maternally transmitted through a mitochondrial mutation. Susceptibility to noise-induced hearing loss may also be genetically determined.

There are >400 syndromic forms of hearing loss. These include Usher's syndrome (retinitis pigmentosa and hearing loss), Waardenburg's syndrome (pigmentary abnormality and hearing loss), Pendred's syndrome (thyroid organification defect and hearing loss), Alport's syndrome (renal disease and hearing loss), Jervell and Lange-Nielsen syndrome (prolonged QT interval and hearing loss), neurofibromatosis type 2 (bilateral acoustic schwannoma), and mitochondrial disorders (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes [MELAS]; myoclonic epilepsy and ragged red fibers [MERRF]; and progressive external ophthalmoplegia [PEO]) **(Table 34-2)**.

APPROACH TO THE PATIENT

Disorders of the Sense of Hearing

The goal in the evaluation of a patient with auditory complaints is to determine (1) the nature of the hearing impairment (conductive vs sensorineural vs mixed), (2) the severity of the impairment (mild, moderate, severe, or profound), (3) the anatomy of the impairment (external ear, middle ear, inner ear, or central auditory pathway), and (4) the etiology. The presence of signs and symptoms associated with hearing loss should be ascertained **(Table 34-3)**. The history should elicit characteristics of the hearing loss, including the duration of deafness, unilateral versus bilateral involvement, nature of onset (sudden vs insidious), and rate of progression (rapid vs slow). Symptoms of tinnitus, vertigo, imbalance, aural fullness, otorrhea, headache, facial nerve dysfunction, and head and neck paresthesias should be noted. Information regarding head trauma, exposure to ototoxins, occupational or recreational noise exposure, and family history of hearing impairment may also be important. A sudden onset of unilateral hearing loss, with or without tinnitus, may represent a viral infection of the inner ear, vestibular schwannoma, or a stroke. Patients with unilateral hearing loss (sensory or conductive) usually complain of reduced hearing, poor sound localization, and difficulty hearing clearly in the presence of background noise. Gradual progression of a hearing deficit is common with otosclerosis, noise-induced hearing loss, vestibular schwannoma, or Ménière's disease. Small vestibular schwannomas typically present with asymmetric hearing impairment, tinnitus, and imbalance (rarely vertigo); cranial neuropathy, in particular of the trigeminal or facial nerve, may accompany larger tumors. In addition to hearing loss, Ménière's disease may be associated with episodic vertigo, tinnitus, and aural fullness. Sound-induced vertigo, autophony, and being able to hear one's own neck or eye movement are highly suggestive of superior semicircular canal dehiscence. Hearing loss with otorrhea is most likely due to chronic otitis media or cholesteatoma.

Examination should include the auricle, external ear canal, and tympanic membrane. In the elderly, the external ear canal is often dry and fragile; it is preferable to clean cerumen with wall-mounted suction or cerumen loops and to avoid irrigation. Irrigation should also be avoided when a tympanic membrane perforation is present or the integrity of the eardrum cannot be established. In examining the eardrum, the topography of the tympanic membrane is more important than the presence or absence of the light reflex. In addition to the pars tensa (the lower two-thirds of the tympanic membrane), the pars flaccida (upper one-third of the tympanic membrane) above the short process of the malleus should also be examined for retraction pockets that may be evidence of chronic Eustachian tube dysfunction or cholesteatoma. Insufflation of the ear canal is necessary to assess tympanic membrane mobility and compliance. Careful inspection of the nose, nasopharynx, and upper respiratory tract is important. Unilateral serous effusion or unexplained otalgia should prompt a fiberoptic examination of the nasopharynx and larynx to exclude neoplasms. Cranial nerves should be evaluated with special attention to facial and trigeminal nerves, which are commonly affected with tumors involving the cerebellopontine angle.

The Rinne and Weber tuning fork tests, with a 512-Hz tuning fork, are used to screen for hearing loss, differentiate conductive from sensorineural hearing losses, and confirm the findings of audiologic evaluation. The Rinne test compares the ability to hear by air conduction with the ability to hear by bone conduction. The tines of a vibrating tuning fork are held near the opening of the external auditory canal, and then the stem is placed on the mastoid process; for direct contact, it may be placed on teeth or dentures. The patient is asked to indicate whether the tone is louder by air conduction or bone conduction. Normally, and in the presence of sensorineural hearing loss, a tone is heard louder by air conduction than by bone conduction; however, with conductive hearing loss of ≥30 dB (see "Audiologic Assessment," below), the bone-conduction stimulus is perceived as louder than the air-conduction stimulus. For the Weber test, the stem of a vibrating tuning fork is placed on the head in the midline and the patient is asked whether the tone is heard in both ears or better in one ear than in the other. With a unilateral conductive hearing loss, the tone is perceived in the affected ear. With a unilateral sensorineural hearing loss, the tone is perceived in the unaffected ear. A 5-dB difference in hearing between the two ears is required for lateralization.

LABORATORY ASSESSMENT OF HEARING

Audiologic Assessment The minimum audiologic assessment for hearing loss should include the measurement of pure tone air-conduction and bone-conduction thresholds, speech reception threshold, word recognition score, tympanometry, acoustic reflexes, and

DESIGNATION	GENE	FUNCTION
DFNB84	*OTOGL*	Otogelin-like protein
DFNB86	*TBC1D24*	GTPase-activating protein
DFNB88	*ELMOD3*	GTPase-activating protein
DFNB89	*KARS*	Lysyl-tRNA synthetase
DFNB91	*SERPINB6*	Protease inhibitor
DFNB93	*CABP2*	Calcium-binding protein
DFN94	*NARS2*	Mitochondrial asparaginyl-tRNA synthetase
DFNA97	*MET*	Oncogene/hepatocyte growth factor receptor
DFNB98	*TSPEAR*	Epilepsy-associated repeats containing protein
DFNB99	*TMEM132E*	Transmembrane protein
DFNB100	*PPIP5K2*	Diphosphoinositol-pentakisphosphate kinase
DFNB101	*GRXCR2*	Maintaining stereocilia bundles
DFNB102	*EPS8*	Epidermal growth factor receptor
DFNB103	*CLIC5*	Chloride ion transport
DFNB104	*FAM65B/RIPOR2*	Membrane-associated protein in stereocilia
DFNB106	*EPS8L2*	Actin remodeling in response to EGF stimulation
DFNB108	*ROR1*	Receptor tyrosine kinase-like orphan receptor
	WBP2	Transcriptional coactivator for estrogen receptor-alpha and progesterone receptor
	ESRP1	Modulates activation of G proteins
	MPZL2	Mediates epithelial cell-cell interactions in developing tissues
	CEACAM16	Cell adhesion molecule
	GRAP	Cytoplasmic signaling protein
	SPNS2	Sphingosine-1-phosphate (S1P) transporter
	CLDN9	Tight junctions
	CLRN2	Maintenance of transducing stereocilia in auditory hair cells
X-linked		
DFNX1	PRPS1	Catalyzes phosphoribosylation of ribose 5-phosphate to 5-phosphoribosyl-1-pyrophosphate
DFNX2	POU3F4	Transcription factor
DFNX4	SMPX	Small muscle protein
DFNX5	AIFM1	Mitochondrial flavin adenine dinucleotide (FAD)-dependent oxidoreductase
DFNX6	COL4A6	Collagen protein

TABLE 34-2 Syndromic Hereditary Hearing Impairment Genes

SYNDROME	GENE	FUNCTION
Alport's syndrome	*COL4A3-5*	Cytoskeletal protein
BOR syndrome	*EYA1*	Developmental gene
	SIX5	Developmental gene
	SIX1	Developmental gene
Jervell and Lange-Nielsen syndrome	*KCNQ1*	Delayed rectifier K^+ channel
	KCNE1	Delayed rectifier K^+ channel
Norrie's disease	*NDP*	Cell–cell interactions
Pendred's syndrome	*SLC26A4*	Chloride/iodide transporter
	FOXI1	Transcriptional activator of *SLC26A4*
	KCNJ10	Inwardly rectifying K^+ channel
Treacher Collins syndrome	*TCOF1*	Nucleolar-cytoplasmic transport
	POLR1D	Subunit of RNA polymerases I and III
	POLR1C	Subunit of RNA polymerases I and III
Usher's syndrome	*MYO7A*	Cytoskeletal protein
	USH1C	Unknown
	CDH23	Intercellular adherence protein
	PCDH15	Cell adhesion molecule
	SANS	Harmonin-associated protein
	CIB2	Calcium- and integrin-binding protein
	USH2A	Cell adhesion molecule
	VLGR1	G protein–coupled receptor
	WHRN	PDZ domain–containing protein
	CLRN1	Cellular synapse protein
	HARS	Histidyl-tRNA synthetase
	PDZD7	PDZ domain–containing protein
WS type I, III	*PAX3*	Transcription factor
WS type II	*MITF*	Transcription factor
	SNAI2	Transcription factor
WS type IV	*EDNRB*	Endothelin B receptor
	EDN3	Endothelin B receptor ligand
	SOX10	Transcription factor

Abbreviations: BOR, branchio-oto-renal syndrome; WS, Waardenburg's syndrome.

acoustic-reflex decay. This test battery provides a screening evaluation of the entire auditory system and allows one to determine whether further differentiation of a sensory (cochlear) from a neural (retrocochlear) hearing loss is indicated.

Pure tone audiometry assesses hearing acuity for pure tones. The test is administered by an audiologist and is performed in a sound-attenuated chamber. The pure tone stimulus is delivered with an audiometer, an electronic device that allows the presentation of specific frequencies (generally between 250–8000 Hz) at specific intensities. Air- and bone-conduction thresholds are established for each ear. Air-conduction thresholds are determined by presenting the stimulus in air with the use of headphones. Bone-conduction thresholds are determined by placing the stem of a vibrating tuning fork or an oscillator of an audiometer in contact with the head. In the presence of a hearing loss, broad-spectrum noise is presented to the nontest ear for masking purposes so that responses are based on perception from the ear under test.

The responses are measured in decibels (dBs). An *audiogram* is a plot of intensity in dBs of hearing threshold versus frequency. A dB is equal to 20 times the logarithm of the ratio of the sound pressure required to achieve threshold in the patient to the sound pressure required to achieve threshold in a normal-hearing person. Therefore, a change of 6 dB represents doubling of sound pressure, and a change of 20 dB represents a tenfold change in sound pressure. Loudness, which depends on the frequency, intensity, and duration of a sound, doubles with approximately each 10-dB increase in sound pressure level. Pitch, on the other hand, does not directly correlate with frequency. The

TABLE 34-3 Signs and Symptoms Suggestive of Hearing Loss

Saying "huh" a great deal

perception of pitch changes slowly in the low and high frequencies. In the middle tones, which are important for human speech, pitch varies more rapidly with changes in frequency.

Pure tone audiometry establishes the presence and severity of hearing impairment, unilateral versus bilateral involvement, and the type of hearing loss. Conductive hearing losses with a large mass component, as is often seen in middle-ear effusions, produce elevation of thresholds that predominate in the higher frequencies. Conductive hearing losses with a large stiffness component, as in fixation of the footplate of the stapes in early otosclerosis, produce threshold elevations in the lower frequencies. Often, the conductive hearing loss involves all frequencies, suggesting involvement of both stiffness and mass. In general, sensorineural hearing losses such as presbycusis affect higher frequencies more than lower frequencies (Fig. 34-3). An exception is Ménière's disease, which is characteristically associated with low-frequency sensorineural hearing loss (though any frequency can be affected). Noise-induced hearing loss has an unusual pattern of hearing impairment in which the loss at 3000–4000 Hz is greater than at higher frequencies. Vestibular schwannomas characteristically affect the higher frequencies, but any pattern of hearing loss can be observed.

Speech recognition requires greater synchronous neural firing than is necessary for appreciation of pure tones. *Speech audiometry* tests the clarity with which one hears. The *speech reception threshold* (*SRT*) is defined as the intensity at which speech is recognized as a meaningful symbol and is obtained by presenting two-syllable words with an equal accent on each syllable. The intensity at which the patient can repeat 50% of the words correctly is the SRT. Once the SRT is determined, discrimination or word recognition ability is tested by presenting one-syllable words at 25–40 dB above the SRT. The words are phonetically balanced in that the phonemes (speech sounds) occur in the list of words at the same frequency that they occur in ordinary conversational English. An individual with normal hearing or conductive hearing loss can repeat 88–100% of the phonetically balanced words correctly. Patients with a sensorineural hearing loss have variable loss of discrimination. As a general rule, neural lesions produce greater deficits in discrimination than do cochlear lesions. For example, in a patient with mild asymmetric sensorineural hearing loss, a clue to the diagnosis of vestibular schwannoma is the presence of greater than expected deterioration in discrimination ability. Deterioration in discrimination ability at higher intensities above the SRT also suggests a lesion in the eighth nerve or central auditory pathways.

Tympanometry measures the impedance of the middle ear to sound and is useful in diagnosis of middle-ear effusions. A *tympanogram* is the graphic representation of change in impedance or compliance as the pressure in the ear canal is changed. Normally, the middle ear is most compliant at atmospheric pressure, and the compliance decreases as the pressure is increased or decreased (type A); this pattern is seen with normal hearing or in the presence of sensorineural hearing loss. Compliance that does not change with change in pressure suggests middle-ear effusion (type B). With a negative pressure in the middle ear, as with Eustachian tube obstruction, the point of maximal compliance occurs with negative pressure in the ear canal (type C). A tympanogram in which no point of maximal compliance can be obtained is most commonly seen with discontinuity of the ossicular chain (type A_d). A reduction in the maximal compliance peak can be seen in otosclerosis (type A_s).

During tympanometry, an intense tone elicits contraction of the stapedius muscle. The change in compliance of the middle ear with contraction of the stapedius muscle can be detected. The presence or absence of this *acoustic reflex* is important in determining the etiology of hearing loss as well as in the anatomic localization of facial nerve paralysis. The acoustic reflex can help differentiate between conductive hearing loss due to otosclerosis and that caused by an inner-ear "third window": it is absent in otosclerosis and present in inner-ear conductive hearing loss. Normal or elevated acoustic reflex thresholds in an individual with sensorineural hearing impairment suggest a cochlear hearing loss. An absent acoustic reflex in the setting of sensorineural hearing loss is not helpful in localizing the site of lesion. Assessment of *acoustic reflex decay* helps differentiate sensory from neural hearing losses. In neural hearing loss, such as with vestibular schwannoma, the reflex adapts or decays with time.

OAEs generated by outer hair cells only can be measured with microphones inserted into the external auditory canal. The emissions may be spontaneous or evoked with sound stimulation. The presence of OAEs indicates that the outer hair cells of the organ of Corti are intact and can be used to assess auditory thresholds and to distinguish sensory from neural hearing losses.

Evoked Responses *Electrocochleography* measures the earliest evoked potentials generated in the cochlea and the auditory nerve. Receptor potentials recorded include the cochlear microphonic, generated by the outer hair cells of the organ of Corti, and the summating potential, generated by the inner hair cells in response to sound. The whole nerve action potential representing the composite firing of the first-order neurons can also be recorded during electrocochleography. Clinically, the test is useful in the diagnosis of Ménière's disease, in which an elevation of the ratio of summating potential to action potential is seen.

Brainstem auditory-evoked responses (*BAERs*), also known as ABRs, are useful in differentiating the site of sensorineural hearing loss. In response to sound, five distinct electrical potentials arising from different stations along the peripheral and central auditory pathway (eighth nerve, cochlear nucleus, superior olivary complex, lateral lemniscus, and inferior colliculus) can be identified using computer averaging from scalp surface electrodes. BAERs are valuable in situations in which patients cannot or will not give reliable voluntary thresholds. They are also used to assess the integrity of the auditory nerve and brainstem in various clinical situations, including intraoperative monitoring, and in determination of brain death.

The *VEMP test* investigates otolith and vestibular nerve function by presenting a high-level acoustic stimulus and evoking a short-latency electromyographic potential; cVEMP (or cervical VEMP) and oVEMP (or ocular VEMP) have been described. The cVEMP elicits a vestibulocollic reflex whose afferent limb arises from acoustically sensitive cells in the saccule, with signals conducted via the inferior vestibular nerve. cVEMP is a biphasic, short-latency response recorded from the tonically contracted sternocleidomastoid muscle in response to loud auditory clicks or tones. cVEMPs may be diminished or absent in patients with early and late Ménière's disease, vestibular neuritis, benign paroxysmal positional vertigo, and vestibular schwannoma. On the other hand, the threshold for VEMPs may be lower in cases of superior canal dehiscence, other inner-ear dehiscence ("third window"), and perilymphatic fistula. The oVEMP, in contrast, is a response involving the utricle primarily and superior vestibular nerve. The oVEMP excitatory response is recorded from the extraocular muscle. The oVEMP is abnormal in superior vestibular neuritis.

Imaging Studies The choice of radiologic tests is largely determined by whether the goal is to evaluate the bony anatomy of the external, middle, and inner ear or to image the auditory nerve and brain. Axial and coronal CT of the temporal bone with fine 0.3-mm cuts is ideal for determining the caliber of the external auditory canal, integrity of the ossicular chain, and presence of middle-ear or mastoid disease; it can also detect inner-ear malformations. CT is also ideal for the detection of bone erosion with chronic otitis media and cholesteatoma. Pöschl reformatting in the plane of the superior semicircular canal is required for the identification of dehiscence or absence of bone over the superior semicircular canal. MRI is superior to CT for imaging of retrocochlear pathology such as vestibular schwannoma, meningioma, other lesions of the cerebellopontine angle, demyelinating lesions of the brainstem, and brain tumors. Both CT and MRI are equally capable of identifying inner-ear malformations and assessing cochlear patency for preoperative evaluation of patients for cochlear implantation.

TREATMENT

Disorders of the Sense of Hearing

In general, conductive hearing losses are amenable to surgical correction, whereas sensorineural hearing losses are usually managed medically. Atresia of the ear canal can be surgically repaired,

often with significant improvement in hearing. Alternatively, the conductive hearing loss associated with atresia can be addressed with a bone-anchored hearing aid (BAHA). Tympanic membrane perforations due to chronic otitis media or trauma can be repaired with an outpatient tympanoplasty. Likewise, conductive hearing loss associated with otosclerosis can be treated by stapedectomy, which is successful in >95% of cases. Tympanostomy tubes allow the prompt return of normal hearing in individuals with middle-ear effusions. Hearing aids are effective and well tolerated in patients with conductive hearing losses.

Patients with mild, moderate, and severe sensorineural hearing losses are regularly rehabilitated with hearing aids of varying configuration and strength. Hearing aids have been improved to provide greater fidelity and have been miniaturized. The current generation of hearing aids is nearly invisible, thus reducing stigma associated with their use. In general, the more severe the hearing impairment, the larger the hearing aid required for auditory rehabilitation. Digital hearing aids lend themselves to individual programming, and multiple and directional microphones at the ear level may be helpful in noisy surroundings. Because all hearing aids amplify noise as well as speech, the only absolute solution to the problem of noise is to place the microphone closer to the speaker than the noise source. This arrangement is not possible with a self-contained, cosmetically acceptable device. A significant limitation of rehabilitation with a hearing aid is that although it is able to enhance detection of sound with amplification, it cannot restore clarity of hearing that is lost with presbycusis.

The cost of a single hearing aid (~$2300 US) is a significant obstacle for many hearing-impaired individuals and usually bilateral amplification is recommended. To reduce cost and spur innovation, a new category of over-the-counter amplification devices that can be purchased similar to reading eyeglasses by simply walking into a store has recently been approved by the US Food and Drug Administration. By reducing the cost of amplification devices to consumers, promoting innovation, and increasing competition, this new class of devices could fundamentally change the way hearing rehabilitation is delivered.

Patients with unilateral deafness have difficulty with sound localization and reduced clarity of hearing in background noise. They may benefit from a contralateral routing of signal (CROS) hearing aid in which a microphone is placed on the hearing-impaired side, and the sound is transmitted to the receiver placed on the contralateral ear. The same result may be obtained with a BAHA, in which a hearing aid clamps to a screw integrated into the skull on the hearing-impaired side. Like the CROS hearing aid, the BAHA transfers the acoustic signal to the contralateral hearing ear, but it does so by vibrating the skull. Patients with profound deafness on one side and some hearing loss in the better ear are candidates for a BICROS hearing aid; it differs from the CROS hearing aid in that the patient wears a hearing aid, and not simply a receiver, in the better ear. Unfortunately, while CROS and BAHA devices provide benefit, they do not restore hearing in the deaf ear. Only cochlear implants can restore hearing (see below). Increasingly, cochlear implants are being used for the treatment of patients with single-sided deafness; they show great promise in not only restoring hearing and reducing tinnitus, but also improving sound localization and performance in background noise.

In many situations, including lectures and the theater, hearing-impaired persons benefit from assistive devices that are based on the principle of having the speaker closer to the microphone than any source of noise. Assistive devices include infrared and frequency-modulated (FM) transmission as well as an electromagnetic loop around the room for transmission to the individual's hearing aid. Hearing aids with telecoils can also be used with properly equipped telephones in the same way. Bluetooth technology has revolutionized connectivity between hearing aids and other devices such as smart phones.

In the event that the hearing aid provides inadequate rehabilitation, cochlear implants may be appropriate **(Fig. 34-4)**. Criteria for implantation include severe to profound hearing loss with open-set sentence cognition of ≤40% under best-aided conditions.

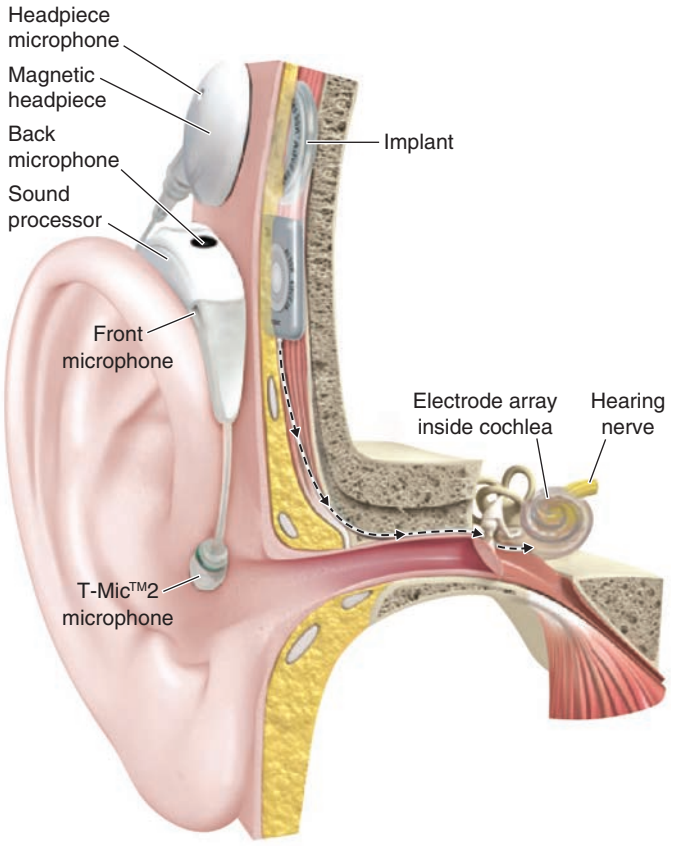

FIGURE 34-4 A cochlear implant is composed of an external microphone and speech processor worn on the ear and a receiver implanted underneath the temporalis muscle. The internal receiver is attached to an electrode that is placed surgically in the cochlea.

Worldwide, >600,000 hearing-impaired individuals have received cochlear implants. Cochlear implants are neural prostheses that convert sound energy to electrical energy and can be used to stimulate the auditory division of the eighth nerve directly. In most cases of profound hearing impairment, the auditory hair cells are lost but the ganglionic cells of the auditory division of the eighth nerve are preserved. Cochlear implants consist of electrodes that are inserted into the cochlea through the round window, speech processors that extract acoustic elements of speech for conversion to electrical currents, and a means of transmitting the electrical energy through the skin. Patients with implants experience sound that helps with speech reading, allows open-set word recognition, and helps in modulating the person's own voice. Usually, within the first 3–6 months after implantation, adult patients can understand speech without visual cues. With the current generation of multichannel cochlear implants, nearly 75% of patients are able to converse on the telephone. Bilateral cochlear implantations are commonly performed, especially in children; these patients perform better in background noise, have better sound localization, and are less fatigued by the "work" compared to monaural hearing.

Hybrid cochlear implants are indicated for the treatment of high-frequency hearing loss in patients who do not have profound hearing loss and yet do not benefit from hearing aids. Patients with presbycusis typically have normal low-frequency hearing while suffering from high-frequency hearing loss associated with loss of clarity that cannot always be adequately rehabilitated with a hearing aid. However, these patients are not candidates for conventional cochlear implants because they have too much residual hearing. The hybrid implant has been specifically designed for this patient population; it has a shorter electrode than a conventional cochlear implant and can be introduced into the cochlea atraumatically, thus preserving low-frequency hearing. Individuals with a hybrid implant use their own natural low-frequency "acoustic" hearing and

rely on the implant for providing "electrical" high-frequency hearing. Patients who have received the hybrid implant perform better on speech discrimination tests in both quiet and noisy backgrounds.

For individuals who were born without cochlea or have had both eighth nerves destroyed by trauma or bilateral vestibular schwannomas (e.g., neurofibromatosis type 2), brainstem auditory implants placed near the cochlear nucleus may provide auditory rehabilitation. Currently, brainstem implants provide sound awareness but unfortunately speech understanding remains elusive.

Tinnitus often accompanies hearing loss. Similar to background noise, tinnitus can degrade speech comprehension in individuals with hearing impairment. Patients with tinnitus should be advised to minimize caffeine ingestion, avoid high dosage of nonsteroidal anti-inflammatory drugs (NSAIDs), and reduce stress. Therapy for tinnitus is usually directed toward minimizing the appreciation of tinnitus. Relief of the tinnitus may be obtained by masking it with background music or white noise. Hearing aids are also helpful in tinnitus suppression, as are tinnitus maskers, devices that present a sound to the affected ear that is more pleasant to listen to than the tinnitus. The use of a tinnitus masker is often followed by several hours of inhibition of the tinnitus. Antidepressants have also been shown to be beneficial in helping patients cope with tinnitus.

Hard-of-hearing individuals often benefit from a reduction in unnecessary noise in the environment (e.g., radio or television) to enhance the signal-to-noise ratio. Speech comprehension is aided by lip reading; therefore, the impaired listener should be seated so that the face of the speaker is well illuminated and easily seen. Although speech should be in a loud, clear voice, one should be aware that in sensorineural hearing losses in general and in hard-of-hearing elderly in particular, recruitment (abnormal perception of loud sounds) may be troublesome. Above all, optimal communication cannot take place without both parties giving it their full and undivided attention.

PREVENTION

Conductive hearing losses may be prevented by prompt antibiotic therapy of adequate duration for AOM and by ventilation of the middle ear with tympanostomy tubes in middle-ear effusions lasting ≥12 weeks. Loss of vestibular function and deafness due to aminoglycoside antibiotics can largely be prevented by careful monitoring of serum peak and trough levels.

Some 10 million Americans have noise-induced hearing loss, and 20 million are exposed to hazardous noise in their employment. Noise-induced hearing loss can be prevented by avoidance of exposure to loud noise or by regular use of earplugs or fluid-filled ear muffs to attenuate intense sound. Table 34-4 lists loudness levels for a variety of environmental sounds. High-risk activities for noise-induced hearing loss include use of electrical equipment for wood- and metalworking, and target practice or hunting with small firearms. All internal-combustion and electric engines, including snow and leaf blowers, snowmobiles, outboard motors, and chainsaws, require protection of the user with hearing protectors. Virtually all noise-induced hearing loss is preventable through education, which should begin before the teenage years. Programs for conservation of hearing in the workplace are required by the Occupational Safety and Health Administration (OSHA) whenever the exposure over an 8-h period averages 85 dB. OSHA mandates that workers in such noisy environments have hearing monitoring and protection programs that include a preemployment screen, an annual audiologic assessment, and the mandatory use of hearing protectors. Exposure to loud sounds above 85 dB in the work environment is restricted by OSHA, with halving of allowed exposure time for each increment of 5 dB above this threshold; for example, exposure to 90 dB is permitted for 8 h; 95 dB for 4 h, and 100 dB for 2 h (Table 34-5).

TABLE 34-4 Decibel (Loudness) Level of Common Environmental Noise

SOURCE	DECIBEL (dB)
Weakest sound heard	0
Whisper	30
Normal conversation	55–65
City traffic inside car	85
OSHA Monitoring Requirement Begins	**90**
Jackhammer	95
Subway train at 200 ft	95
Power mower	107
Power saw	110
Painful Sound	**125**
Jet engine at 100 ft	140
12-gauge shotgun blast	165
Loudest sound that can occur	194

Abbreviation: OSHA, Occupational Safety and Health Administration.

TABLE 34-5 OSHA Daily Permissible Noise Level Exposure

SOUND LEVEL (dB)	DURATION PER DAY (h)
90	8
92	6
95	4
97	3
100	2
102	1.5
105	1
110	0.5
115	≤0.25

Note: Exposure to impulsive or impact noise should not exceed 140-dB peak sound pressure level.

35 Upper Respiratory Symptoms, Including Earache, Sinus Symptoms, and Sore Throat

Rachel L. Amdur, Jeffrey A. Linder

Upper respiratory symptoms are most commonly caused by viral infection but also can be caused by other infectious, inflammatory, allergic, autoimmune, and neoplastic conditions. This chapter will discuss ambulatory antibiotic prescribing and review the most common causes of upper respiratory symptoms, including nonspecific upper respiratory infections.

Ear pain is most commonly caused by otitis externa, acute otitis media (AOM), otitis media with effusion (OME), and acute mastoiditis. Sinus symptoms can be caused by acute sinusitis, invasive fungal sinusitis, nosocomial sinusitis, and chronic sinusitis. Sore throat and neck pain can be caused by streptococcal pharyngitis, nonstreptococcal pharyngitis, acute infectious mononucleosis, other types of bacterial pharyngitis, Lemierre's syndrome, gonococcal pharyngitis, diphtheria, acute HIV infection, head and neck abscesses, epiglottitis, and laryngitis. At the time of presentation, upper respiratory symptoms of most common viral and bacterial etiologies have generally lasted from hours up to a few days.

UPPER RESPIRATORY INFECTIONS

Upper respiratory infections (URIs) are acute respiratory infections that occur above the vocal cords. URIs, including nonspecific upper respiratory tract infection, otitis media, sinusitis, and pharyngitis, are collectively the most common symptomatic reason for seeking care in the United States. In terms of etiology, symptoms, and signs, URIs overlap with lower acute respiratory infections that occur below the vocal cords, such as influenza **(Chap. 200)**, acute bronchitis, and pneumonia **(Chap. 126)**, as well as with noninfectious cough **(Chap. 38)**. The average adult has 2–4 URIs per year; children can have 6–10 URIs annually. URIs can be prevented by hand washing or sanitization, physical distancing, use of facial masks, isolation of persons who are ill, and environmental cleaning **(Chap. 199)**.

SARS-CoV-2, the pathogen that causes COVID-19, can cause virtually any upper respiratory symptom **(Chap. 199)**. COVID-19 symptoms appear 2–14 days after exposure and may include fever, chills, cough, shortness of breath, fatigue, myalgias, headaches, rhinorrhea, sore throat, nausea, vomiting, or diarrhea. New loss of taste or smell appears to be specific for COVID-19. Until there is widespread natural or vaccine-induced immunity, any respiratory symptom occurring in areas where SARS-CoV-2 is circulating should be considered a potential manifestation of COVID-19.

IMPROVING AMBULATORY ANTIBIOTIC PRESCRIBING

The only common acute respiratory infections that should be treated with antibiotics are AOM, sinusitis, streptococcal pharyngitis, and pneumonia. Even for AOM, sinusitis, and pharyngitis, only a minority of cases meet the criteria for antibiotic prescribing. Common respiratory viruses **(Chap. 199)** cause the overwhelming majority of acute respiratory infections, and these infections are generally self-limited; antibiotics neither speed resolution nor prevent complications for the majority of acute respiratory infections. Unfortunately, for this reason, at least half of ambulatory antibiotic prescriptions for acute respiratory infections in the United States are inappropriate. Internationally, population rates of antibiotic prescribing vary nearly threefold, with no differences in infectious complications. Antibiotics cause adverse drug effects, alter the microbiome, cause *Clostridioides difficile* infection **(Chap. 134)**, increase health care costs, and increase the prevalence of antibiotic-resistant bacteria **(Chap. 145)**.

Clinicians prescribe inappropriate antibiotics because of time pressure; fear of missing a rare bacterial diagnosis; concern about preventing a rare bacterial complication; a lack of salience of adverse antibiotic effects; or a mistaken belief that most patients expect, demand, or will not be satisfied without an antibiotic prescription.

AMBULATORY ANTIBIOTIC STEWARDSHIP

Antibiotic stewardship has traditionally been an inpatient concern **(Chap. 144)**, but ambulatory antibiotic use accounts for ~85% of antibiotic use by patients in most developed countries. In 2016, the Centers for Disease Control and Prevention published the "Core Elements of Outpatient Antibiotic Stewardship." The core elements include (1) committing to improving antibiotic prescribing; (2) implementing at least one policy or practice to improve antibiotic prescribing and assessing its effectiveness; (3) monitoring antibiotic prescribing and providing feedback; and (4) providing educational resources to clinicians and patients on antibiotic prescribing. Effective interventions to decrease inappropriate ambulatory antibiotic prescribing include peer comparison, accountable justification, precommitment, clinical decision support, patient education, and multifaceted interventions. Communication training has been particularly effective when it includes making a clear diagnosis, focusing on positive actions patients can take to feel better, reviewing the expected course of illness, and informing patients about concerning symptoms (red flags) for which they should seek or reconnect with care. Telemedicine—synchronous telephone or video or asynchronous electronic messaging—has the potential to improve patient convenience and reduce inappropriate antibiotic prescribing.

Several techniques that seemed promising for the reduction of ambulatory antibiotic prescribing remain unproven, have been ineffective (e.g., procalcitonin testing), or are not durable (e.g., C-reactive protein testing). The practice of delayed antibiotic prescription—i.e., a prescription given to a patient who is asked not to fill it unless symptoms do not improve in a few days—is conceptually flawed and should be avoided. Delayed antibiotic prescriptions are usually given for antibiotic-inappropriate diagnoses (e.g., viral infections); they ignore the natural history of acute respiratory infections, which are self-limited and generally last from 5 to 14 days; they put the burden of clinical decision-making on patients; and they send a confusing, mixed message to patients about the appropriateness of antibiotics for respiratory infections.

NONSPECIFIC UPPER RESPIRATORY INFECTION ("THE COMMON COLD")

DEFINITION AND ETIOLOGY

Nonspecific URI, or the common cold, is a respiratory tract infection in which no single symptom predominates. Nonspecific URI is most commonly caused by respiratory viruses that are acquired through direct contact with infected individuals, contaminated surfaces, and large and small respiratory droplets. The most common viral causes of nonspecific URIs are rhinoviruses (well over 100 serotypes; **Chap. 199**), coronaviruses, parainfluenza virus, respiratory syncytial virus, influenza virus **(Chap. 199)**, adenovirus (57 serotypes; **Chap. 199**), metapneumovirus, and bocavirus **(Chap. 199)**. Making a specific viral diagnosis is not practical, cost-effective, or necessary. Multiplex panels of reverse transcription polymerase chain reaction are available but may be overly sensitive, as prior recent infection can cause false-positive results. Although the diagnosis is usually obvious, clinicians diagnosing a nonspecific URI should also consider influenza **(Chap. 200)**, measles (cough, coryza, and conjunctivitis; **Chap. 205**), acute HIV infection (in which sore throat and rash often predominate; see below and **Chap. 202**), and COVID-19 **(Chap. 199)**.

Individual susceptibility to nonspecific URIs depends on prior exposure, immunity, general health, genetics, microbiome-related factors, and mental health and social factors, including stress. Prior exposure leads to immunity to specific rhinoviruses and adenoviruses, but the number of serotypes makes reinfection likely. Immunity to non-COVID-19 coronaviruses, parainfluenza virus, respiratory syncytial virus, and metapneumoviruses is generally weak or of short duration.

SYMPTOMS AND SIGNS

Common respiratory viruses have incubation periods of 2–8 days after exposure. Symptoms generally begin gradually and include nasal fullness or obstruction, rhinorrhea, sore throat, laryngitis, lymphadenopathy, cough, and low-grade fever. Patients may have myalgias, but this feature usually is not as prominent as it is in influenza. Epistaxis is common with frequent nose blowing.

On physical examination, findings vary, but patients may have conjunctivitis, pharyngeal erythema, pharyngeal exudates, or pharyngeal cobblestoning. Depending on the phase of illness, the nasal mucosa may be pale, boggy, or red and swollen. Nasal mucus can range from watery to purulent. On auscultation, the lungs may be clear, or the patient may have diffuse wheezing or bronchial breath sounds consistent with a viral infection. Symptoms usually last 5–10 days but often last up to 14 days.

TREATMENT

Nonspecific Upper Respiratory Infection

For adults and older children, treatment of nonspecific URI is symptom-based. Fever, myalgias, and sore throat can be treated with acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen. Rhinorrhea can be treated with ipratropium bromide. Nasal congestion can be managed with nasal decongestants such as oxymetazoline (two sprays into each nostril twice a day for up to 5 days) or systemic decongestants such as pseudoephedrine. Products that combine a decongestant with analgesics, antihistamines, or both help relieve symptoms. Although supporting data are weak, cough may be relieved with dextromethorphan or benzonatate (Tessalon Perles). Opioids, while effective at relieving cough, are associated with somnolence, dysphoria, constipation, and addiction.

For children <6 years old, cough and cold medicines should not be prescribed, recommended, or used because of the risks of adverse effects. Honey can help soothe a sore throat for children >1 year old. Cool-mist humidifiers may help with breathing, and saline nasal drops and bulb suctioning can help with nasal congestion.

Patients need to be informed that symptoms generally peak early but can last for up to 14 days; that they are infectious as long as they have symptoms; and that they should rest and drink plenty of fluids to avoid dehydration. Red flags for which patients should seek care include a fever of >102°F, chest pain (other than from a pulled muscle), shortness of breath, dizziness, confusion, new ear or sinus pain, and symptoms lasting >14 days. Although nonspecific URI can be complicated by otitis media and bacterial sinusitis, for an individual patient, an antibiotic is more likely to cause an adverse reaction than to prevent complications.

Other remedies that are ineffective, of questionable benefit, or associated with significant adverse effects include echinacea, zinc, inhaled steam, vitamin C, vitamin D, garlic, antihistamines, Chinese medicinal herbs, intranasal glucocorticoids, *Pelargonium sidoides* herbal extract, saline nasal irrigation, and antiviral drugs.

EAR PAIN

Ear pain is most commonly caused by otitis externa and otitis media. In adults, otologic disease is almost always associated with hearing changes. At >50 years of age, temporal arteritis should be considered in patients who have headache, malaise, weight loss, fever, anorexia, and a normal ear exam. Head and neck cancers should be considered in persons with a history of smoking and alcohol use. In children, the presence of a foreign body should be considered.

Ear pain can also result from other causes of local infection, inflammation, trauma, or tumors or can be referred. Innervation of the ear and surrounding areas includes cranial nerves V, VII, IX, and X and cervical nerves C2 and C3. Neuropathic and myopathic pain syndromes (e.g., trigeminal neuralgia) can cause ear pain. Ramsay Hunt syndrome (herpes zoster oticus) **(Chap. 441)** and Bell's palsy **(Chap. 441)** are both associated with ear pain.

Dental pathology can cause pain that radiates to the ear; caries and abscesses are most common. Bruxism, malocclusion, and temporomandibular disorder may be associated with tenderness in muscular attachments and the temporomandibular joint. Salivary gland pathology and cervical adenopathy can cause pain that radiates to the ear.

Sinusitis, tonsillitis, and pharyngitis cause pain that can radiate to the ear via cranial nerve IX. Gastroesophageal reflux disease **(Chap. 321)** is often associated with ear symptoms. Myocardial infarction can cause ear pain via cranial nerve X.

Relapsing polychondritis **(Chap. 366)** is a rare condition associated with recurrent, sometimes bilateral, erythematous, or violaceous swelling of the auricle (sparing the earlobe). Inflammation from relapsing polychondritis can involve nasal septal, laryngeal, or respiratory cartilage and can cause ocular inflammation, audiovestibular damage, and nonerosive seronegative inflammatory arthritis.

OTITIS EXTERNA

Etiology and Clinical Manifestations Otitis externa is an inflammation or infection of the external auditory canal manifesting as pain, redness, swelling, aural discharge, and hearing impairment. It is often associated with bacterial infection (frequently by *Pseudomonas aeruginosa* or *Staphylococcus aureus*), but fungi like *Aspergillus* or *Candida* can be implicated.

Otitis externa is most common among preteen and teenage children. Risk factors for otitis externa include swimming (with the resulting condition referred to as "swimmer's ear," which is more common in the summer), mechanical trauma (from cotton swabs or hearing aids), narrow ear canals, cerumen obstruction, eczema, and psoriasis. Classic swimmer's ear is associated with bacterial infection. Physical exam is notable for pain on movement of the auricle or tragus and an external auditory canal that is erythematous, edematous, inflamed, and sometimes coated with exudate on otoscopy. In contrast, fungal otitis externa often manifests with pruritus and ear discharge but without much pain.

Otitis externa can co-occur with otitis media. Preauricular, mastoid, parotid, or cervical lymphadenopathy may be present. AOM with tympanic membrane rupture (see below) can be associated with ear discharge and debris in the ear canal but (unlike otitis externa) without sensitivity to movement of the auricle.

Malignant Otitis Externa Malignant otitis externa is a potentially life-threatening form of otitis externa that involves the temporal bone and occurs in patients with diabetes or other types of immunosuppression, often in older adults. Patients may have fever. Progression of malignant otitis externa can affect cranial nerve VII, IX, XI, or XII.

TREATMENT

Otitis Externa

Analgesia should be provided with acetaminophen or an NSAID. The mainstay of treatment is one or more topical antibacterial drugs with a glucocorticoid for 7–10 days. Polymyxin B–neomycin–hydrocortisone is often used but should be avoided in patients with tympanic membrane perforation because of ototoxicity. Ciprofloxacin–hydrocortisone is an alternative.

Topical aluminum acetate may be as effective as a topical antibacterial–glucocorticoid regimen. For patients whose condition does not improve within 2–4 days with topical treatment, ear wicks or gauze impregnated with or soaked in anti-infective agents can be placed. Ineffective treatments include oral antibiotics and topical antifungals. Otitis externa frequently recurs; its recurrence may be prevented with periodic acetic acid or aluminum acetate drops.

For malignant otitis externa, oral antipseudomonal antibiotics are often prescribed. Patients sometimes require IV pain medication, fluids, or other antimicrobials.

ACUTE OTITIS MEDIA

Epidemiology and Etiology AOM—for which patients almost always present within days—is predominantly a disease of children, with incidence peaking at 6–24 months of age. By age 6, ~60% of children will have had an episode of AOM. Younger children appear to be susceptible because of a shorter, more horizontal eustachian tube that more easily accumulates fluid than it does in older children and adults and because their immune system is still developing.

AOM is caused by a viral URI leading to edema and inflammation of the nasopharynx and eustachian tube, collection of fluid, and infection by bacteria that colonize the nasopharynx. Viruses isolated include respiratory syncytial virus, rhinoviruses, enteroviruses, coronaviruses, influenza virus, adenoviruses, and human metapneumovirus. The bacteria most commonly isolated are *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis*.

Symptoms and Signs Symptoms of AOM include ear pain, fever, irritability, otorrhea, and anorexia. Physical examination may be notable for a bulging, inflamed, cloudy tympanic membrane, with obscured landmarks, and immobility of the membrane on pneumatoscopy, the Valsalva maneuver, or swallowing while holding the nose shut. (An immobile tympanic membrane is also indicative of perforation, old middle-ear adhesions, a blocked auditory tube, or the presence of middle-ear fluid.) Patients have conductive hearing loss. Severe signs and symptoms include moderate to severe otalgia, otalgia lasting at least 2 days, and a temperature of >102.2°F.

AOM should be diagnosed in children with moderate to severe bulging of the tympanic membrane or new-onset otorrhea (not due to otitis externa). With mild bulging of the tympanic membrane, AOM can also be diagnosed if the patient has had symptoms for <48 h or if there is intense erythema of the tympanic membrane. AOM should *not* be diagnosed in children who do not have middle-ear effusion.

TREATMENT

Acute Otitis Media

Pain from AOM should be treated with NSAIDs or acetaminophen, which are effective for mild to moderate pain. Topical agents like benzocaine, procaine, or lidocaine may provide some additional, brief benefit beyond that offered by NSAIDs or acetaminophen.

In up to 80% of children, AOM resolves without antibiotics. Indications for antibiotic treatment in children include an age of <6 months, bilateral ear findings in children 6 months to 2 years old, otorrhea in children >6 months old, and—in children of all ages—ear findings with severe otalgia, ear pain for >48 h, or a fever of >102.2°F **(Table 35-1)**.

The benefits of antibiotics are modest and are offset by adverse effects. Antibiotics do not result in early resolution of pain but do decrease pain by day 2 or 3 (number needed to treat, 20 patients treated with antibiotics for 1 patient to have decreased pain by day 2 or 3). More children who receive antibiotics have vomiting, diarrhea, and rash (number needed to harm, 14 patients treated with antibiotics for 1 to have vomiting, diarrhea, or rash). Severe complications like mastoiditis are rare, and the number needed to treat to prevent a case of mastoiditis is ~5000 (i.e., 5000 otitis media patients treated with antibiotics to prevent 1 case of mastoiditis). The American Academy of Family Physicians recommends not routinely prescribing antibiotics for otitis media in children 2–12 years old who have nonsevere symptoms and for whom the observation option is reasonable.

The antibiotic of choice for AOM is high-dose amoxicillin (90 mg/kg per d, up to 3 g). Alternatives include cefdinir, cefuroxime, cefpodoxime, or IM ceftriaxone. If the patient has received amoxicillin in the prior 30 days, clinicians should prescribe amoxicillin/clavulanate (90/6.4 mg/kg per d) in two divided doses. The duration of antibiotic treatment is 10 days for children <2 years old or children with severe symptoms; 5–7 days for children 2–5 years old with mild to moderate AOM; and 5 days for children ≥6 years old with mild or moderate symptoms.

If a patient's condition is not better after 48–72 h of treatment, the antibiotic regimen should be changed to amoxicillin/clavulanate, a second- or third-generation oral cephalosporin, or IM ceftriaxone for 3 days. If, despite a change in antibiotics, the patient's condition still does not improve, that patient should be referred to a specialist. Middle-ear effusions are present in 60–70% of children with AOM; these should resolve over 3 months. Tympanostomy tubes should be considered for recurrent AOM (i.e., three episodes in 6 months or four episodes in 1 year). Mastoiditis is a rare complication of AOM that is suggested by postauricular tenderness, a postauricular mass, or protrusion of the ear lobe.

In adults, AOM is rare and there is little high-quality evidence to guide treatment. For adults, it remains important to differentiate AOM from OME, but AOM is generally treated with antibiotics, regardless of bilaterality or otorrhea. Amoxicillin is the drug of choice. Adults should also be treated with decongestants and analgesics. Adults with more than two episodes in a year or persistent effusion should be referred to an otolaryngologist.

TABLE 35-1 Indications for Antibiotic Treatment of Acute Otitis Media

AGE	INDICATION
<6 months	Antibiotic treatment reasonable for all
6 months to 2 years	Bilateral ear findings
≥6 months	Otorrhea
>2 years	Symptoms worsening or not improving within 48–72 h
All ages	Ear findings with severe otalgia, otalgia lasting at least 2 days, or temperature of >102.2°F

OTITIS MEDIA WITH EFFUSION

Definition and Etiology OME, also called serous otitis media, occurs when there is fluid in the middle ear but no acute infection. Most patients with OME are young children; >60% of cases occur in children <2 years old. Many children have recurrent episodes.

OME is most often a sequela of a viral infection causing AOM, but it can also be caused by allergies. In addition to allergies, predisposing factors include craniofacial abnormalities, gastroesophageal reflux, and enlarged adenoids.

Symptoms and Signs The most common symptoms are decreases in sound conduction and hearing. Children with OME may exhibit impaired language development or communication difficulties. More rarely, patients complain of intermittent ear fullness or earache, tinnitus, or balance problems. On examination, the tympanic membrane may be translucent or gray with fluid (often colorless or amber), air-fluid levels, or bubbles behind the membrane. There is a loss of the light reflex. The tympanic membrane has decreased mobility on pneumatic otoscopy. The evaluation may include audiometry, tympanometry, and, in infants, measurement of auditory brainstem responses.

OME usually resolves spontaneously within 4–6 weeks. If it persists for >3 months, the condition is referred to as chronic OME or chronic serous otitis media.

Cholesteatomas are accumulations of epithelium or keratin in the middle ear that can enlarge, perforate the tympanic membrane, envelop the ossicles, or destroy surrounding tissue. Cholesteatomas can cause labyrinthitis, hearing loss, cranial nerve palsies, vertigo, meningitis, extradural or brain abscess, and lateral sinus thrombophlebitis.

TREATMENT

Otitis Media with Effusion

OME is treated with myringotomy with tympanostomy tube insertion. For young children with nasal obstruction or recurrent infection, adenoidectomy may be considered. Medications, including antihistamines, glucocorticoids, or antibiotics, do not reliably help. Children at risk for speech or language delay may need earlier referral for more aggressive treatment.

ACUTE MASTOIDITIS

Etiology Acute mastoiditis is a serious infection with significant morbidity despite antibiotic and surgical treatment. This condition is most common among children <2 years old but can occur at any age. Acute mastoiditis is often a complication of AOM but may develop without clinically apparent, prior AOM. In older children with acute mastoiditis, clinicians should suspect cholesteatoma.

The pathogenesis of mastoiditis involves spread of organisms from the middle-ear spaces through the aditus ad antrum to the mastoid air cells. *Incipient* mastoiditis consists of fluid within the mastoid air

cells, without bony destruction of the bony septa, and can progress to *coalescent* mastoiditis, with destruction of the bony septa. Acute mastoiditis often causes subperiosteal abscess laterally. The organisms most commonly involved in mastoiditis are *S. pneumoniae*, *Streptococcus pyogenes, H. influenzae, S. aureus* (including methicillin-resistant *S. aureus* [MRSA] strains), and *P. aeruginosa*.

Symptoms and Signs Symptoms of acute mastoiditis include ear pain, fever, lethargy, or fussiness despite adequate treatment of AOM. Patients—especially those with subperiosteal abscess—may have postauricular erythema, tenderness, warmth, fluctuance, and protrusion of the auricle. Otoscopic examination most often yields findings of AOM and may show superoposterior protrusion of the external auditory canal. Complications of mastoiditis include facial nerve palsy, labyrinthitis, skull osteomyelitis, temporal lobe abscess, cerebellar abscess, meningitis, epidural abscess, subdural abscess, venous sinus thrombosis, or Bezold's abscess (an abscess medial to the sternocleidomastoid that tracks into the deep cervical fascia).

Evaluation Laboratory evaluation reveals elevation of inflammatory markers and white blood cells with neutrophilia. Imaging is not necessary in children with a classic history and presentation but may be required if there is concern about complications or severity. CT may show disruption of bony septations, fluid, mucosal thickening, periosteal thickening, disruption of the periosteum, or subperiosteal abscess. MRI with gadolinium permits better visualization of abscesses and vascular problems.

Differential Diagnosis The differential diagnosis of acute mastoiditis includes cellulitis, otitis externa, postauricular lymphadenopathy, perichondritis, and tumors, including rhabdomyosarcoma, Ewing sarcoma, and myofibroblastic tumor.

TREATMENT

Mastoiditis

Patients with mastoiditis should be admitted to the hospital and treated with IV antibiotics and myringotomy, with or without tympanostomy tubes; if there is no improvement within 48 h, mastoidectomy should be undertaken. Tympanostomy or myringotomy samples or subperiosteal abscess drainage should be sent for culture and sensitivity testing. Depending on complications, additional drainage and surgical procedures may be necessary.

Empirical IV antibiotic therapy for children without recurrent AOM or recent antibiotic treatment consists of vancomycin (if there is concern about antibiotic-resistant *S. pneumoniae* or MRSA) or a cephalosporin (e.g., cefepime or ceftazidime). Patients with recurrent AOM or recent antibiotic treatment should be given vancomycin plus an antipseudomonal penicillin. Culture and sensitivity results will guide antibiotic changes. IV antibiotic therapy should be continued for 7–10 days, and patients should complete a 4-week course of oral antibiotics.

SINUS SYMPTOMS

Sinus symptoms are commonly due to respiratory viruses. These symptoms are considered acute if they last <4 weeks, subacute if they last 4–12 weeks, and chronic if they last ≥12 weeks. Beyond sinus infection, the differential diagnosis of rhinitis includes the common cold, allergic rhinitis **(Chap. 352)**, vasomotor rhinitis, rhinitis medicamentosa due to topical decongestants, drug-induced rhinitis (e.g., due to aspirin, ibuprofen, or beta blockers), autoimmune disease (e.g., granulomatosis with polyangiitis), and cerebrospinal fluid leak. Pain over the sinuses can be caused by headaches **(Chap. 430)**, facial pain syndromes, temporomandibular disorder **(Chap. 36)**, and dental pathology. Gastroesophageal reflux can cause referral of symptoms to the sinuses. Patients who have uncontrolled diabetes or are otherwise immunocompromised can have rapidly progressing invasive fungal infections **(Chap. 211)**. More indolent fungal infections should be considered in the event of recurrent or nonresolving sinusitis. In children, it is important to consider the presence of a foreign body as a cause of sinus symptoms.

ACUTE SINUSITIS

Definition and Etiology *Sinusitis* is an inflammation of the paranasal sinuses; *rhinosinusitis* also involves the nasal passages. The majority of acute sinusitis cases are caused by respiratory viruses. A diagnosis of sinusitis is a major reason for unnecessary antibiotic prescribing in adults: although <2% of sinusitis episodes are due to bacteria (most often *S. pneumoniae, H. influenzae,* or *M. catarrhalis*), antibiotics are prescribed at >70% of office visits for sinusitis. According to guideline criteria, no more than 50% of adults—and probably closer to 20%—meet the criteria for antibiotic prescribing.

Symptoms and Signs Sinusitis symptoms commonly include purulent nasal discharge, facial congestion or fullness, and facial pain or pressure. Other symptoms include fever; hyposmia or anosmia; ear pain, pressure, or fullness; postnasal drip; halitosis; maxillary toothache; cough; and fatigue. Risk factors for developing sinusitis include an age of 45–65 years, smoking, asthma, air travel, and allergies.

On physical examination, direct rhinoscopy reveals excess mucus or purulence. Patients may have tenderness over the maxillary sinuses and, in severe cases, erythema and swelling of the maxilla. Sinus transillumination is not accurate in diagnosing sinusitis.

Complications Complications from sinusitis can be dramatic but are extremely rare. These complications may include orbital cellulitis, osteomyelitis, meningitis, intracranial abscesses, and cavernous sinus thrombosis. New symptoms that might indicate a sinusitis complication include confusion, unilateral weakness, proptosis, limited ocular movements, and acute vision changes.

RECURRENT ACUTE SINUSITIS Patients who have four or more episodes of acute sinusitis in a year, without signs or symptoms between episodes, are said to have recurrent acute sinusitis.

INVASIVE FUNGAL SINUSITIS Invasive fungal sinusitis may develop in immunocompromised patients, such as those with uncontrolled diabetes or transplant recipients, and should be considered an emergency. Invasive fungal sinusitis is caused by Mucorales fungi or *Aspergillus* **(Chap. 217)**. Patients may appear to have a rapidly progressive case of rhinosinusitis, with facial pain and pressure, headaches, and fever followed within days by cranial nerve involvement, orbital swelling, cellulitis, proptosis, chemosis, and ophthalmoplegia. Patients may be critically ill. Evaluation should include nasal endoscopy with biopsy and imaging with gadolinium-enhanced MRI as the preferred modality.

NOSOCOMIAL SINUSITIS Nosocomial sinusitis occurs in critically ill patients, often those who are nasotracheally intubated. Nosocomial sinusitis should be suspected in hospitalized patients who have fever without another identifiable cause.

TREATMENT

Acute Sinusitis

All patients with acute sinusitis should be counseled about symptom-based treatments, which may include decongestants, analgesic/antipyretics, nasal saline, or intranasal glucocorticoids. Intranasal decongestants (e.g., oxymetazoline, two sprays in each nostril twice a day for no more than 5 days) and oral decongestants (e.g., 12-h pseudoephedrine [120 mg] during the day) relieve pain, pressure, and rhinorrhea. Analgesics and antipyretics like acetaminophen or NSAIDs (e.g., ibuprofen), nasal saline spray, and nasal washes provide relief. Intranasal glucocorticoids may help, particularly for

TABLE 35-2 Indications for Antibiotic Treatment of Acute Sinusitis

INDICATION	DEFINITION
Persistent	Symptoms lasting ≥10 days
Severe	Fever of >102°F and either purulent nasal discharge or nasal pain for at least 3–4 consecutive days
Worsening	New fever, headache, or increase in nasal discharge following an upper respiratory tract infection that lasted for 5–6 days and was initially improving

Note: In typical populations, roughly 20% and no more than 50% of adults with sinusitis will meet the criteria for antibiotic prescribing.

patients with an allergic cause of sinusitis. Because patients may be accustomed to receiving antibiotics, provision of a clear explanation, symptom-based treatments, and reasons for reconsultation are important. Red flags for which patients should reconsult include recurrent fever of >102°F, sinus symptoms that worsen after initial improvement, and rapid worsening of facial pain that becomes persistent, as well as any other concerning symptoms.

Antibiotic prescribing criteria for sinusitis are based on symptoms (Table 35-2). Only patients with persistent, severe, or worsening symptoms, especially those who have already used decongestants and analgesics for 2–4 days, meet the criteria for antibiotic prescribing. The antibiotic of choice is amoxicillin/clavulanate (875 mg/125 mg bid for 7 days). Amoxicillin (875 mg PO bid for 7 days) is an alternative. For patients with mild penicillin allergies, cefuroxime is a reasonable choice. For those with severe penicillin allergies, doxycycline is a reasonable alternative. Macrolides are specifically not recommended for sinusitis because of high rates of macrolide-resistant *S. pneumoniae*.

Patients who meet the criteria for antibiotic prescribing should show signs of improvement after 3–5 days of therapy. If not, second-line regimens include amoxicillin/clavulanate (2000 mg/125 mg bid for 7 days) or levofloxacin, although fluoroquinolones are associated with dysglycemia, neuropathy, and tendon and aortic rupture. For patients whose condition still is not improving after 3–5 days of treatment with a second-line antibiotic or in whom a complication or an alternative diagnosis is suspected, clinicians should consider referral to an otorhinolaryngologist and/or the performance of imaging tests. The imaging modality of choice is noncontrast CT. Patients with recurrent acute sinusitis may benefit from nasal culture during episodes; imaging between episodes to identify predisposing anatomic abnormalities; and allergic or immunologic evaluation.

Patients with acute fungal sinusitis should be treated with IV antifungal agents and often require surgical debridement. Patients with nosocomial sinusitis should have precipitating factors (e.g., nasotracheal intubation) addressed and should be empirically treated with broad-spectrum antibiotics until culture and susceptibility results are available.

CHRONIC SINUSITIS

Definition and Etiology Chronic sinusitis is defined as inflammation of the paranasal sinuses that lasts >12 weeks. Chronic sinusitis is primarily an inflammatory disease and can also be associated with acute or chronic infection or allergic, structural (e.g., deviated nasal septum or polyps), and immunologic etiologies. Repeated viral infections may lead to chronic sinusitis. Bacterial colonization or chronic infection plays a role in some cases of chronic sinusitis. *S. aureus* and gram-negative bacteria are commonly identified. Commonly involved allergens and irritants are dust mites, mold, tobacco smoke, occupational factors, and other airborne toxins. Functional or immunologic problems can include impaired mucociliary clearance (e.g., due to cystic fibrosis) or immunodeficiency due to acquired conditions or medications. Chronic sinusitis often coexists with allergic rhinitis and asthma.

Symptoms and Signs Cardinal symptoms of chronic sinusitis are facial pain or pressure, nasal discharge or postnasal drip, congestion, and hyposmia or anosmia. Associated symptoms may include fatigue, malaise, ear pressure, hoarseness, and cough. The diagnosis of sinus inflammation must be confirmed with anterior rhinoscopy, nasal endoscopy, or imaging because up to 40% of patients with chronic sinus symptoms do not have mucosal changes evidencing disease.

In practical terms, chronic sinusitis can be divided into three main types (in decreasing order of frequency): (1) chronic sinusitis without polyps, (2) chronic sinusitis with polyps, and (3) allergic fungal sinusitis. In general, chronic sinusitis without polyps is more common among women, develops in childhood and young adulthood, is characterized by presentations with facial pain, and is often due to T_H1 lymphocyte predominance associated with bacterial infection or colonization. Chronic sinusitis with polyps is more common among men; develops in adulthood; is characterized by presentations with decrease or loss of smell, asthma, or aspirin sensitivity (Chap. 287); and is often due to T_H2 lymphocyte predominance associated with eosinophilic inflammation, asthma, or aspirin sensitivity. Allergic fungal rhinosinusitis is also associated with polyp formation; typically occurs in patients in their 20s and 30s who are from warm, humid regions and who have other atopic diseases; and is associated with IgE-mediated allergy and eosinophils (Chap. 217). The mucus in allergic fungal rhinosinusitis is classically greenish-brown, has a peanut butter–like consistency, and includes viable hyphae from *Aspergillus* or other fungal species. Allergic fungal rhinosinusitis is resistant to medical treatments.

Evaluation On anterior rhinoscopy, polyps are seen as white, gray, tan, or yellow translucent growths in the middle meatus. The imaging modality of choice is noncontrast CT. Allergic fungal rhinosinusitis may be unilateral; however, unilateral symptoms or polyps on exam or imaging, especially if associated with bloody discharge, should raise concern about tumors.

TREATMENT

Chronic Sinusitis

Treatment includes avoidance of identifiable triggers such as allergens, smoke, and irritants. Saline sprays and washes provide symptom relief, and higher-volume saline washes are probably more effective. Intranasal glucocorticoids, including mometasone and fluticasone sprays or higher-potency and higher-volume budesonide rinses, are mainstays of treatment, especially for chronic sinusitis with polyps. Intranasal glucocorticoids reduce polyp size. Oral administration of glucocorticoids for 2–3 weeks is sometimes effective against chronic sinusitis that is unresponsive to intranasal steroids—again, especially for patients with polyps. Intranasal or systemic antihistamines may help patients whose illness has an allergic component. Likewise, leukotriene antagonists like montelukast may help.

Although antibiotics are frequently prescribed for 2–4 weeks to patients with chronic sinusitis, there is little evidence that these drugs are effective. Evidence of modest quality supports the use of 3 months of macrolide treatment for patients who have chronic sinusitis without polyps. Antifungal agents have not shown benefit against any subtype of chronic sinusitis. Decongestants should be used only sparingly and briefly.

Endoscopic sinus surgery improves quality of life in patients who have had inadequate responses to medical therapy. Patients with more limited, focal disease may more reliably have better results. The goals of surgery are to remove polyps from the nasal cavity and paranasal sinuses. For patients with allergic fungal rhinosinusitis, medical therapy is classically ineffective, surgery produces good results, and patients should be treated with perioperative glucocorticoids. In children, adenoidectomy may be effective in some cases. In the future, immune endotyping may allow selection of more individualized biological treatments.

TABLE 35-3 Clinical Findings That Suggest Various Forms of Nonstreptococcal Pharyngitis

CLINICAL FINDING(S) OR BEHAVIORAL FACTOR	SUSPECTED DIAGNOSIS
Scarlatiniform rash	Group A β-hemolytic streptococci or *Arcanobacterium haemolyticum*
Cough and otitis media	*Haemophilus influenzae*
Sex between men with associated urogenital symptoms, fellatio between a woman and a man who has current urogenital symptoms, persistent sore throat unresponsive to penicillin	*Neisseria gonorrhoeae*
Travel to endemic areas, pseudomembrane on examination	*Corynebacterium diphtheriae*
Persistent sore throat with bronchopulmonary symptoms	*Mycoplasma pneumoniae*
Marked adenopathy (especially that involving posterior cervical or auricular nodes), splenomegaly, palatine petechiae, gelatinous uvula	Acute infectious mononucleosis
New sexual partner in the previous month; fever, rash, myalgias, headache	Acute HIV infection

TABLE 35-4 The Centor Criteria and the Probability of Streptococcal Pharyngitis for Adults[a]

NO. OF CRITERIA MET[b]	POSTEVALUATION PROBABILITY (%)	RECOMMENDATION
0	2	No test, no antibiotic
1	3	No test, no antibiotic
2	8	Rapid test
3	19	Rapid test
4	41	Empirical antibiotic treatment or rapid test

[a]Assuming a pretest probability of strep throat for adults of 10%. [b]The criteria are (1) a history of fever, (2) an absence of cough, (3) tender anterior cervical lymphadenopathy, and (4) tonsillar swelling or exudate. Each criterion gets 1 point. Roughly 40–60% of adults will meet no criteria or one criterion; ~20% will meet the criteria for antibiotic prescribing.

SORE THROAT AND NECK PAIN

Sore throat is not synonymous with pharyngitis and can also be caused by submandibular space, retropharyngeal and peritonsillar abscesses, thyroiditis, gastroesophageal reflux, tumors, and postnasal drainage.

Acute pharyngitis, in which symptoms are generally present for days, is most often caused by respiratory viruses; is often caused by group A β-hemolytic streptococci (GAS); and can be caused by other bacteria (including *Neisseria gonorrhoeae*), Epstein-Barr virus (EBV), and HIV. On physical examination, pharyngeal erythema is associated most commonly with viral infections, including the common cold and influenza. Pharyngeal exudate should not be confused with *Candida* infection, which looks like cottage-cheese, can be scraped off, and leaves a bleeding surface, or leukoplakia, which cannot be scraped off. History and exam findings may help differentiate sore throat and pharyngitis of various etiologies **(Table 35-3)**.

STREPTOCOCCAL PHARYNGITIS

GAS is the only common cause of sore throat that should be treated with antibiotics. The principal goal in the evaluation of adults with sore throat is to identify patients likely to have GAS pharyngitis, or "strep throat." Prompt antibiotic treatment of adults likely to have strep throat has the potential to reduce symptoms, prevent the spread of disease, and reduce suppurative complications (e.g., peritonsillar abscess). Nonsuppurative complications are rare. In developed countries, the prevalence of rheumatic fever **(Chap. 148)** is extremely low, and antibiotic treatment does not prevent poststreptococcal glomerulonephritis **(Chap. 148)**.

Most patients with non-GAS pharyngitis have various forms of viral pharyngitis and do not require antibiotics. Nevertheless, clinicians prescribe antibiotics to a majority of adults with sore throats. By using a simple clinical scoring algorithm, clinicians can predict the presence or absence of GAS with sufficient accuracy and avoid prescribing antibiotics to patients who are unlikely to have strep throat. Although there is a role for testing (see "Evaluation," below), most adults with sore throat do not need to have a GAS test.

About 10% of adults with sore throat are infected with GAS. Among children with sore throat, the prevalence of GAS can be as high as 35%, with rates peaking from 5 to 15 years of age. The prevalence of GAS is higher in winter and early spring. The risk of streptococcal pharyngitis is elevated among health care and child care workers, teachers, parents of young children, and patients exposed to individuals with strep throat. Clinicians need to be aware of local outbreaks of GAS infection, particularly in military and institutional settings, where the prevalence of GAS and the risk of acute rheumatic fever may be elevated.

Evaluation The Centor criteria consist of four findings, each of which is assigned 1 point: (1) history of fever, (2) absence of cough, (3) tender anterior cervical lymphadenopathy, and (4) tonsillar exudate or swelling. The Centor criteria are easy to assess and accurately stratify adult patients with suspected streptococcal pharyngitis. Patients with no points have a 2% probability of being infected with GAS, whereas those with 4 points have a probability of 41% **(Table 35-4)**. The Centor criteria have an area under the curve of 0.79. Other clinical decision algorithms similar to the Centor criteria may not perform as well, are not as simple, or have not been as rigorously evaluated.

If the test/no treatment threshold is set at 5%, for a GAS prevalence of ~10%, adults meeting no criteria or only one Centor criterion have a probability of GAS pharyngitis so low that they should neither be tested nor be treated with an antibiotic. Adults meeting two or three Centor criteria have an intermediate probability of GAS pharyngitis; they should have a rapid antigen test performed, and the results should guide antibiotic treatment. For adults meeting four Centor criteria, it is reasonable either to perform a rapid test or to institute empirical antibiotic treatment. However, some guidelines recommend—and some ambulatory quality measures require—a GAS test to be associated with antibiotic prescribing in adults, regardless of the number of Centor criteria met.

In children, the Centor criteria are less specific, and streptococcal pharyngitis should be confirmed with testing. Children who have signs of pharyngitis without signs of viral infection (conjunctivitis, runny nose, cough, hoarseness, nonexudative oral lesions) should have testing performed.

Outside of the United States, because complications are rare and even streptococcal pharyngitis is self-limited in the vast majority of cases, some guidelines do not recommend use of rapid GAS testing or routine antibiotic treatment of sore throat.

Clinicians should have a lower threshold for diagnosing and treating GAS pharyngitis in patients with a history of acute rheumatic fever, patients with documented streptococcal exposure in the past week, patients who live in a community with a current strep throat epidemic, and patients who are diabetic or otherwise immunocompromised.

RAPID STREP TESTS Rapid GAS-specific antigen tests have a sensitivity of ~80% and a specificity of ~95%. Results are available within minutes and can be used to make therapeutic decisions before the patient leaves the office. Improper collection technique can adversely affect the sensitivity of rapid strep tests: clinicians should rub the tonsils and pharynx, touching any areas where exudate or ulceration are present.

THROAT CULTURES A single-swab throat culture has a sensitivity of ~85–90%, as defined by isolation of GAS on a second swab. A throat culture can also be falsely positive for true infection: some patients with a culture positive for GAS may be only uninfected carriers, as defined by their failure to exhibit a fourfold increase in antibodies to GAS—the gold standard test. Among adults and children seeking medical care for a sore throat, test specificity may be as low as 50–70% because of

patients who do not exhibit serologic evidence of infection. Throat cultures are not recommended for the routine evaluation of adults with sore throat. The modest gain in sensitivity over rapid testing is outweighed by the 24- to 48-h delay in test results, with a consequent delay in the symptomatic relief associated with antibiotic treatment.

Indiscriminate strep testing in adults with sore throat or respiratory symptoms should be discouraged. Rapid strep tests and culture do not differentiate between patients who have true infection and those who are carriers of GAS (with carriage rates as high as 20% among schoolchildren and ~5% among adolescents and young adults). In adults who meet no Centor criteria or only one criterion—40–60% of adults with pharyngitis—a positive test is highly likely to be falsely positive and/or to represent GAS carriage.

Complications Complications of streptococcal pharyngitis are rare but include acute rheumatic fever (Chap. 148), poststreptococcal glomerulonephritis (Chap. 148), scarlet fever (Chap. 148), sinusitis, peritonsillar abscess, and other invasive GAS infections.

TREATMENT

Streptococcal Pharyngitis

All patients with pharyngitis—nonstreptococcal and streptococcal—should receive analgesics (acetaminophen or NSAIDs). Saline gargles, humidification, soft foods, and tea with honey soothe a painful throat.

Penicillin is the antibiotic of choice for streptococcal pharyngitis (Table 35-5). Penicillin is a narrow-spectrum, low-cost, and well-tolerated drug to which no GAS isolate has been resistant. Amoxicillin is an acceptable alternative in children as it comes in a palatable liquid form. For patients with mild penicillin allergy, cephalexin and cefadroxil are good alternatives. For patients with severe penicillin allergies, clinicians should prescribe erythromycin, clarithromycin, or clindamycin. Unlike other infections for which emerging evidence supports progressively shorter antibiotic courses, streptococcal pharyngitis requires longer courses (7–10 days), which are more effective.

Glucocorticoids (e.g., dexamethasone, 10 mg as a single oral dose) have so far been poorly studied as an adjunctive treatment for sore throat and strep throat and are not recommended. These drugs may result in decreased pain within 24 h but do not decrease school or work absenteeism or relapse rates. Even short courses of steroids are associated with increased rates of sepsis, gastrointestinal bleeding, congestive heart failure, venous thromboembolism, and fracture within 30 days.

Streptococcal and nonstreptococcal pharyngitis should resolve in 3–5 days. Symptoms that should lead patients to seek further care include shaking chills (rigors), neck swelling (beyond lymphadenopathy), trouble swallowing, drooling, or symptoms that persist for >5 days without improvement.

TABLE 35-5 Antibiotic Treatment of Group A Streptococcal Pharyngitis

ANTIBIOTIC	DOSING
Antibiotic of Choice	
Penicillin	500 mg PO qid or 1000 mg PO bid × 10 days
Alternative for Non-Penicillin-Allergic Patients	
Amoxicillin	500 mg PO bid or 1000 mg qd × 10 days
Alternatives for Non-Anaphylactic Penicillin-Allergic Patients	
Cephalexin	500 mg PO bid × 10 days
Cefadroxil	1 g PO qd × 10 days
Alternatives for Patients with Severe Penicillin Allergy	
Erythromycin	250–500 mg PO qid or 500–1000 mg PO bid × 5 days
Clarithromycin	500 mg PO bid × 5 days
Clindamycin	300 mg PO tid × 10 days

NONSTREPTOCOCCAL PHARYNGITIS

Acute Infectious Mononucleosis New EBV infection may be the cause of pharyngitis in 1–6% of young adults (Chap. 194). EBV is rarely the cause of pharyngitis in adults >40 years of age. The full-blown acute syndrome, which is present in only about one-fourth of patients with infectious mononucleosis ("mono"), is characterized by a triad of clinical, hematologic, and serologic findings. The clinical presentation is typified by the development over several days of malaise, fever, sore throat, and marked adenopathy that is particularly evident in the cervical lymph nodes. On physical examination, marked adenopathy is virtually always documented and is most specific for mononucleosis when the posterior cervical or posterior auricular nodes are involved. Splenomegaly and exudative pharyngitis with prominent tonsillar swelling, palatine petechiae, and a gelatinous uvula are often noted. The classic hematologic findings are an absolute lymphocyte count of >4000/μL or a relative lymphocyte count of >50% with "atypical" morphologic features in >10% of the lymphocytes. The characteristic serologic finding is the heterophil antibody, which is detectable in only 40% of patients during the first week of illness but in 80–90% of patients by the third week.

Other Bacterial Pharyngitis Non–group A streptococci (especially group C and group G streptococci), *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *N. gonorrhoeae*, and *H. influenzae* have all been associated with sore throat in some studies. Although antibacterial treatment has not been proven to speed the resolution of symptoms and signs of any of these types of nonstreptococcal pharyngitis, antibiotic treatment is indicated if throat cultures from a patient with persistent sore throat yield group C or group G streptococci.

LEMIERRE'S SYNDROME Lemierre's syndrome consists of septic thrombophlebitis of the internal jugular vein accompanied by metastatic infections, most commonly of the lung but with possible involvement of the joints, bones, liver, meninges, and brain. Lemierre's syndrome is most commonly caused by *Fusobacterium necrophorum*, although it can also be caused by species of *Bacteroides, Eikenella, Streptococcus, Peptostreptococcus,* or other bacterial genera. This syndrome probably occurs predominantly in male patients. Clinicians should consider Lemierre's syndrome in a teenage or young adult patient who has non-GAS pharyngitis that is not resolving, particularly if it is accompanied by rigors, neck pain or swelling, or other extrapharyngeal symptoms.
